At the root of the neck, the left phrenic nerve is commonly stated to leave the medial edge of scalenus anterior and to pass anterior to the first part of the left subclavian artery and behind the thoracic duct. However, sometimes the right and left nerves are symmetric in their cervical course, and so the left phrenic nerve may cross anterior to the second part of the left subclavian artery, separated from it by scalenus anterior at the level of the thoracic inlet. Thereafter, the left phrenic nerve crosses anterior to the left internal thoracic artery, descending across the medial aspect of the apex of the left lung and its pleura to the first part of the subclavian artery, which it crosses obliquely to reach a groove between the left common carotid and subclavian arteries. It passes anteromedially, superficial to the left vagus nerve just above the aortic arch and behind the left brachiocephalic vein, and then passes superficial to the aortic arch and the left superior intercostal vein, anterior to the left pulmonary hilum, to lie between the fibrous pericardium covering the surface of the left ventricle and the mediastinal pleura (see Fig. 56.1).

Diaphragmatic relationships

The right phrenic nerve passes through the central tendon of the diaphragm, either by the caval aperture or just lateral to it. The left phrenic nerve passes through the muscular part of the diaphragm anterior to the central tendon, just lateral to the left cardiac surface and more anterior than the right phrenic nerve (Fig. 58.2). At the diaphragm or slightly above it, each phrenic nerve supplies fine branches to the parietal pleura above, and the parietal peritoneum below, the central diaphragm. Typically, the trunk of each nerve then divides into three branches as it passes through the diaphragm. These are commonly arranged as follows (with some variation): an anterior (sternal) branch, which runs anteromedially towards the sternum and connects with its fellow; an anterolateral branch, which runs laterally anterior to the lateral leaf of the central tendon; a short posterior branch, which divides into a posterolateral ramus coursing behind the lateral leaf and a posterior (crural) ramus which supplies the crural fibres. Posterolateral and crural branches may arise separately from the phrenic nerve. These main branches may be submerged in diaphragmatic muscle or lie below it. They supply motor fibres to the muscle and sensory fibres to the peritoneum and pleura related to the central part of the diaphragm. They also relay proprioceptive fibres from the musculature. The right phrenic nerve supplies the part of the right crus to the right of the oesophagus, and the left phrenic nerve supplies the left crus and the part of the right crus that lies on the left of the oesophagus. Phrenic rami connect with branches of the coeliac plexuses on the inferior surface of the diaphragm, and there is a small phrenic ganglion on the right, at the junction of the plexuses. Rami from the plexuses supply the suprarenal glands and, on the right, the hepatic falciform and coronary ligaments, the inferior vena cava and, possibly (via connections with coeliac and hepatic plexuses), the gallbladder.

Lesions of the phrenic nerve

An appreciation of the location of the main branches of the phrenic nerves is important to avoid iatrogenic surgical damage. Radial incisions in the diaphragm from the costal margin to the oesophageal hiatus lead to diaphragmatic paralysis, whereas thoracoabdominal incisions in a circumferential manner in the periphery of the diaphragm do not involve any significant branches of the phrenic nerves and preserve diaphragmatic function. Similarly, incisions of the central tendon are safe.

Division of the phrenic nerve in the neck completely paralyses the corresponding half of the diaphragm, which atrophies. If an accessory phrenic nerve exists, section or crushing of the main nerve as it lies on scalenus anterior will not produce complete paralysis. The phrenic nerve may be involved with traumatic lesions of the upper brachial plexus. Historically, it was deliberately injured in order to collapse, and hence rest, the lung in patients with pulmonary tuberculosis. Cardiac surgery is one of the most common medical causes of phrenic nerve injury, especially as a result of the instillation of saline slush for myocardial preservation. Other causes include thoracic surgery, tumours of the lung or mediastinum, and infections such as polio. Respiratory muscle weakness of rapid onset is a feature of Guillain–Barré syndrome.

Phrenic nerve damage leads to paradoxical movement of the diaphragm that is best observed fluoroscopically, with the patient first in the upright position (diaphragm unloaded), and then supine with a small weight on the abdomen (diaphragm loaded). Diaphragmatic paralysis can also be assessed by ultrasound examination with a sniff manoeuvre. The ‘gold standard’ for assessment of the phrenic nerve/diaphragm unit is electrical or magnetic stimulation of the phrenic nerve with recording of the compound muscle action potential and/or the transdiaphragmatic pressure. Electrical stimulation of the diaphragm, by ‘pacing’ of one or both phrenic nerves, has been used with some success in infants with central alveolar hypoventilatory syndrome (‘Ondine’s curse’) and in patients with high cervical lesions of the spinal cord, in whom the diaphragm is paralysed but the lower motor neurones are intact. Electrodes are placed adjacent to the nerves, sometimes in the neck but more usually in the chest, and a ventilatory rhythm is established by trains of stimuli delivered by an implanted device. Because this is an unphysiological way of recruiting the muscle, the fibres must be ‘conditioned’ during the initial period of stimulation, so that they acquire the necessary resistance to fatigue.

Referred pain

Diaphragmatic pain is frequently felt at the tip of the shoulder, reflecting common nerve root origins in the neck. It usually occurs when there is inflammation of the diaphragmatic pleura, e.g. in basal pneumonia, pleural effusions or malignant disease.

Accessory phrenic nerve

The accessory phrenic nerve is described in Chapter 28.

ANATOMY OF BREATHING

Breathing is a highly coordinated abdominal and thoracic process. The diaphragm is the major muscle of inspiration, responsible for approximately two-thirds of quiet breathing in healthy humans. The external intercostal muscles are most active in inspiration, and the internal intercostals, which are not as strong, are most active in expiration. Increasing the vertical, transverse and anteroposterior dimensions of the chest increases the volume of the pleural space, and the resulting decrease in intrapleural pressure draws air into the lungs. During expiration, the diaphragm relaxes and moves superiorly. Air is expelled from the lungs and the elastic recoil of the lung creates a subatmospheric pressure that returns the lateral and anteroposterior dimensions of the thorax to normal (De Troyer & Estenne 1988, Celli 1998).

During inspiration, the lowest ribs are fixed, and contraction of the diaphragm draws the central tendon downwards. In this movement, the curvature of the diaphragm is scarcely altered. The cupolae move downwards and a little forwards almost parallel to their original positions. The associated downward displacement of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this extensibility is soon reached. The central tendon, its motion arrested by the abdominal viscera, then becomes a fixed point from which the fibres of the diaphragm continue to contract. This causes the second to tenth ribs to be elevated and the inferior portions of the ribs are turned outwards as a result of direct transmission of pressure through the zone of apposition (Fig. 58.4). The medial aspect of the rib is elevated and this increases the transverse dimension of the chest in the same manner as a bucket handle swinging outwards (Fig. 58.5A). This effect is most evident in the lower ribs (seventh to tenth ribs). Movements at the costovertebral joints cause elevation of the anterior ends of the ribs that push the body of the sternum and the upper ribs forwards. This ‘pump handle’ movement is most evident in the superior ribs (second to sixth ribs) and increases the anteroposterior dimension of the thorax (Fig. 58.5B). The right cupola of the diaphragm, which lies on the liver, has a greater resistance to overcome than the left, which lies over the stomach, and so the right crus and the fibres of the right side are more substantial than those of the left. The balance between descent of the diaphragm, protrusion of the abdominal wall (‘abdominal’ breathing), and elevation of the ribs (‘thoracic’ breathing) varies in different individuals and with the depth of ventilation. The thoracic element is usually more marked in females, but increases in both sexes during deep inspiration.

Fig. 58.4 Inspiratory movements: pressure changes during inspiration.

(Adapted from Drake, Vogl and Mitchell 2005.)

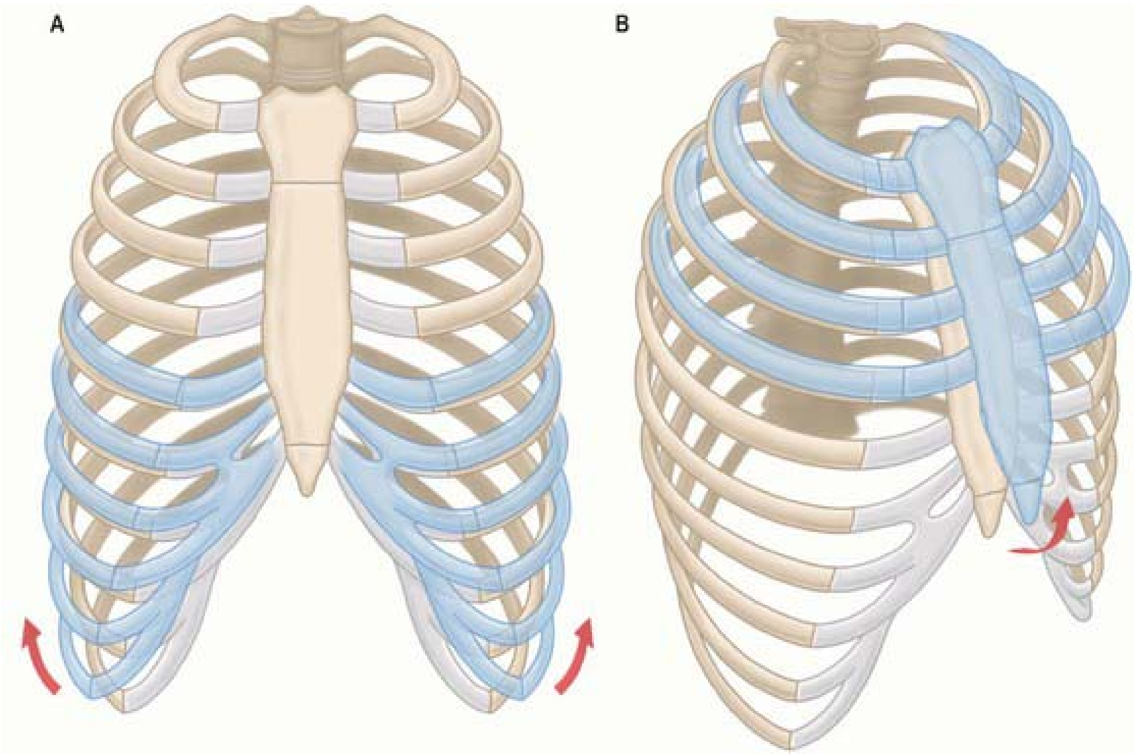

Fig. 58.5 Movements of the ribs during inspiration (**A**) increase the transverse diameter of the chest by the ‘bucket handle’ movement, and (**B**) increase the anteroposterior dimension of the thorax by the ‘pump handle’ movement.

Diaphragmatic excursion is typically 1.5 cm in quiet breathing. During deep ventilation, the maximum movement ranges from 6 to 10 cm. After a forced inspiration, e.g. when breathing is partially obstructed, the right cupola of the diaphragm can descend to about the level of the eleventh thoracic vertebra, while the left cupola may reach the level of the body of the twelfth thoracic vertebra. After a forced expiration, the right cupola of the diaphragm is level anteriorly with the fourth costal cartilage, laterally with the fifth, sixth and seventh ribs, and posteriorly with the eighth rib, and the left cupola is a little lower.

The level of the diaphragm is affected by the phase and depth of ventilation, and by the degree of distension of the stomach and intestines and the size of the liver. Radiographs show that the height of the diaphragm within the thorax also varies considerably with posture. It is highest when the body is supine, and in this position it performs the greatest ventilatory excursions with normal breathing. When the body is erect, the diaphragm is lower, and its ventilatory movements become smaller. The diaphragmatic profile is still lower in the sitting posture, and ventilatory excursions are smallest under these conditions. When the body is horizontal and on one side, the two halves of the diaphragm do not behave in the same way. The uppermost half sinks to a lower level than that seen when sitting, and moves little with ventilation. The lower half rises higher in the thorax than it does even in the supine position, and its ventilatory excursions are considerably greater. Changes in the level of the diaphragm with alterations in posture explain why patients with severe dyspnoea are most comfortable, and least short of breath, when sitting up.

The primary role of the intercostal muscles is to stiffen the chest wall, preventing paradoxical motion during descent of the diaphragm in inspiration. This becomes most obvious immediately after high spinal injury, when there is flaccid paralysis of the entire trunk and only the diaphragm is left functioning. In a healthy adult with a vital capacity of 4.5 L, some 3 L is accounted for by diaphragmatic excursion. Immediately after high spinal injury, the vital capacity decreases to about 300 mL, even though the diaphragm is moving maximally, because some 2.7 L is lost by paradoxical incursion of the flaccid chest wall as the diaphragm descends. With time (usually several weeks), the paralysis becomes spastic, stiffening the chest wall, and the vital capacity increases towards its phrenic limit of about 3 L.

In the same way, high spinal injury reveals the role of the abdomen in inspiration and expiration. The abdominal musculature plays a major role in active expiration in man. During the flaccid stage of high spinal paralysis, the only mechanisms available for returning the relaxed diaphragm into the thorax on expiration are passive recoil of the lungs and chest wall, and the weight of the abdominal viscera. The latter is the most important, and operates only when patients are lying down. If they are sat up or raised upright, they are unable to breathe out. Trussing the abdomen with an elastic binder can help such patients. Conversely, when paralysis becomes spastic, the stiff abdominal wall opposes inspiration.

The role of the abdomen in breathing is often underestimated. If, for example, the anterolateral wall were made of steel and linked the pelvic rim rigidly to the costal margins, inspiration would be impossible. The diaphragm could not descend (because the abdominal contents are incompressible), and the ribs could not rise (because the links to the pelvis would be inextensible). During normal breathing, the abdomen relaxes as the diaphragm contracts. It is possible to oppose this motion by tensing the abdomen, as in the ‘beach posture’ adopted to exaggerate the size of the chest. In this case, the abdominal contents fix the central tendon of the diaphragm, so that it raises the ribcage as it contracts, but it is a condition of that manoeuvre that the gap between the ribs and the pelvic rim widens.

The ventilatory muscles must also work during sleep, when the pharyngeal muscles relax and upper airway resistance increases. It is now appreciated that in some people, particularly the obese, this relaxation can lead to periodic apnoea and marked hypoxia during sleep, implying that the pharyngeal muscles play an important ventilatory role in waking life. It is also clear that although ventilatory muscles rarely tire in normal life, they do fatigue when placed under abnormal loads, e.g. in chronic obstructive pulmonary disease.

The different pulmonary regions do not all move equally in ventilation. In quiet ventilation, the juxtahilar part of the lung scarcely moves and the middle region moves only slightly. The superficial parts of the lung expand the most, and the mediastinal surface, posterior border and apex move less, because they are related to less movable structures. The diaphragmatic and costomediastinal regions expand most of all. Most of the volumetric change during ventilation occurs in the alveoli.

CHAPTER 59

Development of the thorax

THORACIC WALL AND DIAPHRAGM

The thorax as an entity is not apparent in embryos until the end of the embryonic stage of development (stage 23). It develops around the early pericardial cavity and the associated pericardioperitoneal canals (Fig. 59.1A; see Fig. 59.3A). The pericardioperitoneal canals give rise to the pleural cavities surrounding the lungs and that part of the peritoneal cavity surrounding the lower end of the foregut, which becomes the oesophagus, stomach and duodenum within the thoracic cage. Later these portions of peritoneal cavity are sequestered into the abdominal cavity by the development of the diaphragm.

The position of the pericardium is shown by a dotted line. Dorsolateral growth of the pleural sacs also split the body wall dorsocaudally defining the costodiaphragmatic recess.

In stage 14 embryos, the heart is at the level of the upper cervical somites and above the upper limb buds. The thoracic somites are opposite the midgut. The putative thoracic region contains the pericardial cavity ventrally and the pericardioperitoneal canals posteriorly, on each side of the foregut. The future pleural cavities are as yet undefined regions of the pericardioperitoneal canals. Below the heart, septum transversum mesenchyme (see Fig. 73.5A) that has arisen from the caudal pericardial wall is being invaginated by endodermal epithelial cells from the foregut hepatic primordium.

The heart and pericardial cavity are relatively large in the early embryo (Fig. 59.1B; see Fig. 59.3A). Throughout development the lungs remain unexpanded and do not achieve their full size within the thorax, reflecting the fact that the placenta, and not the lungs, is the organ of fetal respiration. The lower partition of the thorax, the diaphragm, can be identified in stage 13 embryos; it migrates caudally in line with the craniocaudal progression of development and the elongation of the neck. The parietal pericardium remains attached to the diaphragm as it descends.

For the lungs to inflate and deflate, they must be surrounded by a complete pleural cavity slightly larger than the capacity of the lungs. The synchronous development of the thoracic cage, diaphragm and the pleural cavities is therefore of vital importance for the normal development of the lungs and postnatal functioning of the respiratory system. Before birth, fetal breathing movements may be observed using ultrasonography. These can have no respiratory function, but it is thought that these phasic changes lead to the release of growth factors which promote normal lung development. These movements require an intact thoracic and abdominal cavity, so that the diaphragm can descend towards the rigid pelvic bowl, pushing out the abdominal wall. In conditions where this is not the case, for example omphalocele, the lungs may be smaller than normal. Other causes of interference with these movements include neuromuscular disorders of antenatal onset, such as severe spinal muscular atrophy and myotonic dystrophy inherited from the mother, and reduced volume of amniotic fluid, for example in Potter's syndrome (bilateral renal agenesis, oligohydramnios sequence).

The lung buds are invested by splanchnopleuric mesenchyme derived from the medial walls of the pericardioperitoneal canals, whereas the lateral walls produce somatopleuric mesenchyme, which contributes to the body wall. This latter mesenchyme is penetrated by the developing ribs which arise from the thoracic sclerotomes. In the midline, the somatopleuric mesenchyme gives rise to the sternum and costal cartilages. The bony and cartilaginous cage provides insertions for the intercostal muscles, which arise from the ventrolateral edge of the epithelial plate of the somites. The somatopleuric coelomic epithelium, after its proliferative phase, gives rise to the mesothelium of the parietal layer of pleura.

As the lung buds project into the pericardioperitoneal canals (Figs 59.1C, 59.2A), they subdivide them into primary pleural coeloms around the lung buds cranially, and paired peritoneal coeloms caudally, which are continuous with the wider peritoneal coelom around the mid- and hindguts. The communications with the pericardial and peritoneal coeloms become termed the pleuropericardial and pleuroperitoneal canals, respectively. When separation between these fluid-filled major coelomic regions is advancing towards completion, they are named the pericardial, pleural and peritoneal cavities. In early embryos, the cavities retain substantial volumes of fluid and their walls are separate: they provide the route for a primitive type of circulation until superseded by the blood vascular system. In later fetal and postnatal life, the cavity walls are coapted, so that a mere microscopic film of serous fluid intervenes between them.

Fig. 59.2 **A**, Dorsolateral view of the foregut between the pericardio-peritoneal canals. The respiratory diverticulum arises from the ventral side of the pharynx and grows caudally. Bilateral lung buds extend dorsally into the pericardio-peritoneal canals dorsolaterally. Later changes in position of the common cardinal veins contribute to the formation of the pericardio-pleural membranes cranial to the developing lungs whereas folds of coelomic epithelium, pleuroperitoneal membranes, separate the pleural cavities from the peritoneal cavity. **B**, Components of the diaphragm.

A curved elevation of tissue, the pulmonary ridge, develops on the lateral wall of the pleural coelom and partly encircles the pleuropericardial canal. The ridge is continuous with the dorsolateral edge of the septum transversum. The developing lung bud abuts on the ridge, which as a result divides into two diverging membranes meeting at the septum transversum. One is cranially placed and termed the pleuropericardial membrane (Fig. 59.2A); embedded within it are the common cardinal vein and phrenic nerve, which reach the septum transversum by this route. The other membrane, caudally placed, is termed the pleuroperitoneal membrane (Fig. 59.2A,B). As the apical part of the lung forms, it invades and splits the body wall and extends cranially on the lateral aspect of the common cardinal vein, preceded by an extension from the primary pleural coelom to form part of the secondary, definitive, pleural sac. In this way the common cardinal vein and the phrenic nerve come to lie medially in the mediastinum. The pleuropericardial canal, which lies medial to the vein, is gradually narrowed to a slit, which is soon obliterated by the apposition and fusion of its margins. Closure occurs early and is mainly effected by the growth and expansion of the surrounding viscera (heart and great vessels, lungs, trachea and oesophagus), and not by active growth of the pleuropericardial membrane across the opening to the root of the lung.

In addition to its extension in a cranial direction, the lung and its associated visceral and parietal pleurae also enlarge ventromedially and caudodorsally. With the ventromedial extension, the lungs and pleurae therefore excavate and split the somatopleuric mesenchyme over the pericardium, separating the latter from the ventral and lateral thoracic walls (Fig. 59.3B–D). The ventrolateral fibrous pericardium, parietal serous pericardium and mediastinal parietal pleura, although topographically deep, are therefore somatopleuric in origin.

Congenital disorders of the chest wall

The dorsal portion of the thorax is derived from somites, the sclerotomal portions of which form the thoracic vertebrae and ribs (Ch. 44). Vertebral anomalies, including formation of hemivertebrae and block vertebrae (where cranial and caudal sclerotomal halves do not separate), may contribute to scoliosis. Five percent of scoliosis is congenital; it may be associated with multiple other anomalies, e.g. the VACTERL (**V**ertebral; **A**norectal; **C**ardiac; **T**racheal; **E**sophageal; **R**enal; **L**imb) association or with congenital syndromes such as Marfan’s and congenital neurofibromatosis. The diagnosis may be missed at birth. There are a number of syndromes in which the chest wall does not develop properly, and the lungs are consequently hypoplastic. These include Jeune’s syndrome, asphyxiating thoracic dystrophy (an autosomal recessive condition which may be associated with short limb dwarfism and polydactyly). Rib cage abnormalities also occur in thanatrophic dwarfism, achondroplasia, chondroectodermal dysplasia and giant exomphalos. Many of these conditions are fatal soon after birth; milder forms may improve with time, but affected individuals may need prolonged respiratory support.

DIAPHRAGM

The separation of the pleural and peritoneal cavities is effected by development of the diaphragm, which forms from a portion of the septum transversum mesenchyme above the developing liver (Fig. 59.2A,B). The septum transversum is a population of mesenchymal cells which arises from the coelomic wall of the caudal part of the pericardial cavity. As the population proliferates, it forms a condensation of mesenchyme, caudal to the pericardial cavity and extending from the ventral and lateral regions of the body wall to the foregut. Dorsal to it on each side are the relatively narrow pleuroperitoneal canals. The endodermal hepatic bud grows into the caudal part of the septum transversum, whereas the cranial portion will form the diaphragm.

The oesophagus and stomach are medial to the pleuroperitoneal canals. As development proceeds, the lower portion of the oesophagus inclines ventrally anterior to the descending thoracic aorta. Although the oesophagus has no true ventral or dorsal mesentery, in descriptions of diaphragmatic development the portion of mesenchyme between the oesophagus and aorta at the level of the forming diaphragm is often homologized with part of a dorsal meso-oesophagus. The pleuroperitoneal membranes, which remain small, are dorsolateral to the canals, and the mesonephric ridges, suprarenal glands and gonads are dorsal. Just as the enlargement of the pleural cavity cranially and ventrally is effected by a process of burrowing into the body wall, so is its caudodorsal enlargement. The expanding pleural cavities extend into the mesenchyme dorsal to the suprarenal glands, the gonads and (degenerating) mesonephric ridges. Thus somatopleuric mesenchyme is peeled off the dorsal body wall to form a substantial portion of the dorsolumbar part of the diaphragm (Fig. 59.3C). The pleuroperitoneal canal is closed by the fusion of its edges, which are carried together from posterolaterally to anteromedially by growth of the organs surrounding it, in particular by growth of the suprarenal gland. The right pleuroperitoneal canal closes earlier than the left, which presumably explains why an abnormal communication persisting between the pleural and peritoneal cavities is more frequently encountered on the left.

While these changes are occurring, the septum transversum undergoes a progressive alteration in relative position. The dorsal border of the septum transversum which initially lies opposite the second cervical segment, migrates caudally as the embryo grows and the heart enlarges. At first the ventral border moves more rapidly than the dorsal, but after the embryo has attained a length of 5 mm, the dorsal border migrates more rapidly. When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (C3, 4 and 5) and portions of the corresponding myotomes, grow into it and accompany it in its later migrations. The dorsal border of the septum transversum does not come to lie opposite the last thoracic and first lumbar segments, the final position occupied by some of the dorsal attachments of the diaphragm, until the end of the second month. The main derivatives of the central part of the diaphragm lie at considerably more cranial levels.

The diaphragm is therefore composed of the dorsal mesooesophagus and paired pleuroperitoneal membranes (posteriorly); septum transversum mesenchyme (ventrally); and excavated body wall (posteriorly and laterally).

Diaphragmatic herniae

Diaphragmatic herniae may result from failure of fusion of the component parts or from a primary defect. Posterolateral defects (Bochdalek’s hernia) are the most common (85–90%) and may be bilateral (5%) or unilateral. Of the unilateral defects, the left side is more commonly affected (80%). Although these hernias have been attributed to failure of fusion of the pleuroperitoneal membrane, there is increasing evidence that the primary abnormality is lung hypoplasia, and the herniation of the abdominal contents is secondary, which has important implications for treatment (Jesudason 2002). A non-muscular membranous sac, possibly derived from the pleuroperitoneal canal wall is present in 10–15% of cases, signifying the early occurrence of this lesion prior to closure of the pleuroperitoneal canal. Hernias between the costal and sternal origins (Morgagni hernia) are rare (1–

2%). Midline defects in the central tendon arise from septum transversum defects. The incidence of congenital diaphragmatic hernias is about 1 : 3000 to 1 : 5000 in neonates, with a prenatal incidence of 1 : 2000.

Diaphragmatic hernias can usually be diagnosed by antenatal ultrasound examination. The presence of bowel in the thorax and mediastinal shift may be seen. The main causes of death in babies with diaphragmatic hernias are pulmonary hypoplasia and hypertension. Pulmonary hypoplasia is related to the abnormal branching of the airways both ipsilaterally and contralaterally, resulting in the formation of reduced numbers of alveoli. Pulmonary hypertension is related to pulmonary hypoplasia, and also to the increased muscularization and reactivity of the pulmonary circulation. There may be associated abnormalities, including trisomy 13 and 18, and diaphragmatic hernia may be part of a number of syndromes, many of which may lead to termination of the pregnancy or to death of the neonate.

Diaphragmatic eventration is a condition in which a (usually) right-sided abnormal diaphragmatic silhouette is seen on X-ray with an abnormal medial bulge into the thorax. This is a benign condition, often a chance finding, and usually requiring no treatment: it is occasionally associated with rib and cardiac abnormalities.

OESOPHAGUS

The development of the oesophagus is described in Chapters 35 and 73. Failure of separation of the oesophagus and trachea is described on page 1036. Oesophageal atresia and tracheo-oesophageal fistula may present antenatally with polyhydramnios due to failure of fetal swallowing, and choking and inability to swallow saliva in the neonatal period.

Neonatal thorax and diaphragm

A number of differences between the neonatal and adult thorax and diaphragm are significant in early postnatal life, especially in the preterm infant. The full-term neonatal thorax has a rounded circumference whereas the adult profile is dorsoventrally flattened. The compliance of the adult chest wall and lung are approximately equal, but the neonatal chest wall is up to five times more compliant than the lungs and so is easily deformable: indrawing of the chest wall is an important sign of increased work of breathing in the neonate. The diaphragm is relatively flat at birth and gains its dome shape as the thorax and abdominal viscera grow. The arrangement of the ribs and diaphragm in the neonate means that contraction of the diaphragm pulls the compliant ribs inwards, which does not contribute to inspiration and leads to chest distortion, and which may be opposed by the stabilizing action of the expiratory muscles. The neonatal diaphragm exhibits an exaggerated asymmetric movement: the posterior portion shows a considerably greater excursion than the anterior portion.

A neonate undertakes relatively greater work in order to breathe, and is much more vulnerable to developing respiratory muscle fatigue and respiratory muscle failure than an adult. Experimental animal studies suggest that neonates may be especially vulnerable to respiratory muscle failure because of the initial immaturity of synapses. Moreover, myosin isoforms are developmentally regulated in the diaphragm: the reduced power output and work performance of the newborn diaphragm may reflect these molecular differences.

In expiration, there may be active braking of airflow, caused by inspiratory muscle activity and partial constriction of the larynx: this produces grunting on expiration especially if the lungs are stiff, for example in neonatal respiratory distress. A very preterm neonate is difficult to study, but respiration is likely to be even more compromised by the compliant chest wall and lack of reserve than it is in the term newborn (Mortola 2002).

At all ages, there is a reduction, if not loss, of tonic intercostal activity during rapid eye movement (REM) sleep. The mechanism is believed to be related to a descending spinal inhibition of the muscle spindle system. In addition, although during REM sleep the diaphragm descends further, this inspiratory effort is dissipated in sucking in the ribs and enlarging the abdomen, thus the rib cage and abdominal ventilatory movements become out of phase. The neonate is at particular risk in this respect, because the chest wall is flexible, and much of the infant sleep activity is of the REM type. Furthermore, the upper airway musculature may lose tone during REM sleep, so that the soft tissues of the pharynx are sucked in during inspiration, limiting the cross-sectional area of the upper airway, and further increasing the work of breathing.

HEART AND GREAT VESSELS

Cardiac differentiation and morphogenesis are intimately related processes, achieved by a highly complicated transcriptional network. The cardiac transcription factor Nkx2–5, which has a homogeneous distribution over the embryonic heart tube, is generally important for cardiac-specific gene expression. In the human, mutations in this factor cause atrial septal defects and disturbances of atrioventricular conduction; in *Drosophila* the heart will not form in its absence. The recent discovery of the involvement of the role of T-box transcription factors, which are locally expressed, provides some evidence of the further complexity of patterning the heart. Whereas Tbx5 confers caudo-cranial positional information over the heart tube, thereby determining the regional development of the cardiac chambers along these axes, Tbx2 and 3 prevent regional formation of the cardiac chambers, permitting the myocardium in these regions to differentiate into the conduction system. Tbx18 is involved in the development of the sinus venosus and Tbx1 in the development of the outflow tract of the heart.

A number of terms must be specified before development of the heart and discussion of the cardiac chambers can be described. The inflow tract of the heart starts at the transition of the systemic tributaries (sinus venosus) into the primary heart tube. Within the straight heart tube, one atrial and one ventricular chamber are initially discerned, separated by an atrioventricular canal. The inflow tract thus connects the sinus venosus with the forming atrium, whereas the outflow tract connects the ventricle with the aortic sac; a proximal portion (close to the ventricle) and a distal portion can be defined within the outflow tract.

CELLS THAT GIVE RISE TO THE HEART

The heart is formed from tissues derived from the midline splanchnopleuric coelomic epithelium with later contributions from neural crest mesenchyme. The splanchnopleuric coelomic epithelium gives rise to the myocardium, including the conduction system of the heart, and the endocardium, including its derived cardiac mesenchymal population which produces the valvular tissues of the heart. Splanchnopleuric coelomic epithelium is also the source of the epicardium, coronary arteries and interstitial fibroblasts.

Primitive cardiac myocytes can first be seen in embryos at stage 9. During the onset of neurulation and somitogenesis, the intraembryonic coelom forms across the midline, initially above the endoderm, in a horse shoe-shaped area termed the cardiac crescent (Fig. 59.4). As the head fold emerges, the coelom undergoes a reversal, so that the future pericardial cavity comes to lie ventral to the endodermal foregut (Figs 59.1, 59.5). The splanchnopleuric wall of the pericardial coelom, subjacent to the endoderm, provides a germinal epithelium that produces early cardiac myocytes. It is characterized by the expression of myocardial specific markers, such as cardiac myosin heavy chain. This initial origin of myocardial cells is termed the primary heart-forming field, distinguishing it from later myocardial additions from mesenchyme localized central and peripheral to the cardiac crescent on the embryonic disc, termed the second heart-forming field (Fig. 59.4). It is not yet known whether these two sources of myocardium represent distinct myocardial lineages, or a single part which develops into separate components later on.

The endocardium also develops during stage 9 from the coelomic splanchnopleuric epithelium. Cells arise singly close to the ventro-lateral edges of the cranial intestinal portal and form an endocardial plexus between the splanchnopleuric coelomic epithelium and the foregut endoderm. These groups of cells are now termed angioblastic mesenchyme; they are amongst the earliest intraembryonic vascular precursors to appear and express markers for the endothelial cell lineage. The cells aggregate to form an epithelium, the endocardium, which encloses small cavities which coalesce in the vicinity of the developing foregut to establish bilateral, hollow endocardial tubes. The latter fuse across the midline progressively, commencing at the outflow tract, or arterial pole, and extending to the inflow tract, or venous pole (Fig. 59.5). By stage 10 a single endocardial tube is present and is almost completely surrounded by myocardial cells. This arrangement of an outer myocardial sleeve containing an inner endocardial tube constitutes the primary heart tube. The inner endocardial epithelium induces the myocardial cells to synthesize specific extracellular matrix proteins which form a fine extracellular reticulum that holds the endocardial tube apart from the developing myocardium. Close to the foregut endoderm, the myocardial cells at the reflections of the pericardial splanchnopleuric epithelium form the dorsal mesocardium, which may stabilize the developing endothelium and promote the fusion of the bilateral endocardial tubes. The dorsal mesocardium encompasses a mesenchymal population specifically referred to as mediastinal mesenchyme, and is contiguous with the splanchnopleuric mesenchyme surrounding the embryonic foregut.

Much later in heart development, neural crest cells, arising from the region between the otic vesicle and the caudal limit of somite three, grow into the outflow tract of the heart. They are believed to play a role in the spatio-temporal regulation of the division of the outflow tract into the aortic and pulmonary pathways, and the development of the muscular sub-pulmonary infundibulum.

The epicardium, sometimes included in descriptions of the myocardium as ‘epimyocardium’, is not present at the early stages of heart development (but see p. 1027).

Endocardial cushions

The extracellular matrix of the heart, historically termed cardiac jelly, promotes occlusion of the endocardial tubular lumen during myocardial contraction, thus providing mechanical assistance for the generation of the flow of blood. It also acts as a site for the deposition of inductive factors from the myocardial cells, which, in turn, modify the differentiation of specific endocardial cells. It has been called a gelatinoreticulum, a myoepicardial reticulum (Fig. 59.5C,D) and, more recently, the myocardial basement membrane. Here, the term cardiac extracellular matrix will be used. It is composed of, among other things, hyaluronic acid, hyaluronidase and fibronectin. Inductive signals originating from the myocardial cells cause a subset of endocardial cells lining the atrioventricular canal and the proximal outflow tract to transform into mesenchyme (cardiac mesenchyme); the endocardial cells in other regions of the heart tube, such as those in the ventricle, do not undergo such a transition. When activated by myocardial inductive factors, the endocardial cells lose their cell-to-cell associations, show decreased expression of neural cell adhesion molecule, and increased expression of substrate adhesion molecules such as chondroitin sulphate and fibronectin. They undergo rearrangement of their cytoskeleton necessary for migration, and they express type I procollagen. Uniquely, they retain their expression of endothelial markers. This epithelial to mesenchymal transition may, perhaps, be the only example of a mesenchymal population that is derived from an endothelial lineage.

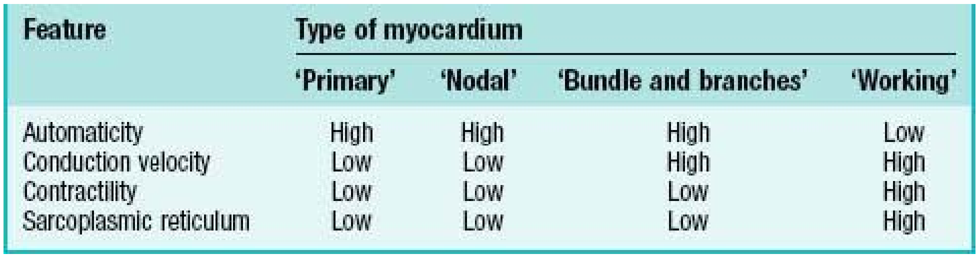
Formation of cardiac mesenchymal cells at the atrioventricular canal and the proximal myocardial outflow tract is followed by their migration into the cardiac extracellular matrix. These cells proliferate between the endocardium and myocardium and, with local accumulation of extracellular matrix molecules, produce protrusions, termed endocardial or cardiac cushions, which bulge into the primary heart tube and initially provide the valvular mechanisms required in the atrioventricular canal and outflow tract. Their position corresponds to the future positions of the definitive cardiac valves. In the distal part of the outflow tract, which initially has myocardial walls, cells which are derived from the neural crest subsequently make significant contributions to the mesenchyme of the endocardial cushions. Although proper migration of these cells from the neural crest is crucial for normal development of the outflow tract and formation of the leaflets and sinuses of the arterial valves, their function is largely obscure. They are no longer found in the leaflets of the arterial valves in the formed heart, or in the muscular subpulmonary infundibulum, which is also derived from the outflow cushions. The endocardial cushions themselves ultimately fuse, forming a wedge of mesenchyme that serves to guide the union of the internal muscular septal structures (see p. 1024). At their time of fusion, the atrioventricular endocardial cushions are large relative to the size of the atrioventricular orifices; they will provide the scaffold for formation of the leaflets of the tricuspid and mitral valves.

Cardiac myocytes – contraction, conduction and automaticity

Cardiac myocytes share a number of characteristic features that distinguish them from other cells. All cardiac myocytes have sarcomeres and a sarcoplasmic reticulum and, in principle, share the capacity of producing an intrinsic cycle of electrical activity resulting in contraction. This phenomenon is called automaticity, or pacemaker activity. An absolute requirement for effective pacemaking is poor electrical coupling of the cells, which also implies slow conduction. It allows the cells to build up sufficient electrical charge which is then propagated through the surrounding myocardium. Thus ‘a small node can drive a large heart’ (see p. 1021).

Varying degrees of differentiation are seen in early populations of cardiac myocytes which can be categorized as forming working, nodal, conducting and primary myocardium (Table 59.1). Cells of the atrial and ventricular working myocardium display virtually no automaticity, but are well coupled and have well developed sarcomeres and sarcoplasmic reticular structures. The development of the synchronously (fast) contracting working myocardium requires fast conduction of the depolarizing impulse, and so the cells possess well-developed gap junctions. In marked contrast, the cells forming the nodes of the cardiac conduction system have the opposite phenotype, and resemble the myocytes which are found initially in the primary heart tube. The cells of the putative atrioventricular and peripheral ventricular conduction system have an ambiguous phenotype: the cells are well-coupled, thus allowing fast conduction of the depolarizing impulse, but otherwise retain an embryonic phenotype. The division does not imply that the cells belonging to one group are identical, but rather that they share distinguishing features developed to variable degrees.

Table 59.1 Basic phenotypes of cardiac myocytes.



Feature	Type of myocardium			
	'Primary'	'Nodal'	'Bundle and branches'	'Working'
Automaticity	High	High	High	Low
Conduction velocity	Low	Low	High	High
Contractility	Low	Low	Low	High
Sarcoplasmic reticulum	Low	Low	Low	High

Automaticity and slow conduction are features of the myocardium of the primary heart tube. The slow conduction of the depolarizing impulse over the heart tube causes a peristaltic wave of contraction, by means of which the blood is pushed towards the arterial pole. During the waves of contraction, the accumulated cardiac extracellular matrix closes the endocardial tube and prevents the backward flow of blood. Unambiguous morphologic markers are often lacking in the early embryonic heart, which means that it is not possible to distinguish the various cells phenotypically; automaticity and the speed of conduction have therefore become important functional parameters with which to describe the development of the different parts of the heart.

HEART TUBE

During the process of embryonic folding, the midline splanchopleuric coelomic epithelium, which is derived from the primary heart field (cardiac crescent) becomes positioned ventral to the foregut. The splanchopleuric epithelium is proliferative and gives rise to mesenchymal populations and particularly early cardiac myocytes which arise from the coelomic wall adjacent to the endoderm of the foregut (Fig. 59.5). After folding, the second heart field contributes cells to both the arterial and venous poles of the heart. It has been suggested that the secondary heart field may contribute cells only to those cardiac components that are required for the pulmonary circulation, namely the right ventricle and outflow tract at the arterial pole, and the atrial septum and the dorsal atrial wall at the venous pole. Extending this suggestion, the original primary heart-forming field would give rise to those components that are required for the systemic circulation, namely the systemic venous sinus and its tributaries, the initial atrium, the left ventricle, and the arterial conus, as seen in the outflow tract of primitive fishes, although this latter structure has no homologue in mammalian hearts.

During the process of folding, the pericardial cavity and concomitantly the myocardium, gradually extend around the forming endocardial tube, leaving the dorsal mesocardium, a transient connection that is analogous to the mesentery of the intestines (Fig. 59.5C,D). The persisting stalk of the dorsal mesocardium connects the venous pole of the heart with the splanchnopleuric mesenchyme around the developing lung buds and with the septum transversum mesenchyme, which will give rise to the liver. The dorsal mesocardium is the site of early mediastinal mesenchyme production. It disappears as a mesenteric entity during the third week of development, when the embryo has from 4 to 12 somites; at the same time, the endocardial heart tube becomes entirely surrounded by the myocardium, and enclosed within the pericardial cavity. The breakdown of the dorsal mesocardium establishes a passage across the pericardial cavity, from side to side dorsal to the heart, which persists as the transverse sinus of the pericardium.

At this stage, the heart is bilaterally symmetrical and has the form of an inverted ‘Y’. The legs of the Y are positioned caudal to each side of the cranial intestinal portal, where they form the venous pole of the heart (59.6A,B). The stem of the Y connects cranially with the great arteries, forming the arterial pole of the heart. From the outset, both poles are connected with the systemic vessels running from the embryo, the yolk sac, and the placenta. The pulmonary veins form later, during the fifth week of development, the initial venous primordium becoming evident in the mesenchyme derived from the dorsal mesocardium caudally. Also at this site, mediastinal myocardium continues to be added to the heart, forming the smooth dorsal wall of the left atrium, and providing the site of formation of the primary atrial septum.

Recent fate maps have shown that the primary heart tube contains cell lines which will contribute to only two compartments. The myocardium of the stem of the inverted Y contains only precursor cells of the left ventricle, and both legs of the inverted Y contain precursor cells of the atrioventricular canal and parts of both atrial chambers. There is no evidence to support the previous, traditional concept of heart development, i.e. that all the putative cardiac segments are already present in the straight heart tube and develop to contribute to the various parts of the definitive cardiac chambers. This hypothesis has now been disproved by elegant experimental studies which have shown that the definitive cardiac chambers are formed by local differentiation and expansion, or ‘ballooning’, of the myocardial walls of the primary heart tube.

Looping of the heart tube

Cranial and caudal recruitment of myocardium and endocardium produces considerable lengthening of the primary heart tube. Recent studies of the mechanism of proliferation in the avian heart have shown that cardiac myocytes stop dividing after overt differentiation. The tube continues to elongate, largely as a result of the recruitment of additional myocytes to the tube, as shown by studies of both morphology and molecular lineages, and to a lesser extent because of an increase in the size of the myocytes which form the walls of the tube. The lengthening heart tube bends ventrally and rightwards, concomitant with the breakdown of the dorsal mesocardium. The bend is called the ventricular loop, since the left ventricle subsequently balloons and expands at its outer curvature, which is the original ventral side of the straight tube. The inner curvature of this loop was originally its dorsal side.

It is often stated that looping of the tube is the first visual evidence of asymmetry in the embryo, although careful examination reveals that the atrioventricular canal has become asymmetric prior to the start of looping. Although the sense of laterality of the developing organs of the body, including the atrial appendages, develops during gastrulation, the pathway of signalling that governs rightward looping of the heart tube remains unknown. However, it is now well established that signalling pathways including *Pitx2*, *nodal*, *lefty*, and *cited-2*, determine the formation of the morphologically left-sided or right-sided features seen in organs such as the lungs, the bronchial tree, the liver and spleen, and the atrial appendages.

By the time the primary heart tube has formed its ventricular loop, it is possible to distinguish the atrial and ventricular components of the developing heart (Figs 59.6D-G, 59.7A,B) and to recognize an outflow tract connected with the aortic sac and developing pharyngeal arch arteries. The cells which, at this stage, make up the outflow tract, will, at later stages, be found within the right ventricle. At the proximal side of the outflow tract, cells are recruited to the developing right ventricle and, contemporaneously, new cells are recruited to the outflow tract from the second heart-forming field. The atrial and ventricular components are separated one from another by the atrioventricular canal, which at this stage has significant length. The systemic venous tributaries drain directly to the atrial cavity.

The sinus venosus with right and left sinus horns, which forms at the confluence of the systemic venous tributaries, is a prominent structure in lower vertebrates. In mammals, it does not become recognizable as a morphologic entity until the systemic veins have excavated themselves from the mesenchyme of the body and been surrounded by myocardium. It then becomes incorporated into the pericardial cavity so that the sinus horns become part of the heart. All of these processes occur up to the 25th day of development in humans: only after this stage is it possible to consider development of the definitive atrial and ventricular chambers.

INFLOW TRACT

The working myocardium of the atrium differentiates locally at the dorsolateral sides of the heart tube (59.6D–G). The developing atrium then expands enormously, in dorsal, lateral and, most prominently, in a cranial direction. The cranial expansion is seen as pouches which become the left and right atrial appendages (Fig. 59.7A,B). The floor of the atrium, including the sinus venosus, and the atrioventricular canal, are made of primary myocardium. Less cellular proliferation occurs in these parts than in the expanding atrial chambers: the primary myocardium marks the inflow to, and the outflow from, the initial atrial chambers as ‘rings’ which are also associated with the formation of the conduction system (see p. 1021). The ring at the inflow defines the sinu-atrial junction, whilst the atrioventricular canal, which forms the atrial outlet during development, will eventually be incorporated into the definitive right and left atrial chambers as the atrial vestibules. Although it is possible to recognize the forming left and right atrial appendages at this stage, the right being more extensive than the left, the atrium itself has a single cavity and there is no evidence of septum formation. The myocardium of the sinus venosus and the newly forming mediastinal myocardium are smooth-walled, whereas the myocardium of the appendages shows ridges, the pectinate muscles, on the inner surface. The formation of the different appendages is under control of the *Pitx2* signalling pathway. The myocardium of the appendages has a chamber phenotype, or is working myocardium; it expresses atrial natriuretic factor and connexin40 among other markers.

Right atrium

The further development of the right atrium is characterized by the incorporation of the sinus venosus into the right part of the primary atrium. This process is under control of the T-box transcription factor Tbx18. At about 4 weeks of development, the sinuatrial junction of the looping primary heart tube is positioned symmetrically in the midline (Fig. 59.8; see also Figs 13.1B, 73.8). The left and right common cardinal veins drain directly into the cavity of the primary atrium. The atrial myocardium extends to the margins of the pericardial cavity, and strictly speaking the sinus venosus is not yet formed, because the systemic venous tributaries are embedded within the mesenchyme of the septum transversum.

Fig. 59.8 The changes to the sinus venosus. **A**, Dorsal view of the early heart tube shown in **Fig. 59.6D**. **B**, Changes to the circulation brings the venous circulation to the right. This causes enlargement of the right horn of the sinus venosus and atrium and attenuation of the left horn of the sinus venosus. **C**, The right horn of the sinus venosus becomes absorbed into the atrium. The left horn of the sinus venosus becomes the coronary sinus. **D**, Dorsal view of the embryonic heart showing the relative changes to the sinus venosus.

During subsequent development, the pericardial cavity expands to enclose the terminal segments of the systemic venous tributaries, and at the same time their walls differentiate as myocardium. They can now be termed the left and right horns of the sinus venosus; each horn receives the union of the corresponding umbilical vein, vitelline radicles, and common cardinal vein (Fig. 59.8; see also Fig. 73.8). Concomitantly, the constriction between the left horn and the atrium becomes more pronounced. As the dorsal wall of the left atrium is formed from additions of mediastinal myocardium, the left horn becomes incorporated into the developing left atrioventricular junction, its orifice draining to the newly formed right atrium. At the same time, the left-sided venous tributaries diminish in size; the left common cardinal vein forms the oblique vein of the left atrium, and the left sinus horn forms the coronary sinus (Fig. 59.8), maintaining its own myocardial wall as it becomes incorporated into the atrioventricular junction.

The right sinus horn increases rapidly in size with growth of the liver (see Figs 73.8, 73.9). The vitello-umbilical blood flow enters the right horn through a wide but short hepatocardiac channel, which becomes the cranial end of the inferior vena cava. The right horn also receives the right common cardinal vein, draining the blood from the right side of the body (Fig. 59.8B,C). Later, when transverse connections are established between the cardinal veins, the blood from the left side of the body also reaches the heart via the veins draining the right side (see Fig. 13.4). As these changes take place, the right sinus horn, including the proximal parts of the superior and inferior cardinal veins, becomes incorporated into the right atrium, forming the smooth-walled systemic venous sinus, also known as the sinus venarum.

The right sinus horn opens into the right atrium through its dorsal and caudal walls (Fig. 59.8; see Fig. 59.12). The sinuatrial orifice becomes elongated and slit-like, guarded by two muscular folds, the left and right sinuatrial (venous) valves. These two valves meet cranially and become continuous with a fold that projects from the atrial roof, the septum spurium. The valves also meet caudally, and merge with the inferior atrioventricular cushion. With ongoing development, the cranial part of the right sinu-atrial valve loses its fold-like form, but its position is indicated in the adult heart by the site of the crista terminalis of the right atrium. Its caudal part forms the valve of the coronary sinus, also known as the Thebesian valve, and most of the valve of the inferior vena cava (Eustachian valve). The union of the two valvular remnants then passes through the tissue which separates the orifice of the coronary sinus from the fossa ovalis. This area is known as the ‘sinus septum’, but in reality this ‘septum’ is no more than a muscular fold in the dorsal wall of the right atrium. The continuation of the venous valves persists as the tendon of Todaro, an important landmark to the location of the atrioventricular node in the definitive heart. The left venous valve blends with the right side of the atrial septum; there is usually no trace of it in the postnatal heart.

Left atrium

Following the formation of the primary atrium and the left atrial appendage, the left atrium takes shape by the formation and incorporation of mediastinal myocardium. While the tributaries of the sinus venosus approach the atrium caudally, the differentiating pulmonary veins gain their entrance to the atrial cavity through the dorsal mesocardium (Fig. 59.5). The topographical relationships seen in the postnatal heart are thus established as soon as differentiation of the pulmonary venous portal occurs.

Early in the development of the atrium, the pulmonary vein develops as a solitary channel from angiogenic cells derived from the dorsal mesocardium, and establishes continuity with the vascular plexus formed in the mediastinal mesenchyme around the developing lung buds. The solitary pulmonary vein opens into the caudo-dorsal wall of the atrium adjacent to the developing atrioventricular junction, its atrial orifice being flanked by two prominent ridges. The primary atrial septum develops from the right ridge, following incorporation of the left sinus horn into the right side of the primary atrium, thus confining the pulmonary venous orifice to the developing left atrium (Fig. 59.12). The pulmonary vein initially branches within the dorsal mediastinal mesenchyme, its tributaries draining blood from the developing lung. With continuing development, the walls of the venous channels become surrounded by myocardium, this process occurring to the level of the second bifurcation. The veins then expand, and are incorporated into the roof of the left atrium, eventually forming the greater part of its cavity. However, all four pulmonary veins do not achieve their separate opening into the atrial roof until well after the completion of atrial septation, and probably not until the 10th or 11th week of development. Variations in the precise pattern of pulmonary venous drainage are quite common. With these changes, the left half of the primary atrium becomes progressively restricted to the mature appendage. The myocardial sleeves surrounding the pulmonary orifices taper off, and become intermingled with fibrous tissue. In later life, it is likely that this intermingling of myocardial and fibrous tissues forms the substrate for some forms of atrial fibrillation. The opening of the solitary pulmonary vein to the left of the right pulmonary ridge is an essential pre-requisite for atrial septation.

VENTRICLES

The ventricles develop at the ventral side of the looping primary heart tube during the fourth week of development (Figs 59.6, 59.7). The left ventricle develops from the stem of the Y-shaped heart, the right ventricle develops later, downstream relative to the left ventricle, when more myocardium has been added to the cardiac tube. As a result of the looping of the heart tube, the right ventricle is positioned at the right of the left ventricle, which is a prerequisite for the appropriate connection with the expanding atrial component of the heart. Unlike the atrial chambers, the morphological differences between the right and left ventricles are not part of the general asymmetry between the right- and left-sided organs of the body, but rather are under control of the signalling pathways which determine caudo-cranial differentiation. Retinoic acid, and its downstream transcription factor Tbx5, play a crucial role in this process.

The myocardium at the inner curvature, the original dorsal side of the cardiac tube, remains smooth-walled and maintains its molecular phenotype, whereas the myocardium at the outer curvature of the myocardial tube displays trabeculations in the fifth week of development (Fig. 59.7B). By stage 17, the trabeculations have achieved a typical spatial orientation, giving a sponge-like appearance to the internal aspect of both ventricles (Fig. 59.9). The definitive trabeculations, coarse in the right ventricle but much finer in the left, are first observed about the 40th day of gestation: they appear initially in the walls of both ventricles at the level of the atrioventricular junction and develop towards the apex of the heart. By the time the fetus is 10 weeks old, the trabeculations are much sparser, and are confined to the apical regions. This process of remodeling is accomplished without the intervention of macrophages or inflammatory cells in the immediate interstitium. The ventricular myocardium, encompassing the trabeculations and exterior wall, possesses a chamber phenotype, the myocytes expressing, among other proteins, the gap-junctional protein Cx40 and atrial natriuretic peptide. This myocardium stops proliferating and differentiates into the fast-conducting peripheral ventricular conduction system, whereas the outer layer becomes highly proliferative and forms the compact layer of the ventricular wall.

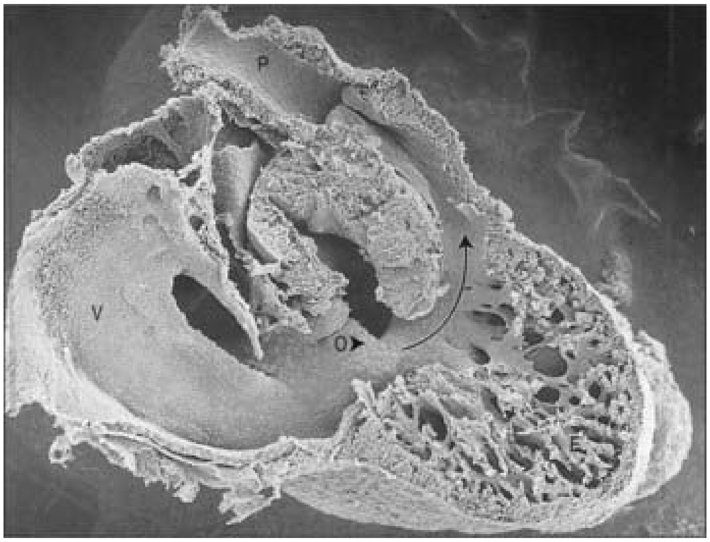

Fig. 59.9 SEM of human heart at 42 days' gestation. The right lateral wall of the right atrium, right ventricle and the outflow tract have been removed. The valve of the sinus venosus (V) is prominent. There is no septal cusp of the tricuspid valve guarding the inlet portion of the right ventricle. The parietal cusp has been removed. The atrioventricular cushions are fused. Note the adjacent right lateral tubercles (O). A small interventricular foramen (secundum, see text) is indicated (small arrowhead). There is a well developed right ventricular outflow tract (curved arrow). E, embryonic trabeculae; P, pulmonary trunk

OUTFLOW TRACT

Initially the outflow tract possesses myocardial walls up to the pericardial reflections. It displays a characteristic bend, which has a proximal part arising from the developing right ventricle and a distal part which becomes continuous with the aortic sac beyond the pericardial reflections. Although this bend is a conspicuous morphologic feature, it is highly unlikely that the cells to either side of it retain their position during subsequent development. Instead, it seems probable that cells are recruited from the second heart-forming field, and pass through the outflow tract to contribute to the definitive right ventricle. Subsequently, still more cells are recruited from pharyngeal mesenchyme, passing proximal to the pericardial reflections and forming the intrapericardial components of the arterial trunks. There remains much disagreement as how best to describe these morphological parts of the outflow tract. Some authors have labeled the proximal myocardial part the *conus*, calling the distal part the *truncus*, and the intrapericardial portion of the outflow tract the *aortic sac*. Others have called the entire myocardial outflow tract the *bulbus*, since the myocardial outflow tract of primitive vertebrates, called the *conus arteriosus* in primitive fish, and the *bulbus cordis* in amphibia, is presumed to develop into the right ventricle in higher vertebrates. Because the terms conus and truncus have been inconsistently used in literature, we prefer simply to describe proximal and distal parts of the myocardial outflow tract, and to describe, when it appears, an intrapericardial arterial portion of the outflow tract, this part interposing between the muscular component and the ventral aorta, the distal junction occurring at the pericardial reflections.

Given that different authors use different terminologies, it is not surprising that formation of the outflow tract remains one of the most confusing areas of cardiac development. The recent finding that the stem of the heart tube contains precursor cells exclusively for the left ventricle makes it essential to adopt descriptions which follow dynamic events, rather than continuing to use static names. Thus, as soon as the primary heart tube bends to produce its ventral ventricular expansion, by definition the developing ventricle achieves inlet and outlet components, even though these structures are not the definitive ventricular inlets and outlets. Cells that, initially, are found in the ventricular outflow tract subsequently become cells of the right ventricle. Furthermore, working myocytes can easily be distinguished from the primary myocytes of the straight heart tube. The primary myocardium is smooth-walled, whereas the developing myocardium of the ventricles is trabeculated, and expresses specific markers such as atrial natriuretic peptide and connexin40. Thus, that part of the primary heart tube downstream of the developing ventricular loop is termed the outflow tract, irrespective of the fact that eventually it will largely become incorporated within the definitive right ventricle (Figs 59.6, 59.7). Moreover, within the inner curvature of the ventricular loop, the walls of the outflow tract and atrioventricular canal fade into one another without a clear boundary. Indeed, ventricular working myocardium never develops at the inner curvature. It is within this ventricular part of the primary heart tube that the cushions of the atrioventricular canal and the outflow tract must achieve appropriate connections with the muscular ventricular septum in order to divide this part of the tube into left and right compartments. The cavity of the tube within which these events take place has been called ‘interventricular foramen’. This is incorrect, since it is rather the region between adjacent parts of the primary heart tube. It is, nonetheless, the remodelling of this inner curvature that sets the scene for the completion of cardiac septation.

CARDIAC FUNCTION AND THE CONDUCTION SYSTEM

Although only mammalian hearts have a well-defined conduction system, an essentially similar electrocardiogram can be recorded from animals as diverse as fish and man, indicating that the electrical connections between the cardiac components have been conserved during vertebrate evolution. Indeed, the development of the conduction system of the heart is inextricably associated with the development of the basic building plan for the heart. The conduction system is best defined as the system that initiates and conducts the sinus impulse. In mammals, it encompasses the sinu-atrial node, the atrioventricular node, the atrioventricular bundle, the bundle branches and their terminal ramifications. The nodes and the atrioventricular bundle can be considered the central conduction system, while the bundle branches and their ramifications represent the peripheral ventricular conduction system. The sinus impulse is generated in the sinus node, whence it is rapidly propagated through the atrial myocardium towards the atrioventricular node, where propagation is delayed. After an essential period of atrioventricular delay, the impulse travels rapidly through the atrioventricular conduction axis and the peripheral ramifications to reach the ventricular myocardium, which is then rapidly depolarized. Following repolarization, the sequence recurs in endless fashion throughout the life of the individual. The term ‘conduction system’, as opposed to the working myocardium of the chambers, may suggest that the working myocardium does not conduct, while the conduction system conducts rapidly. In order to produce powerful synchronous contractions, the working myocardium of the chambers must also, of necessity, conduct rapidly, whereas to act as a pacemaker, the cells of the nodes need to be poorly coupled, and hence display slow conduction.

The vertebrate heart is myogenic, implying that all cardiomyocytes have the capacity to generate and conduct the depolarizing impulse. Because cardiac myocytes are electrically coupled, the cells with the highest pacemaking activity take the lead. In the formed normal heart, the leading pacemaker is always within the sinus node. In embryonic hearts, the leading pacemaker is always found at the venous pole. Thus, it is the most recently recruited cells at the venous pole which always have the highest pacemaking activity. All regions of the early embryonic heart tube possess poorly coupled cells and display intrinsic automaticity, thus permitting slow propagation of the depolarizing impulses along the cardiac tube, and producing matching peristaltic waves of contraction which push the blood in an antegrade direction. The myocytes of a developing heart do not have well-developed sarcomeric structures, and have a poorly developed sarcoplasmic reticulum. This tissue has been called primary myocardium, distinguishing it from the rapidly conducting and well-developed working myocardium of the atrial and ventricular chambers.

As development proceeds, the ventricular chambers develop in the cranial part of the heart tube, by ventral expansion, and the atrial chambers in the caudal part by dorso-lateral expansion (Fig. 59.6). An adult type of electrocardiogram can be recorded from such hearts, showing rapid atrial depolarization, a period of atrioventricular delay, and rapid ventricular depolarization. The electrocardiographic tracings reflect the development of fast-conducting components within a slowly conducting heart tube, i.e. the development of a morphologic conduction system. The newly developed working myocardium expresses atrial natriuretic factor, along with the gap junctional proteins connexin40 and 43, which permit fast conduction.

Like the early peristaltic heart, flow through the developing chambered heart remains directional because the dominant pacemaking activity is still at the inlet of the heart. Peristaltic hearts do not need valves, whereas chambered hearts require the presence of one-way valves at the inlets to, and the outlets from, the chambers. The slowly conducting atrioventricular canal, interposed between the atrium and the ventricle, and the outflow tract positioned between the ventricle and the great arteries, are the parts which contain the endocardial cushions. These are able to function as sphincteric valves, as a result of their prolonged duration of contraction. These components retain their function until the definitive leaflets of the one-way valves have been sculpted from the cushions. The primary myocardium of the outflow tract does not regress until the arterial valves have been formed, and does not disappear in its entirety until around the twelfth week of human development. The primary myocardium of the atrioventricular canal is eventually incorporated into the atrial vestibules at the same time as the formation of the atrioventricular valves, becoming sequestrated on the atrial side of the atrioventricular junctions between 6 and 12 weeks of development (Fig. 59.10). An important part of the canal persists dorsally, where it differentiates into the slowly conducting atrioventricular node.

The purple part of the interventricular ring will give rise to the atrioventricular bundle and bundle branches, whereas the yellow part of the interventricular ring will not participate in the formation of the adult conducting system. **B**, The truncus arteriosus, now divided into the pulmonary trunk and aorta, is presented between the right and left atria which expand lateral to it The right atrium is now positioned entirely above the right ventricle and the outflow tract has expanded to the left; the left ventricle has access to the aorta. **C**, The position of the original primary heart tube ring indicated in the formed heart. The pulmonary trunk has been removed.

Considerable progress has been made over recent years in deciphering the pathways involved in establishing the building plan of the heart (Fig. 59.11). The combined action of the transcription factors Tbx5 and Nkx2–5 is required for the formation of the myocardium of the atrial and ventricular chambers. Tbx5 is expressed in a gradient over the heart tube, decreasing in concentration from caudal to cranial and may impose positional information. However, its pattern cannot explain the localized formation of the chambers and the conduction system. Localized expression of the transcriptional repressors Tbx2 and Tbx3 in the inflow tract, the floor of the atrium, the atrioventricular canal, the inner curvature of the ventricular region, and the outflow tract prevents the differentiation of primary into working myocardium. Tbx2 and Tbx3 effectively compete for binding to the promoters of the chamberspecific genes, such as atrial natriuretic factor and connexin40. The remaining primary myocardium of these regions initially induces the endocardium to undergo epithelial-to-mesenchymal transition, by which process the cardiac cushions become filled with mesenchyme. The myocardium also participates in the alignment of the atrial and ventricular chambers (which is essential for proper cardiac septation, and which is guided by the fusing cardiac cushions), and it forms the conduction system, including the sinus and atrioventricular nodes, the atrioventricular bundle, the floor of the developing right atrium (the internodal region), and the entirety of the atrioventricular canal. In the early chamber-forming heart of the mouse, Tbx3 is expressed in the atrioventricular canal, the floor of the atrium and around the orifices of the systemic venous tributaries, but not in the dorsal mesocardium surrounding the entrance of the pulmonary vein. During subsequent development, the domain of expression of Tbx3 expands from the atrioventricular canal to form a crescent on the crest of the ventricular septum. The dorsal aspect of this crescent develops into the atrioventricular bundle, while the atrioventricular node is formed at the dorsal junction with the atrioventricular canal. The ventral parts subsequently disappear during development.

Fig. 59.11 The early heart: distribution of the T-box transcription factors involved in patterning the heart.

The fact that the ventricular conducting system originates from a single primary ring provides a solid base for understanding the disposition of the conducting system in a number of congenital malformations. The concept accounts particularly well for the morphology and disposition of the atrioventricular node and bundle in hearts with straddling tricuspid valves, with double inlet left ventricles, and with congenitally corrected transposition.

SEPTATION OF THE EMBRYONIC CARDIAC COMPARTMENTS

The flow of blood on the right and left sides does not intermingle even in the developing heart, because flow is laminar, and the pressures are similar at the right and left sides. It is only after birth that the pressures in the ‘left’ systemic circulation become higher than those in the ‘right’ pulmonary circulation, and therefore the different flows have to be separated physically in order to prevent admixture of oxygenated and deoxygenated blood. Prior to birth the lungs are not functioning and blood flow to them is small. Even so, normal development of the heart requires that all cardiac compartments receive an adequate amount of blood. To this end, even before birth, the systemic blood of the right atrium is guided to the left atrium so that the left half of the heart and the brain is provided with a normal flow of blood. The right ventricle, in contrast, drains to the dorsal aorta via the ductus arteriosus (see Fig. 35.8). The walls that separate the right and left sides of the heart are largely formed in the fourth and fifth week of development. Some time later, not only the components of the primary heart tube, specifically the atrioventricular canal and the outflow tract, but also the atrial and ventricular chambers, must be separated physically into right and left halves. However, each compartment is separated in markedly different fashion.

Septation of the atrial chambers

As a prelude to atrial septation, the right horn of the sinus venosus is incorporated into the right part of the atrium and the pulmonary vein arises as a midline structure within the dorsal mesocardium. Internal separation into right and left atria is mainly effected by growth of two septa coupled with remodelling of the venous compartments. At the end of the fourth week of development, a crescentic fold, the primary atrial septum or septum primum, grows by active proliferation from the dorso-cranial atrial roof into the direction of the atrioventricular canal, extending downwards just to the right of the entrance of the pulmonary vein (Fig. 59.12A,D). It is separated from the left sinu-atrial valve by the interseptovalvular space. The leading edge of the septum primum is covered by a mesenchymal cap in continuity dorsally with extracardiac mesenchyme (mediastinal mesenchyme) derived from the dorsal mesocardium which forms the vestibular spine, or spina vestibuli. The ventral horn of the septum primum reaches the ventral (cranial) atrioventricular cushion, while the dorsal horn reaches the dorsal (caudal) cushion. Thus the primary atrial foramen, the foramen or ostium primum, is entirely surrounded by mesenchyme derived from endocardium. Ventral and caudal to the advancing edge of the septum primum, the developing atrial chambers communicate through the foramen primum (Fig. 59.12A,D).

As the foramen primum diminishes in size, the upper margin of the septum primum perforates by apoptosis, and thus right to left shunting of blood continues through a secondary foramen, the foramen or ostium secundum. The latter is formed before the end of the fifth week of development. Initially it lacks an upper rim, since its upper border is the atrial roof. The foramen primum is finally occluded in the median plane, as the edge of the septum primum merges with the fusing atrioventricular cushions (Fig. 59.12B,E). The foramen secundum then enlarges to permit free passage of blood from the right to the left atrium.

The solitary opening of the pulmonary vein into the roof of the left atrium, which is originally adjacent to the atrioventricular junction, becomes incorporated into the atrial wall, ultimately forming four separate orifices at the corners of the atrial roof. As this development continues, the muscular atrial roof itself invaginates on the right side of the primary atrial septum (Fig. 59.12B,E), the invaginated fold constituting the septum secundum. The free edge of the septum secundum overlaps the foramen secundum. When left atrial pressure exceeds right atrial pressure in postnatal life, the septum primum closes against the septum secundum as a flap-valve (Fig. 59.12C,F). The passage taken by blood as it passes from the right atrium, under the crescentic edge of the septum secundum, then obliquely towards and through the foramen secundum to the left atrium, persists throughout intrauterine life as the foramen ovale. At first, the foramen ovale is sited cranio-dorsally relative to the atrial septum, but with remoulding of the venous components, it achieves a cranio-ventral position.

Septation and appropriate positioning of the atrioventricular canal

Extracellular matrix accumulates between the endocardium and myocardium of the primary heart tube. However, it mostly disappears in the regions of ballooning of the chamber myocardium of the developing atria and ventricles. The matrix becomes filled with mesenchyme in the persisting regions of the primary heart tube. In conventional accounts of the process, these regions are called the atrioventricular canal and the outflow tract, or conotruncus. The dorsal or inferior atrioventricular cushion continues into the floor of the atrium, which is made of primary myocardium. As the cushion extends dorsally, it meets the mediastinal mesenchyme in the region initially termed the spina vestibuli, where it continues as a mesenchymal cap running along the leading edge of the septum primum until it meets the ventral, or cranial, atrioventricular cushion (Fig. 59.12 and see Fig. 59.14). The dorsal cushion also has a significant ventricular extension in the inner curvature of the heart tube, which comes to lie on top of the developing muscular ventricular septum. The two atrioventricular cushions fuse in the sixth week of development, dividing the atrioventricular canal into its right and left components. The cushions are very large relative to the canal, leaving narrow right and left slits, which increase markedly in size during further development.

The atrioventricular cushions extend onto the leading edge of the septum primum (although the mesenchymal cap on the atrial septum, see **Fig. 59.12**, probably has a different developmental origin).

At the start of stage 10, the venous pole, the atrioventricular canal, the developing left ventricle and the outflow tract are all positioned symmetrically around the midline (Fig. 59.13A). As a result of the subsequent rapid growth of the cardiac tube, the atrioventricular canal moves in its entirety to the left (Fig. 59.13B), as the ventricular part of the heart tube loops to the right, thus placing the developing left ventricle on the left, and the forming right ventricle on the right (Fig. 59.7). This ventricular loop is conspicuous throughout the fourth and fifth weeks of development, and it is at this stage that a deep interventricular groove appears externally. Over this period the atrial floor, including the developing systemic venous sinus (sinus venosus) and the atrioventricular canal, move to the right (Fig. 59.13C). The developing pulmonary vein remains anchored in the midline and, subsequent to these manoeuvres, the atrioventricular canal once more becomes positioned in the midline: this process facilitates the appropriate connections of the developing muscular septum with the atrioventricular and outflow cushions. The orifice of the sinus venosus is by now positioned to the right. From the outset, the muscular ventricular septum develops in line with the right side of the dorsal (inferior) atrioventricular cushion (Fig. 59.14), so that the separating right atrium always has direct access to the developing right ventricle. The process also ensures that space remains ventrally for incorporation of the subaortic component of the outflow tract into the left ventricle.

Septation of the ventricles

After the looping of the heart tube, it is easy to gain the impression that the atrioventricular canal communicates exclusively with the developing left ventricle, while the outflow tract is supported exclusively by the developing right ventricle. In the definitive heart, blood entering the right ventricle passes in through the right atrial vestibule and exits through the muscular subpulmonary infundibulum, while blood entering the left ventricle passes in through the left atrial vestibule, and exits through the aortic root. The changes needed to produce the definitive connections between the cardiac components are complex. Three distinct structures contribute to the formation of the postnatal ventricular septum: the muscular ventricular septum, the proximal parts of the outflow cushions and the atrioventricular endocardial cushions. The latter two components separate those parts of the primary heart tube that are committed to the right and left ventricles, as opposed to the ballooned apical ventricular components. Inappropriate formation and connection of the cushions with the muscular ventricular septum underscores deficiencies of the definitive ventricular septum; such lesions account for about two-thirds of all cardiac septal defects.

Separation between the right and left ventricles is initially heralded by the appearance of a caudal crescentic ridge within the ventricular loop. The trabeculated parts of the ventricles contain less extracellular matrix than the walls of the primary heart tube, and it is these parts of the chambers that expand on each side of the ridge that remains between them. The crest of the developing septum, therefore, is its oldest portion. The more apical parts are added concomitant with enlargement of the chambers, as if they were expanding like balloons. The impression can be gained that the dorsal and ventral horns of the ventricular septum grow along the ventricular walls, meeting and fusing with the right extremities of the dorsal and ventral cushions of the atrioventricular canal. In reality, the crest of the septum marks the position of the original primary heart tube, and becomes the atrioventricular bundle. The septum has a free sickle-shaped margin that, together with the fused caudal surface of the endocardial cushions, bounds an ovoid foramen. Previously this foramen has erroneously been termed the interventricular, or bulboventricular foramen: it is no more than a locus within the cavity of the primary heart tube. The apical trabecular components of the ventricles balloon from the ventral side of the primary heart tube. At the dorsal side, or the inner curvature, there is no chamber myocardium, only the smooth walls of the primary heart tube. Therefore, from the outset of the process, the forming apical parts of the ventricles are separated by a muscular septum. The foramen marked caudally by the crest of the ventricular septum provides the initial inlet to the developing right ventricle, and the outlet for the developing left ventricle. Completion of ventricular septation requires division of this primary foramen, rather than its closure. It also demands appropriate connection between the muscular septum and the divided atrioventricular canal, including its cushions, and with the divided outflow tract, along with its cushions (Fig 59.14).

Use of inappropriate terminology means that the entire region upstream relative to the foramen has previously been called the primitive ventricle, the entire downstream region the bulbus, and the junction between them, the bulboventricular junction. In the account presented here, the area is termed the primary junction, initially marked by a distinct notch on the outside of the heart, and inside by the corresponding ridge of the developing ventricular septum. The ridge is positioned between the atrioventricular orifice, which is initially a common structure, and the caudal part of the forming right ventricle.

Appropriate connection with the separating atrioventricular and arterial junctions is essential for the development of a four-chambered heart. The serendipitous discovery of the expression of a ‘neural’ antigen in the primary junctional myocardium, surrounding the so-called primary interventricular foramen, has clarified the steps involved in the remodeling of this region at the inner curvature.

Septation and appropriate positioning of the outflow tract

The length of the myocardial portion of the outflow tract decreases markedly between the fourth and eighth weeks of development. In part, the myocardium becomes incorporated into the ventricles, and in part it disappears by apoptosis: in the definitive heart, there is no distinct myocardial outflow tract present within the left ventricle, because the myocardium which initially separated the developing mitral and aortic valves disappears, leaving the fibrous aortic-mitral continuity distinctive for the postnatal heart. In the right ventricle, the proximal myocardial outflow tract persists as the smooth-walled muscular subpulmonary infundibulum. Formation of the part adjacent to the aortic root requires muscularization of the most proximal parts of the outflow cushions to form the greater part of the supraventricular crest, or crista supraventricularis.

Key to separation of the outflow tract is the appearance of the two outflow ridges, or cushions, which spiral one round another as they run from the distal end of the right ventricle, where they are positioned septally and parietally, to the aortic sac (Figs 59.14, 59.15). Within the aortic sac, a transverse wedge of tissue, termed the aorto-pulmonary septum, separates the origins of the arteries traversing the fourth and sixth pharyngeal arteries. The septum is formed from dorsal mediastinal mesenchyme. Myocardial precursor cells and non-myocardial cells are added to the outflow tract, the latter forming the intra-pericardial components of the arterial trunks. Neural crest cells migrate from the pharyngeal mediastinal myocardium into the outflow cushions. They do not appear to populate the septum itself, but form the larger parts of the walls of the intrapericardial portions of the truncus arteriosus. The precise relationship between the outflow cushions and the newly formed aortic arch arteries, which never possess a septum between them, has still to be assessed.

(By courtesy of Prof G Steding, Göttingen, with permission from Oostra RJ, Steding G, Lamers WH, Moorman AFM. Steding’s and Virágh’s scanning electron microscopy atlas of the developing human heart. New York: Springer-Verlag, 2006.)

The spiral outflow ridges start to fuse from the sixth week onward, initially in the distal part of the outflow tract, and fusions continue gradually in the direction of the ventricular septum (Figs 59.15, 59.16A). The most proximal parts of the cushions remain unfused when the aorta and pulmonary trunk have gained their separate existence within the pericardial cavity. At this time, the proximal part of the outflow tract, upstream to the intrapericardial arterial trunks, remains encased in a myocardial sleeve. The arterial valves and sinuses then develop within the more distal part of this myocardial outflow tract; the outer myocardial wall does not disappear completely until well after the completion of septation. The most proximal parts of the cushions are the last ones to fuse, and they then muscularize and join the muscular ventricular septum, thereby joining the aorta into the left ventricle. The dorsal atrioventricular cushion maintains its mesenchymal character, becoming the membranous part of the interventricular septum in the formed heart. Formation of its interventricular and atrioventricular components does not become evident until the septal leaflet of the tricuspid valve delaminates from the surface of the ventricular septum.

NON-MYOCARDIAL COMPONENTS OF THE HEART

The non-myocardial components of the heart are the epicardium, including the coronary vasculature, and the interstitial fibroblasts and the valvular apparatus, which are formed in their larger part from endocardially derived mesenchyme. From the outset, the atrioventricular valves, mitral and tricuspid, are formed at the site of the initial atrioventricular canal, whereas the aortic and pulmonary valves are initially developed within the myocardial outflow tract, and only later achieve the semilunar attachments of the leaflets, which cross the anatomic ventriculo-arterial junctions. All of the leaflets form initially as internal endocardial projections which enclose a myocardial basement membrane, matrix, and mesenchymal cells. The precise mechanisms involved in the formation of these areas have still to be determined.

Development of the epicardium and the coronary vasculature

The epicardium, coronary vascular bed, and interstitial fibroblasts develop from a mesothelially covered protrusion of mesenchymal cells, the pro-epicardium, which arises from the pericardium in the region of the sinus venosus during week 5. The base of the pro-epicardium encompasses bi-potential pericardial cells which are recruited either to the cardiac lineage to form the venous pole of the heart, or else to the epicardial lineage. Bone morphogenetic proteins and fibroblast growth factors influence which lineage is followed; the precise mechanism of specification is not yet clear. Cells detach from the pro-epicardium and spread over the myocardial tube from caudally to cranially, and from dorsally to ventrally. Thus, in successive stages, the pro-epicardial cells approach the myocardial surface of the developing atria, atrioventricular canal, ventricles, and the proximal part of the outflow tract. The distal part of the outflow tract, as it becomes arterialized with regression of the initial myocardial walls, is covered by an outgrowth of the pericardial mesothelium at the site of the initial pericardial reflections. After the formation of the epicardium, a space is formed between the developing epicardium and the outer myocardial layer, which is particularly pronounced at the atrioventricular and outflow regions of the heart tube. This is the subepicardial space, or subepicardium: it is subsequently populated by mesenchymal cells which are largely derived from the epicardium and which play an important role in the formation of the coronary vasculature. The precursors of coronary fibroblasts, smooth muscle cells and endothelium are all derived from these pluripotent cells, which possibly also play roles in the development of non-vascular tissues, including the mesenchyme of the atrioventricular cushions and some myocardial elements. The remnants of the pro-epicardium can be found in the area of the developing systemic venous tributaries up to stage 15.

The coronary arteries were previously assumed to form by means of angiogenesis, or sprouting from the aortic root. However, recent studies have demonstrated that the vessels develop prior to the formation of the arterial orifices in the aortic sinuses: it is now thought that the vessels arise by vasculogenesis, and that mesenchymal cells in the subepicardial space give rise to primitive vessels which invade the myocardium and spread over the myocardial surface. Sprouts of this plexus approach the base of the outflow tract, and connect to the sinuses of the aortic root. Ultimately only solitary right and left coronary arteries remain, although in up to one-third of human hearts small accessory branches of the coronary arteries take origin directly from the coronary sinuses. The vessels that remain acquire a medial wall and an adventitial covering, whereas those that do not form a medial wall are destined to regress. The coronary veins develop in a similar manner from a plexus of capillaries which sprouts subepicardially; they empty into the coronary sinus and directly to the atrial chambers. The mature coronary vascular pattern is established by remodeling of the capillary plexuses, and reduction in the number of arteriovenous anastomoses.

Atrioventricular valves

Initially, the atrial myocardium is continuous with the ventricular myocardium through the myocardium of the atrioventricular canal. The atrioventricular canal itself is characterized by the tissues of the atrioventricular groove on the epicardial side, and of the endocardial cushions on the endocardial side. As the atrioventricular valves develop, these tissues fuse at the ventricular margin of the canal, and so disrupt myocardial continuity. Molecular lineage studies in mouse have demonstrated that the valvular leaflets and their tendinous cords are subsequently derived in their entirety from the endocardium.

The atrioventricular valves develop as shelf-like projections from the margins of the atrioventricular orifices. They are directed as almost complete conical sheets towards the ventricles, their advancing edges continuing, initially as trabecular ridges, deep into the ventricular cavity. With continued differential growth and excavation on their ventricular aspects, each sheet develops major indentations forming the mitral and tricuspid orifices and defining their principal leaflets. Minor marginal indentations subdivide some leaflets into scallops. Each leaflet develops functionally significant regional variations in surface texture and its core condenses as a collagenous fibrous lamina, supported either by the fibro-fatty tissue of the atrioventricular groove, or by a fibrous anulus. The anterior leaflet of the tricuspid valve and the aortic and mural leaflets of the mitral valve all appear at about the time of fusion of the atrioventricular and outflow cushions. Delamination of the septal leaflet of the tricuspid valve occurs after the completion of ventricular septation, producing the interventricular and atrioventricular components of the membranous septum, and continuing until at least week 11 (Fig. 59.16B).

Aortic and pulmonary valves

The aortic and pulmonary valves form from endocardial cushions within the distal end of the myocardial outflow tract and become populated by neural crest cells, in addition to endocardial and pharyngeal derived mesenchyme. The fusing outflow cushions divide, providing two rudiments each for the developing aortic and pulmonary valves. The remaining leaflet for each valve is then produced from the newly appearing intercalated cushions (Fig. 59.15). Each cushion-derived intrusion grows, and is also excavated on its mural aspect to form a semilunar valvular leaflet. Similar events affect the adjacent wall. In this way, the pouches between the valves and the walls of the cushions gradually enlarge, the mural aspect of each cushion forming the valvular sinuses. The core of each leaflet forms a collagenous fibrous lamina, delicate and thin in each crescentic lunule, thick and compact in the central nodule, with marginal radiate and basal bands. The dynamic nature of cardiac development makes it difficult to describe the positions of the leaflets precisely in space and therefore it is best to describe the right, left, and non-coronary sinuses and leaflets of the aortic valve, and the adjacent and non-adjacent leaflets of the pulmonary valve.

FETAL CIRCULATION

As the cardiovascular system develops, the embryonic circulation (see Ch. 13) is modified into a fetal circulation which maintains a placental circulation and is also able to establish the pulmonary circulation at birth. Extensive remodeling of the early aortic arch arteries and (initially bilateral) dorsal aortae occurs (see Ch. 35). The dorsal aortae persist on the cranial side of the third aortic arches as continuations of the internal carotid arteries (see Fig. 35.8). The dorsal aorta between the third and fourth aortic arches, the carotid duct, diminishes and finally disappears. From the fourth arch to the origin of the seventh intersegmental artery, the right dorsal aorta becomes part of the right subclavian artery, and caudal to the seventh intersegmental artery, the right dorsal aorta disappears as far as the locus of fusion of the thoracic aortae. After disappearance of the left carotid duct, the remainder persists to form the descending part of the arch of the aorta. The fused right and left embryonic dorsal aortae persist as the definitive descending thoracic and abdominal aorta. A constriction, the aortic isthmus, is sometimes present in the aorta between the final site of origin of the left subclavian artery and the orifice of the arterial duct.

Concomitant changes also occur in the early venous system. The precardinal veins enlarge as the head and brain develop. They are further augmented by the subclavian veins from the upper limb buds, which become the chief tributaries of the common cardinal veins, gradually assuming an almost vertical position as the heart descends into the thorax (see Fig. 13.4). That part of the original precardinal vein rostral to the subclavian vein is now the internal jugular vein, and their confluence is the brachiocephalic vein of each side. The right and left common cardinal veins are originally of the same diameter: by the development of a large oblique transverse connection, the left brachiocephalic vein carries blood across from the left to the right (see Fig. 13.4). The part of the original right precardinal vein between the junction of the two brachiocephalic veins and the azygos veins forms the upper part of the superior vena cava. The caudal part of this vessel, below the entrance of the azygos vein, is formed by the right common cardinal vein.

The left precardinal and left common cardinal veins caudal to the transverse branching of the left brachiocephalic vein largely atrophy: the precardinal constitutes the terminal part of the left superior intercostal vein, while the common cardinal is represented by the ligament of the left superior vena cava and the oblique vein of the left atrium (see Fig. 13.4). The remainder of the left superior intercostal vein is developed from the cranial end of the postcardinal vein and drains the second, third and, on occasion, the fourth, intercostal veins. The oblique vein passes downwards across the back of the left atrium to open into the coronary sinus, which represents the persistent left horn of the systemic venous sinus.

The fetal circulation contains a number of relatively large vessels which permit the majority of the blood flow to bypass the liver and lungs. The placenta serves as the organ for fetal nutrition and excretion, receiving deoxygenated fetal blood and returning it oxygenated and detoxified. Fetal blood reaches the placenta via two umbilical arteries and in early fetal life returns by two umbilical veins (Fig. 59.17). The right umbilical vein later disappears, whereas the persisting left umbilical vein enters the abdomen at the umbilicus, traverses the edge of the falciform ligament to reach the hepatic surface, and then joins the left branch of the portal vein at the hepatic portal. Opposite the junction, a large vessel, the ductus venosus, arises and ascends posterior to the liver to join the left hepatic vein near its termination in the inferior vena cava. (For a detailed developmental account of the circumhepatic veins, see Ch. 73, Figs 73.8–73.10.) The portal vein is small in the fetus compared to the size of the umbilical vein. Parts of the left branch of the umbilical vein, proximal and distal to their junctions, function as branches of the portal vein, carrying oxygenated blood to the right and left parts of the liver. Blood in the left umbilical vein therefore reaches the inferior vena cava by three routes: some enters the liver directly and reaches the vena cava via the hepatic veins; a considerable quantity circulates through the liver with portal venous blood before also entering by the hepatic veins; the remainder is bypassed into the inferior vena cava by the ductus venosus.

Fig. 59.17 Plan of the fetal circulation. The arrows indicate the direction of blood flow. The placenta is drawn to a greatly reduced scale.

The refreshed placental blood passes almost directly to the aorta for distribution to the head and upper limbs. Blood from the ductus venosus and hepatic veins mixes in the inferior vena cava with blood from the lower limbs and abdominal wall and enters the right atrium. Because right atrial pressure is much greater than left atrial pressure, it forces the flap-like valve of the septum primum to the left, which permits passage of blood from the right to the left atrium. The valve of the inferior vena cava is so placed as to direct 75% of the richly oxygenated blood from the umbilical vein to the foramen ovale and left atrium, where it mingles with the limited venous return from the pulmonary veins. From the left atrium, blood enters the left ventricle and thence the aorta, by which it is probably distributed almost entirely to the heart, head and upper limbs, which means that little reaches the descending aorta.

Blood from the head and upper limbs returns to the right atrium via the superior vena cava, flows through the right atrioventricular orifice into the right ventricle (together with the small amount of blood that is returned via the inferior vena cava), and then passes into the pulmonary trunk. However, because the fetal lungs are largely inactive, only a little of the blood from the right ventricle flows through the right and left pulmonary arteries and returns to the left atrium via the pulmonary veins. The greater part of the outflow through the pulmonary trunk is carried by the ductus arteriosus directly to the aorta, where it mixes with the small quantity of blood that passes from the left ventricle into this part of the aorta. The mixture descends in the aorta and most is returned via the umbilical arteries to the placenta: some is distributed to the lower limbs and the organs of the abdomen and pelvis.

CHANGES IN THE FETAL CIRCULATION AND OCCLUSION OF FETAL VESSELS AFTER BIRTH

At birth, as pulmonary respiration begins, increased amounts of blood from the pulmonary trunk flow through the pulmonary arteries to the lungs and return by the pulmonary veins to the left atrium: pressure therefore increases within the left atrium. A decrease in pressure also occurs in the inferior vena cava as a result of the reduction of venous return concomitant with occlusion of the umbilical vein and ductus venosus. Atrial pressures become equal and the valvular foramen ovale is closed by apposition, and subsequent fusion, of the septum primum to the rims of the foramen. Contraction of the atrial septal muscle, synchronized with that in the superior vena cava, may assist this closure, which occurs after functional closure of the ductus arteriosus. Although the foramen ovale closes functionally after pulmonary respiration is established, it does not become structurally closed until some time later. It is obliterated in fewer than 3% of infants 2 weeks after birth, and in 87% by 4 months after birth. Fusion is sometimes incomplete and a potential atrial communication (atrial septal defect) persists throughout life. Almost always this has no functional effect, because the inequality of atrial pressures and the valve-like arrangement of the opening do not favour passage of blood.

Soon after birth, a number of fetal vessels occlude, although the majority remain patent. This differential constriction suggests that the walls of a population of fetal vessels are different to those of the remaining vessels. Bradykinin, one of the kinin polypeptide hormones which induce contraction or relaxation of smooth muscle, forms in the blood of the umbilical cord when the temperature of the cord decreases at or shortly after birth. It is also formed and released by granular leukocytes in the lungs of the neonate after exposure to adequate oxygen. Bradykinin is a potent constrictor of the umbilical arteries and veins and of the ductus arteriosus, and is also a potent inhibitor of contraction of the pulmonary vessels.

Ductus arteriosus

The ductus arteriosus shunts blood from the pulmonary trunk to the arch of the aorta, bypassing the fetal lungs (Figs 59.17, 59.18). It arises as a direct continuation of the pulmonary trunk at the point where it divides into right and left pulmonary arteries. It is 8–12 mm long, and joins the aorta at an angle of 30–35° on the left side, anterolaterally, below the origin of the left subclavian artery. The opening of the ductus arteriosus into the aorta is greatly elongated. Its diameter at its origin from the pulmonary trunk, when distended with blood, is 4–5 mm, which is nearly equal to the diameter of the adjacent ascending aorta (5–6 mm). Both arteries taper to a smaller diameter as they pass inferiorly and the aorta remains slightly larger (4 mm) (Fig. 59.19). In the neonate, the ductus arteriosus is closely related to the left primary bronchus inferiorly and the thymus gland anteriorly.

Fig. 59.19 Anterior view with the heart removed to show the relationship between the left primary bronchus, the aortic arch and the ductus arteriosus in a full-term fetus. (After Crelin ES 1969 Anatomy of the Newborn. Philadelphia: Lea and Febiger.)

The ductus arteriosus differs from the other great vessels which arise from the heart because its tunica media contains smooth muscle rather than layers of elastin. It has been suggested that the relationship between the recurrent laryngeal branch of the vagus nerve and the developing ductus arteriosus is responsible for this histological difference on the grounds that the left recurrent laryngeal nerve (which, in a stage 16 embryo, is very large in relation to the aortic arch system) supports the ductus arteriosus as it enwraps it, thereby permitting the ductus to develop as a muscular, and not an elastic, artery.

It is essential that the ductus arteriosus remains patent during intrauterine life. Prostaglandins appear to have a role in maintaining this patency. Fetal and neonatal ductal tissue can produce prostaglandins E_2, I_2 and F_2a, which inhibit the ability of the ductus to contract in response to oxygen.

Closure of the ductus arteriosus

The ductus arteriosus starts to close immediately after birth, although blood probably continues to flow intermittently through it for a week or so. The flow is reversed relative to that occurring in the fetal circulation, reflecting the increased systemic vascular resistance which follows exclusion of the placental circulation, and the decreased pulmonary resistance which follows expansion of the lungs. Initial constriction at birth has been attributed to increased oxygen tension. A neural factor may also be involved: the muscular wall has afferent and efferent nerve endings and responds to adrenaline and noradrenaline.

The first stage of ductal closure is completed within 10–15 hours and the second stage takes 2–3 weeks. The first stage consists of contraction of the smooth muscle cells and development of subendothelial oedema. Destruction of the endothelium and proliferation of the intima subsequently occurs, and leads to permanent closure. Diverse factors which may promote ductal closure have been identified. They include: increased oxygen tension; increased plasma catecholamine concentrations; suppression of prostaglandin I_2 production; switching off prostaglandin E receptors; a synergistic role of prostaglandin F_2a and oxygen concentrations; a decrease in plasma adenosine concentration. After birth, these interrelated events result in the closure of the ductus arteriosus. It has been proposed that the high oxygen tension of the reversed blood flow through the ductus initiates the synthesis of a hydroperoxy fatty acid which suppresses prostacyclin production, thus exposing the ductus to the contractile effects of prostaglandin endoperoxide. After closure, the duct becomes the ligamentum arteriosum, which connects the left pulmonary artery (near its origin) with the aortic arch.

FETAL AND NEONATAL HEART

At full term, the heart is situated midway between the crown of the head and the lower level of the buttocks (see Fig. 14.4). The anterior surface is formed mainly by the right atrium and right ventricle, as it is in the adult. This surface is usually covered by the thymus, which may extend over the base of the right ventricle. The heart is relatively large at birth, weighing around 20 grams. The cardiac output is around 550 ml per minute, and the blood pressure is 80/46 mmHg. The heart rate during fetal life, as term approaches, is around 150 beats per minute. It increases at birth to around 180 beats, decreases over the first 10 minutes after birth to 170 beats, and reaches 120–140 beats per minute from 15 minutes to 1 hour after birth. Any signs of fetal distress will increase this general basic level. The heart rate decreases further with increasing age: it is normally 113–127 beats per minute from 6 months to 1 year, and settles to around 100 beats per minute by the end of the first year.

Considered relative to the thoracic landmarks, the foramen ovale lies at the level of the third intercostal space, with its long axis in the median plane. It is 4–6 mm in vertical length and 3–4 mm wide (see Fig. 14.4). It is almost exactly in the coronal plane of the body, so that blood passes from the anterior, or ventral, right atrium posteriorly and upwards to reach the upper and posterior part of the left atrium. After birth, the intra-atrial pressures are equalized, and the free edge of the flap valve formed by the primary atrial septum is kept in contact with the left side of the rims of the fossa, promoting subsequent anatomic fusion, albeit that the foramen remains probe-patent in up to one-third of all individuals. The initially free crescentic margin of the infolded superior interatrial fold forms the border of the fossa after fusion; the flap valve formed by the primary septum accounts for its floor in the adult heart.

Functionally, the ventricular septum is often considered to be part of the left ventricle: while this is certainly true in terms of the orientation of the myocardial aggregates which make up the ventricular walls, it is not correct from a cellular lineage perspective. The ratio of cardiac weight is usually expressed as the weight of the right ventricle relative to that of the left ventricle and the septum. Calculated in this fashion, the left ventricle at birth weighs about 25% more than the right ventricle. However, the right ventricle has been working against the systemic pressure in the fetus, the pulmonary circulation not yet being active, and there is a preponderance of right ventricular function in the first 2 or 3 months after birth. With the establishment of the pulmonary circulation, the work of the right side of the heart decreases, and the left side of the heart, particularly the ventricle, grows rapidly to meet the demands of the active neonate. By the end of the second year, the left side weighs twice as much as the right, a ratio that continues to middle age. At birth, the average thicknesses of the lateral walls of the ventricles are approximately equal (5 mm). By the end of the third post natal month, the left ventricle has already become thicker than the right, it becomes twice as thick by the second year, and three times as thick by puberty.

CONGENITAL HEART DEFECTS

Defects of cardiac development may not come to light until after birth, although many, if not most, can now be observed on fetal ultrasonic examination. They may affect any part of the developing heart, and include more complex forms with inappropriate connections of cardiac components. They include anomalies such as double inlet ventricle; absence of one atrioventricular connection, commonly described as tricuspid or mitral atresia; and discordant atrioventricular and ventriculo-arterial connections, also known as congenitally corrected transposition.

Congenital cardiac malformations are often multiple, and probably occur more frequently in siblings and in children of consanguineous marriages: there is a low correlation among monozygotic twins. Ventricular septal defects are the most common lesions, making up around one-fifth of all cases, followed by persistent patency of the ductus arteriosus, coarctation, pulmonary stenosis, Fallot's tetralogy, transposition, aortic stenosis, and hypoplasia of the left heart.

Atrial septal defects

A persistent communication between the atrial chambers within the fossa ovale is common, and results from the failure of the flap valve of the primary atrial septum to fuse with the infolded muscular rims of the fossa. When the flap valve is still able to overlap the rims, the communication is of no functional significance as long as left atrial pressure is greater than right, which is usually the case. However, when the flap valve is smaller than the fossa ovale, or when it is perforate, there is a true atrial septal defect (Fig. 59.20A).

Doubly committed juxta-arterial defects
• beneath aortic and pulmonary valves
• can extend to become perimembranous
Perimembranous defects
• abut on central fibrous body
• can extend to open between inlet, apical trabecular or outlet trabecular components, or can be confluent
Muscular defects
• entirely enclosed in muscular septum
• can occur between inlet, apical trabecular or outlet ventricular components

Fig. 59.20 **A**, Location of the defects that produce an interatrial communication. Only defects within the fossa ovalis are true atrial septal defects. **B**, Shunting across an atrioventricular septal defect. This can be atrial (left), ventricular (right) or at both levels (middle), depending on the attachment of the bridging cusps. **C**, Ventricular septal defects. Depending on the structure of the anatomic borders seen from the right ventricle, these defects can be placed into perimembranous, muscular or doubly committed groups.

*(**B** and **C** by courtesy of Professor RH Anderson, Institute of Child Health, University College, London.)*

In normal development, the free leading edge of the septum primum merges with the atrioventricular endocardial cushions, permitting subsequent formation of the atrioventricular septum. When this does not happen, there is a common atrioventricular junction and an atrioventricular septal defect. This can occur when the leaflets of the atrioventricular valves are fused to the crest of the ventricular septum (Fig. 59.20A), producing an interatrial communication at the expected site of the atrioventricular septum. This is the so-called ostium primum defect, and in reality is an atrioventricular septal defect permitting exclusive atrial shunting. Other interatrial communications can be formed in the mouths of the vena cavae, most frequently the superior vena cava, and are usually associated with drainage of the right pulmonary veins into the cavo-atrial junction. Known as sinus venosus defects (Fig. 59.20A), their essential feature is a bi-atrial connection of the involved caval vein. An interatrial communication can also occur through the mouth of the coronary sinus when there is a deficiency or absence of the walls that usually separate the sinus from the left atrium.

Atrioventricular septal defects result from failure of fusion of the endocardial atrioventricular cushions, producing a common atrioventricular orifice and deficiencies of the adjacent septal structures (Fig. 59.20B). The common orifice is guarded by a basically common valve, with superior and inferior leaflets bridging the scooped-out ventricular septum and tethered in both right and left ventricles. Although the left component of the valve thus formed is often interpreted as a 'cleft mitral valve', in reality it bears no resemblance to the normally structured mitral valve, because it has three leaflets; the 'cleft' forms the zone of apposition between the left ventricular components of the bridging leaflets. Two major subgroups are identified. The more frequent pattern has a common atrioventricular orifice, and the potential for shunting through the septal defect at both atrial and ventricular levels (Fig. 59.20B). The less common form has separate right and left atrioventricular orifices, and shunting occurs only at atrial level. Occasionally, when the bridging leaflets are attached to the underside of the atrial septum, shunting is confined at ventricular level, and is typically small.

Ventricular septal defects

The most common defect of the ventricular septum occurs around the expected site of the membranous septum in the right wall of the aortic vestibule, below the zone of apposition between the non-coronary and right coronary leaflets of the aortic valve (Fig. 59.20C). The defect is closely related to the septal leaflet of the tricuspid valve, but can extend to open into the ventricular outlet beneath the supraventricular crest. It occurs because the ventricular septum is incompletely closed by its membranous component, and it is often associated with overriding of the crest of the muscular septum by the aortic orifice, together with pulmonary stenosis or atresia and hypertrophy of the right ventricle (this latter combination is known as Fallot's tetralogy). Rarely, the pulmonary trunk can be normal or even dilated with this combination of abnormalities (Eisenmenger complex). Peri-membranous defects, which retain the remnant of the membranous septum as part of their perimeter, can also occur with abnormal ventriculo–arterial connections, e.g. the pulmonary trunk may override the muscular septum, (the Taussig–Bing anomaly). In perimembranous ventricular septal defects, the atrioventricular bundle and its right and left branches are always found along the postero-inferior margin of the defect.

Less commonly, a septal defect can be found in the ventricular outflow tracts roofed by the conjoined facing leaflets of the aortic and pulmonary valves. Such juxta-arterial defects are doubly committed, in that they open beneath the orifices of both aortic and pulmonary valves. They are the result of the failure of formation of the free-standing subpulmonary muscular infundibulum, but with appropriate septation of the ventriculo-arterial junctions. They usually have a muscular postero-inferior rim, which protects the atrioventricular bundle, but can extend to become peri-membranous.

The third type of ventricular septal defect occurs within the musculature of the septum: defects may affect all parts of the septum, and can be multiple, producing a so-called 'Swiss-cheese' septum.

Defects within the inlet part of the septum are important, because the atrioventricular bundle passes in their upper border. Perimembranous defects open into the inlet of the right ventricle, where the atrioventricular bundle is postero-inferiorly located.

ABNORMAL CONNECTIONS OF THE GREAT ARTERIES AND VEINS

A number of outflow anomalies may occur should the outflow cushions either fail to develop, or fuse in inappropriate fashion. When the spiral septum cushions fail to fuse, the result is a common arterial trunk, represented by an undivided arterial channel, guarded by a common arterial valve, positioned above and astride the free margin of the muscular ventricular septum (Fig. 59.21). There is, therefore, a coexisting juxta-arterial deficiency of the ventricular septum. The right and left pulmonary arteries usually arise via a confluent segment, but can take independent origin from the common arterial trunk, which continues as the ascending aorta. The common valve usually has three leaflets, but may have two, four or more. The lesion is almost certainly linked to abnormal migration of cells into the heart from the neural crest.

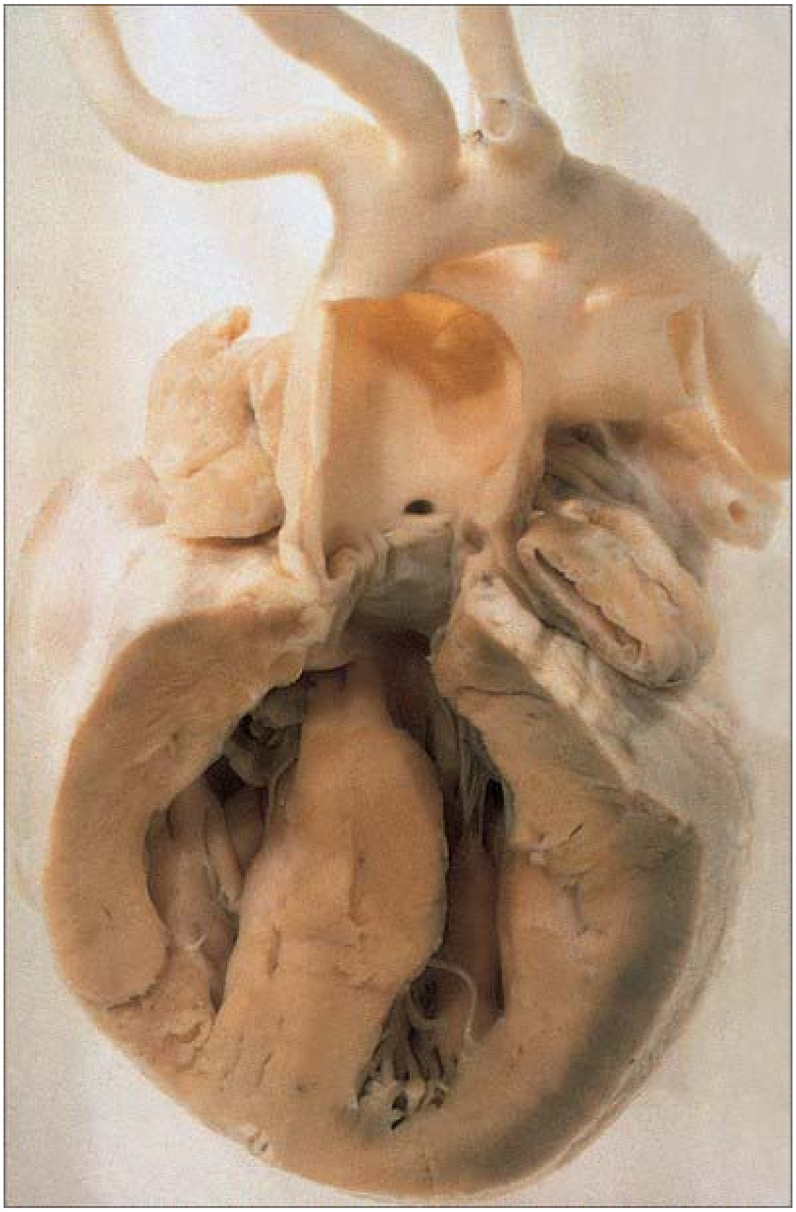

Fig. 59.21 This heart possesses a common arterial trunk, with a common truncal valve over-riding a juxta-arterial deficiency of the ventricular septum, the result of failure of septation of the arterial pole of the developing heart.

(By courtesy of Professor RH Anderson, Institute of Child Health, University College, London. Specimen prepared by Dr Leon M Gerlis.)

Transposition of the arterial trunks (also referred to as transposition of the great vessels) is the condition in which the aorta arises from the right ventricle and the pulmonary trunk from the left. Better described as having discordant ventriculo-arterial connections, such hearts can co-exist with deficiencies of cardiac septation. They can also be found with discordant connections at the atrioventricular junctions, producing congenitally corrected transposition. The developmental history of discordant connections remains unknown.

Double outlet ventricle exists when the greater parts of both arterial valves are attached within the same ventricle, almost always the right. For the circulation to continue, it is then necessary for the ventricular septum to be deficient, although the septal defect can rarely close as a secondary event. The position of the septal defect serves for subclassification. It is usually beneath the aorta or the pulmonary trunk, but can be doubly committed or even non-committed.

Either the systemic or pulmonary veins can be anomalously connected. Right and left superior vena cavae are present in some animals, and occasionally persist in mankind. The most common systemic anomaly is a persistent left superior vena cava draining into the right atrium through the enlarged orifice of the coronary sinus. More rarely, the persisting left-sided vena cava may connect directly with the superior aspect of the left atrium, usually associated with so-called ‘unroofing’ of the coronary sinus, so that the orifice of the sinus functions as an interatrial communication. The most common lesion of the inferior vena cava is when its abdominal course is interrupted, with drainage to the heart via the azygos or hemiazygos venous system. This lesion is found most frequently with isomerism of the left atrial appendages. The pulmonary veins can be connected to an anomalous site individually or in combination. Totally anomalous connection is of most significance. Usually, the veins form a confluence behind the left atrium that then connects to the superior vena cava, the coronary sinus, or the portal venous system after traversing the diaphragm.

A right aortic arch is found most frequently with Fallot’s tetralogy or with a common arterial trunk. It can also exist, together with a left arch, in various combinations known as arterial rings, which compress the oesophagus, giving so-called dysphagia lusoria. Persistent patency of the ductus arteriosus must be distinguished from delayed closure. The persistently patent ductus can be an obligatory part of the circulation when associated with aortic or pulmonary atresia. Coarctation of the aorta can be found as an isolated lesion when the ductus arteriosus is closed, or with an open duct, when it is more likely to be associated with additional lesions within the heart (see p. 984).

In the adult, the right subclavian artery occasionally arises from the arch of the aorta distal to the origin of the left subclavian artery, and then passes upwards and to the right, behind the trachea and oesophagus. This condition is possibly explained by the persistence of the embryonic right dorsal aorta and the obliteration of the fourth aortic arch of the right side.

NEONATAL ARTERIAL AND VENOUS VESSELS

In the neonate, the blood vessels of the trunk and their associated visceral branches are relatively larger than the vessels in the limbs, an arrangement which favours central pooling of blood. Neonatal peripheral vessels are nearly microscopic: their cannulation consequently poses much more of a problem than is the case with their adult counterparts. Large vessels are in the same relative positions as in the adult, but may correspond to different vertebral levels. Thus, although the bifurcation of the common carotid artery into internal and external carotid arteries occurs at the level of the upper border of the thyroid cartilage, in both neonate and adult, the thyroid cartilage is relatively higher in the neonatal neck than it is in the adult. The renal arteries also arise higher in the neonate, often between T12 and L1, whereas they arise at the upper border of L2 in the adult. The abdominal aorta bifurcates into common iliac arteries at the upper border of L4, rather than at the lower border of L4 as occurs in the adult.

Central venous catheterization

Small-bore catheters can be fed into large central veins or into the right atrium via needles or catheters inserted in the peripheral veins. Typically, the median cubital or basilic veins are used in the upper limb and the long saphenous vein at the medial malleolus in the lower limb. The tip of the catheter is sited at the entrance to the right atrium. The required catheter length is assessed from direct measurement of the distance between the point of surface entry in the limb to the right atrium, estimated at midsternal level. For details of umbilical catheterization, see Chapter 73.

RESPIRATORY TREE

The development of the respiratory system can be conceptualized as the growth of six intertwined trees: the bronchial tree of conducting airways and exchange spaces; the systemic arterial and venous trees supplying the airways; the pulmonary arterial and venous trees which will provide blood oxygenation after birth; the lymphatic tree. Development of each tree is related to the other and all proceed in proximal to distal growth and expansion.

The development of the respiratory diverticulum can first be seen at stage 12 (approximately 26 days), when there is a sharp onset of epithelial proliferation within the foregut at regions of the endoderm tube destined to become the lungs, stomach, liver and dorsal pancreas. The specialist respiratory epithelium forms from the endoderm; the other elements of the airway wall are of mesenchymal origin. The future respiratory epithelium bulges ventrally into the investing splanchnopleuric mesenchyme, then grows caudally as a bulb-shaped tube (Figs 59.1, 59.22; see Fig. 73.9). By stage 13, the caudal end of the tube has divided asymmetrically to form the future primary bronchi: with growth the right primary bronchus becomes orientated more caudally whereas the left extends more transversely. The trachea is clearly recognizable at stage 14. From this time the origin of the trachea remains close to its site of evagination from the future oesophagus, however, longitudinal growth of the trachea causes the region of the future carina to descend. Failure of complete separation between trachea and oesophagus will result in the baby being born with a tracheo-oesophageal fistula (see below). Lung development is controlled by groups of homeobox genes, transcription factors and growth factors (summarized in detail by Roth-Kleiner & Post 2005). The formation of the lung bud is dependent on the transcription factors hepatocyte nuclear factor-3β (*HNF-3* β), thyroid transcription factor (*TTF-1*) and sonic hedgehog (SHH). *Gli* proteins and retinoic acid receptors are implicated in the mesenchymal-epithelial cell interactions that are essential for lung branching morphogenesis.

There is a sexual dimorphism in lung development. Androgens delay fetal lung maturation while stimulating fetal lung growth: in males, type II cells are less mature than in females as they develop during the cannalicular phase, perhaps because androgens block the effects of cortisol on fibroblast–pneumocyte factor concentrations. It is possible that in male fetuses surfactant production is delayed. The clinical counterpart is the observation that preterm males may have worse respiratory distress than females after control for other risk factors such as degree of prematurity.

TRACHEA

The trachea starts to develop at stage 12, as a ventral outgrowth from the endodermal foregut into the mesenchyme surrounding the sinus venosus and inflow tract of the heart (Fig. 59.1B,C; see Figs 73.3, 73.5). The point at which the original respiratory diverticulum buds from the foregut, the laryngotracheal groove, remains at a constant level during the embryonic period, and the trachea lengthens distally as the bifurcation point descends. The respiratory diverticulum generally becomes surrounded by angiogenic mesenchyme which connects to the developing sixth aortic arch artery and which is essential for airway branching. By stage 17, the mesenchyme around the trachea is beginning to condense to form cartilage.

Initially, the tracheal mesenchyme is continuous with that surrounding the ventral wall of the oesophagus (Fig. 59.3). Progressive lengthening and continued division of the tracheal bud, together with deviation of the lung buds dorsally, isolates the oesophagus and trachea within tissue-specific mesenchyme and facilitates regional differentiation, not only between trachea and lungs, but also within the lungs themselves, i.e. the number of lobes, or the degree of growth and maturity of a particular lung. Each lung develops by a process of dichotomous branching. For branching to occur, a cleft must develop in the tip (or side) of the epithelial tube. The epithelium then evaginates each side of the cleft, forming new branches which lengthen, and the process is then repeated. At the tips of the developing epithelial buds, the mesenchyme is flattened and densely packed, whereas it forms an ordered row of cuboidal cells along the side of the bud and in the clefts. Cells in both arrangements send processes towards the epithelial basal lamina, which is thicker in the clefts, but so attenuated as to be almost indistinguishable on the tips of the buds where the epithelium and mesenchymal cells form intimate contacts. Tenascin, an extracellular matrix molecule, is present in the budding and distal tip regions, but absent in the clefts. Conversely, fibronectin, an extracellular matrix molecule found commonly in basal laminae, is found in the clefts and along the sides of the developing bronchi, but not on the budding and distal tips.

The control of the branching pattern of the respiratory tree resides with the splanchnopleuric mesenchyme. Experimental recombination of tracheal mesenchyme with bronchial respiratory endoderm results in inhibition of bronchial branching, whereas recombination of bronchial mesenchyme with tracheal epithelium will induce bronchial outgrowths from the trachea. Experimental exposure of rat fetal airway to chick mesenchyme produces a chick airway branching pattern. Broadly, receptor tyrosine kinases and their ligands positively modulate growth and branching morphogenesis, while transforming growth factor β (TGF β) family members have an inhibitory effect.

In the normal neonate, the trachea is relatively small in relation to the larynx (Fig. 14.4). The walls of the trachea are relatively thick and the tracheal cartilages are relatively closer together than in the adult. The trachea begins at the upper border of the sixth cervical vertebra, a relationship that is conserved with growth, and it bifurcates at the level of the third or fourth thoracic vertebra.

Endotracheal intubation in the neonate

The insertion of an endotracheal tube is a procedure that may be required for resuscitation of the newborn at birth and subsequently to enable artificial ventilation. The tube is introduced usually orally initially and guided through the vocal cords with the help of a laryngoscope. The length of the trachea in the neonate can be as short as 3.1 cm in premature infants, and the T1-to-carina distance ranges from 1.4 cm in babies weighing 500–1000 g, to 1.8 cm in those weighing 3001–3500 g. Once in place, the tip of the tube should be in the midtrachea, well above the carina.

The required length of the tube can be estimated according to birth weight. If a shouldered tube is used, only the distal, tapered portion of the tube is inserted beyond the vocal cords, and the shoulders should prevent the tube being advanced too far. Confirmation of correct positioning of the endotracheal tube is obtained from a chest X-ray. The anatomical reference points used for the X-ray to assess the position of the endotracheal tube are the clavicles, the bodies of the vertebrae and the carina (although the last of these is not always visible on X-ray). Previously, it was advised that the tip of the endotracheal tube should be placed just below the clavicles, at the level of the first rib or 1–2 cm above the carina. Recently, this has been revised because positioning of the clavicles can vary according to angulation and placement of the baby, and the carina cannot always be identified. It is now suggested that the body of the first thoracic vertebra (T1) is a more stable reference point as the target for the tip of the endotracheal tube.

LUNGS

Branching of the conducting airways is generally complete by week 16. Airways subsequently increase in size, but not in number. Alveolar development is largely (but not completely) a postnatal phenomenon. The development of pre-acinar blood vessels follows the conducting airway development, whereas development of intra-acinar blood vessels follows the development of the alveolar ducts and alveolar sacs. Lung development is described histologically as progressing through embryonic, pseudoglandular, canalicular, saccular and alveolar phases. (For further details see Rosenthal & Bush 2002; Bush 2005.)

Embryonic phase

The lung buds grow dorsally, passing each side of the relatively smaller oesophagus and bulge into the medial walls of the laterally situated pericardioperitoneal canals (Fig. 59.22; see Fig. 73.5A). The investing splanchnopleuric mesenchyme surrounding the lung buds contains a mixed population of cells. Further mesenchymal cells will differentiate into the smooth muscle cells that surround both the respiratory tubes and the blood vessels. In stage 13 embryos, proliferation of the adjacent splanchnopleuric coelomic epithelium (of the primary pleural cavities) is especially evident. The proliferative activity decreases in stage 14, and the mesenchyme becomes arranged in zones around the developing endoderm. Key molecules in airway branching include the fibroblast growth factors (FGF) especially FGF-10, and their four receptors. There is almost certainly redundancy in the system, since mice null for either FGF-1 or FGF-7 exhibit normal lung development, despite the potent *in vitro* effects of these mediators. The key receptor appears to be FGFR2IIIb, and those ligands that bind it. SHH is another gene important in lung development: it is tightly regulated and over-expression leads to the formation of excessive lung mesenchyme. The three members of the gli family of transcription factors are implicated in SHH signalling. SHH produced in distal epithelial cells appears to act on mesenchymal cells to suppress FGF-10 to limit budding. Other signals interacting with this process include bone morphogenetic protein 4 and TGF-β1.

At stage 15, angiogenetic mesenchyme is apparent around the primary bronchi. It forms an extensive capillary network around each lung bud, receiving blood from the developing sixth aortic arch artery and draining it into an anastomosis connected to the dorsal surface of the left atrium in the mediastinal mesenchyme. The pulmonary arteries arise from the sixth aortic arch arteries and the pulmonary veins develop from a solitary channel derived from the dorsal mesocardium which establishes continuity with the vascular plexus formed in the mediastinal mesenchyme. The pulmonary veins become surrounded by myocardium to the level of the second bifurcation; the veins themselves expand and are incorporated into the roof of the left atrium: cardiac muscle is therefore found in the central branches of the pulmonary venous tree (Hislop 2005).

The lung buds on each side of the oesophagus project dorsally into the pericardioperitoneal canals at stage 15. After this stage, the coelomic epithelium at the perimeter of the lung surface follows a differentiation pathway to form the visceral pleura. Lobar or secondary bronchi can be seen at stage 16, and the bronchopulmonary segments are present at stage 17 (see Fig. 73.3). Later stages of respiratory development involve the repeated division of the bronchial tree to form the subsegmental bronchi.

Pseudoglandular phase

By stage 17 (late sixth to early seventh week), the separation of the lungs from the digestive system is complete and the pseudoglandular phase of pulmonary development, which includes the development of the lower conducting airways and the appearance of the acinar structures, can be identified. During this period, virtually the complete branching structure of the future bronchial tree is laid down, giving rise to 20 generations.

The growth and branching of the endoderm epithelium is controlled by the local investing splanchnopleuric mesenchyme. The airways begin to differentiate during this stage. Primitive ciliated cells appear at about week 7, initially in the region of the membranous trachea, and in the cartilaginous region by week 12. The *in utero* function of these early ciliated cells in the trachea is obscure; elsewhere in the embryo, primary cilia have important developmental functions, e.g. in determining organ situs (nodal cilia). It is unclear whether airway ciliated cells develop from an undifferentiated precursor, or through the further development of a population of secretory cells. The epithelium differentiates into ciliated and goblet cells. The proximal airways develop basal cells from week 11, and ciliogenesis is complete at birth in humans. Mucous glands develop by 12 weeks and enlarge in the submucosa: secretory activity has been identified in the trachea at 14 weeks. The splanchnopleuric mesenchyme condenses around the epithelium and differentiates into connective tissue cell types and smooth muscle, which differentiates proximal to the tips of the developing airways as they develop, from week 6 onwards. Smooth muscle cells are innervated from as early as week 8 (see below). First trimester human tracheal smooth muscle cells have a fluctuating resting membrane potential which is associated with the spontaneous development of tone and peristalsis-like contractions of the airway of a myogenic nature, probably modified by neuro-humoral factors. These contractions are important in moving fluid from distal to proximal within the airways, which is essential for normal lung development, and may stimulate mediator release. Clara cells develop in the peripheral airways during the pseudoglandular period. They produce a 10-kDa protein (CC10) which has immuno-modulatory and anti-inflammatory activity as well as producing a surfactant apoprotein. Cartilage also develops during this period, and is found in the airways in an adult distribution by 24 weeks. By the end of this period, the airway branching and the pre-acinar vascular patterns are fully mature. A normal airway ‘template’ is essential for normal alveolar formation: in conditions characterized by an abnormal airway branching pattern (e.g. both ipsilateral and contralateral to a diaphragmatic hernia), a degree of pulmonary alveolar hypoplasia is inevitable.

Endothelial development is also seen in the pseudoglandular phase when capillary networks form around the developing lung buds. These networks will become capillary anastomoses around the future alveoli. The mesenchyme produces both the endothelium and the smooth muscle cells of the tunica media of the vessels. Vimentin occurs in the cells around developing vessels in the pseudoglandular stage, but is replaced by desmin in the saccular phase.

Canalicular phase

During the canalicular phase, about two to three generations of branching take place, after which the amount of mesenchyme around the branching tips of the dividing respiratory tree decreases and the distal airspaces widen. At 23 weeks, longitudinal sections of the future distal regions show a sawtooth margin, which may indicate the site of further acini. Peripheral growth is accompanied by an increase in the capillary network around the distal airspaces. In many places, the capillaries are in close contact with the respiratory cuboidal epithelium. The primitive cuboidal cells, which hitherto predominated in this part of the lung, differentiate into Type 2 epithelial cells (pneumocytes), containing lamellar bodies which form the intracellular storage bodies of surfactant, and Type 1 epithelial cells (pneumocytes). Type II pneumocytes are believed to be the stem cells of the alveolar epithelium. Apposition of the capillary networks to the thin pneumocytes (Type 1), and reduction of the interstitial tissue of the lung, are prerequisites for future effective gas exchange. By 24 weeks of gestation the histological characteristics of the airways are the same as in the adult.

Saccular phase

Thin walled terminal saccules are apparent at the saccular stage: they will become alveolar ducts as development proceeds. The expansion of the prospective respiratory airspaces which occurs during this period is accompanied by a further decrease in the amount of interstitial tissue, and the capillary networks become ever more closely opposed to the pneumocyte epithelium. Invaginations termed secondary crests develop from the saccule walls. As a crest protrudes into a saccule, part of the capillary network becomes drawn into it. After the later expansion of the saccules on each side of the crest, a double capillary layer becomes annexed between what are now alveolar walls. During the saccular stage, elastin is deposited beneath the epithelium (an important step for future alveolar formation), and surfactant production, from Type 2 pneumocytes, matures (essential for the survival of a preterm neonate).

Alveolar phase

Exactly when the saccular structure of the lung can be termed alveolar is not yet clear: opinions range from 28 to 32 weeks. The distal airspaces expand during late gestation and continue to do so after birth. This process is accompanied by fusion of adjacent capillary nets, so that shortly after birth there is an extensive double capillary net. Fusion of these layers is apparent at 28 days postnatally and extensive at 1.5 years; it is probably complete by 5 years. The alveolar stage continues into childhood, perhaps up to 8 years of age, although the balance of the evidence is that most alveoli are present by two years of age. The number of alveoli present at birth (variously estimated as between none to 5×10^7) and the age at end of alveolarization (estimated at between 2 and 20 years) is controversial. The process of forming new alveoli is rapid for six months, and by then mostly complete, with a plateau phase to two years with formation of alveoli largely complete at this time. Thereafter, probably growth of new alveoli is minimal.

The formation of millions of alveoli is accomplished by a complex process of folding and division. Existing walls of distal airspaces become thinner as pneumocyte epithelial cells flatten, and some cells undergo apoptosis. Ridges subsequently grow out from the sides of the saccule walls, forming primitive alveoli. The secondary septa contain a double capillary layer, and further new alveoli form by the infolding of one of these layers, further subdividing the air spaces. The double capillary networks then undergo remodeling to form the familiar single capillary sheet around each alveolus. Conducting airways also undergo profound postnatal changes, and exhibit increased smooth muscle and bronchoconstrictor responsiveness. Although the precise molecular signalling for these processes is unknown, it is acknowledged to be tightly developmentally regulated, thus dexamethasone treatment of rats during the alveolarization period permanently abrogates alveolar development. This finding implies that iatrogenic damage to the developing alveoli when ventilating a preterm baby with oxygen-enriched mixtures is probably irreversible.

It is becoming clear that elastin gene expression, possibly modulated through retinoic acid, is of pivotal importance in alveolar budding. Retinoic acid treatment of rats increases alveolarization, and salvages some alveoli in the steroid treatment model, whereas mice with a deletion in the retinoic acid receptor γ have impaired alveolarization. Retinoic acid regulates the expression of a number of growth signalling molecules, homeobox genes and lung epithelial genes; other gene groups involved in alveolarization probably include TGF-β, platelet-derived and fibroblast growth factors.

Development of the intrapulmonary vasculature and lymphatics

In an adult lung, the pulmonary arteries accompany the airways. The pulmonary veins have a similar number of branches but are separated from the airways by the alveoli: they have a different embryological origin deriving from the mediastinal mesenchyme proximally rather than splanchnopleuric mesenchyme around the bifurcating respiratory tree. The mesenchyme around the single lung bud contains a number of cells staining positively for CD34 and CD31, which are markers for endothelial cells. The earliest pulmonary vessels form in the mesenchyme by vasculogenesis: the capillaries coalesce to form small blood vessels alongside the airways. By 34 days of gestation, blood circulates from the aortic sac via pulmonary arteries into a capillary plexus around the two lung buds, and drains to the developing atrium. As each new airway forms in the mesenchyme, a new plexus forms as a halo around it, and coalesces with the vessels already alongside the previous airway. In this way, addition of the newly formed tubules to the existing vessels is sustained: the airways acting as a template for the development of blood vessels. Vessel formation occurs at least until the end of the pseudoglandular stage and is probably controlled by production of VEGF from the epithelial cells of the peripheral lung buds. As the arteries increase in size they acquire a muscular wall. Initially this arterial tunica media is derived from the bronchial smooth muscle of the adjacent airways, but as the vessels enlarge further, cells derived from the splanchnopleuric mesenchyme differentiate around the wall to form layers of smooth muscle cells. The muscular wall is thick relative to the lumen and this in part increases resistance to blood flow, although only 10% of blood flow goes through the pulmonary circulation of the lung during intra-uterine life. At 20 weeks, the structure of the pulmonary vessels is the same as it is in the adult. Vascular innervation follows muscularization; the vasoactive peptides in these nerves are predominantly vasoconstrictor.

As the pulmonary veins enlarge they become separated from the airways by lymphatic vessels which lie within connective tissue. At around week 12, the peripheral veins develop a single layer of smooth muscle cells in their walls. This layer is derived only from the splanchnopleuric mesenchyme and not from bronchial smooth muscle (as occurs in the arteries). The lumen of each vein is relatively large and the wall is relatively thin at all levels. Arteries and veins continue to develop in the canalicular phase, probably by angiogenesis; dividing cells are seen in the peripheral capillaries. The epithelium of the most peripheral conducting airways flattens when the developing capillaries come to lie immediately subjacent to it during this phase. (For a review of the development of the pulmonary circulation see Hislop 2005.)

Lymphatic capillaries and vessels run within bronchovascular bundles. Lymphatic channels develop from outgrowths of vascular endothelial cells. The molecular trigger for lymphatic sprouting is VEGF-C and D, acting through the VEGF receptor 3 (Janér et al 2006).

As well as developing a pulmonary circulation, the lung also develops a bronchial supply from the systemic circulation. Two or three bronchial arteries grow from the descending aorta from week 8 onwards, entering the lung at the hilum. These arteries extend down the intrapulmonary airways, eventually forming sub-epithelial and adventitial plexuses, which by birth have reached the distal portions of the bronchioli. The bronchial veins from the periphery of the lungs drain into the pulmonary veins. Bronchial arteries also supply the pleura near the hilum, and form vasa vasorum in the adventitia of the large arteries and veins. Post-natally, inflammatory lung conditions such as bronchiectasis cause hypertrophy of the bronchial circulation; these vessels may bleed, giving rise to massive haemoptysis in some cases.

Intra-uterine maturation of the lungs

There are more than 30 different cell types within the adult lung which mature during development. Only a few important changes which are relevant to human disease will be highlighted here.

Pulmonary surfactant is produced by Type 2 alveolar epithelial cells, and stored in lamellar bodies. It is crucial for maintaining the functional integrity of alveoli: the main morbidity of extreme prematurity reflects surfactant deficiency causing neonatal respiratory distress (treatment has been transformed by the availability of exogenous surfactant). Fetal breathing movements appear to be important in surfactant synthesis: the functional maturation of the surfactant system can be accelerated therapeutically by the administration of steroids to the mother.

Normal lung development requires sufficient intrathoracic space, normal fetal breathing movements and sufficient amniotic fluid. There is evidence that perturbation of fetal lung blood flow also affects lung growth, even though most of the right ventricular output of the heart is shunted away from the lungs through the ductus arteriosus: pulmonary valve stenosis is associated with pulmonary hypoplasia.

Although many fetal organs are able to grow to normal proportions even if they are in abnormal locations, this is not the case for the lungs. Lung growth becomes impaired by restricted expansion, and distension of the developing lung may provide a major stimulus to growth during normal development. Absence or impairment of fetal breathing movements, and defects affecting diaphragmatic activity, are all associated with pulmonary hypoplasia. It is believed that normal fetal breathing movements increase the lung volume and stimulate growth of the distal airspaces. Fetal breathing movements involve rhythmic activation of the diaphragm and the muscles of the upper respiratory tract. Even though such movements are necessarily very small compared with those seen after birth, because the fetal airways are filled with lung fluid, there is evidence that these phasic movements are important in the release of growth factors.

During development, the mucous glands of the trachea and bronchi secrete a chloride-rich fluid, which usually passes up the respiratory tract to mix with the amniotic fluid. The relationship between lung fluid and amniotic fluid is far more complex than was previously believed. Pulmonary hypoplasia at birth may be associated with severe congenital urinary obstruction and oligohydramnios (Potter’s syndrome). In renal agenesis, reduced bronchial branching occurs as early as 12–14 weeks of gestation (i.e. at a time before amniotic fluid is produced by the kidneys), which suggests that a direct renal factor supports lung development. Later, the presence of amniotic fluid is necessary for normal fetal lung development. The fetal lung is a net fluid secretor, the output of fluid reaching as high as 5 ml/kg shortly before birth. Most of the fluid produced within the lungs remains there because of the mechanical effect exerted by amniotic fluid pressure, and normally only a small amount of this fluid contributes to the amniotic fluid. The normal functioning of the kidneys regulates the volume and pressure of the lung airway fluid and may in turn provide the pressure needed for expansion and enlargement of the bronchial and pulmonary systems. Interestingly, obstruction to the fetal airway causes accelerated maturation of alveoli; this approach has been used therapeutically in congenital diaphragmatic hernia, where intermittent inflation and deflation of an intra-tracheal balloon in a lamb model resulted in better lung growth and maturation (Nelson et al 2005).

FUNCTIONAL CHANGES IN THE LUNG AROUND THE TIME OF BIRTH

Just prior to birth, the placenta is the organ of respiration. Virtually all the venous return to the right heart is shunted away from the lungs through the foramen ovale and the ductus arteriosus. Pulmonary vascular resistance (PVR) is maintained at a very high level by the muscular precapillary vessels. At birth, the umbilical cord is tied and cut, and within seconds the lungs must take over all respiratory function in order to maintain life. They also must convert from secreting fluid to absorbing it. The mechanisms that mediate these dramatic changes are obscure. However, it is clear that the first breath results in vasodilatation by at least two mechanisms. First, the mechanical effect of traction on the vasculature: as the chest wall expands, it pulls open the pulmonary vessels. Second, oxygen entering the lungs for the first time produces pulmonary vasodilatation. The experimental demonstration that PVR falls even if the fetus is delivered into an atmosphere of pure nitrogen, implies that other mediators, including cyclo-oxygenase metabolites, are undoubtedly important. The gene for cyclo-oxygenase 1 (but not 2) in endothelium and vascular smooth muscle shows enhanced expression in late fetal and early post-natal life. Endothelin receptor expression increases around the time of birth, implying a role for this system in postnatal adaptation. The role of nitric oxide in postnatal adaptation is controversial, and there are likely to be important species differences. Nitric oxide synthase (NOS) is more abundant in young compared with mature animals, and smooth muscle sensitivity to nitric oxide may be greater at birth than in older animals. The effects of mediators may differ ante- and postnatally, e.g. endothelin (ET)-1 causes vasodilatation in fetal sheep, but vasoconstriction postnatally.

Immediately after birth, and before structural remodeling has taken place, PVR may rise steeply if the baby becomes even minimally hypoxic or acidaemic. The fetal shunts (foramen ovale and ductus arteriosus) reopen and right to left shunting causes profound hypoxemia, ‘persistent fetal circulation’.

POSTNATAL LUNG DEVELOPMENT

The amount and type of connective tissue in the lung change after birth. The neonatal lung has abundant Type III and Type IV collagen, but little Type I collagen. Types III and IV collagen are not mechanically strong, suggesting that the neonatal lung has a phenotype that facilitates the changes in cell shape and orientation which characterize adaptation to extrauterine life. It is probable that the rapid deposition of Type I collagen postnatally contributes structural stiffness to the blood vessel walls.

Lung volume increases most rapidly during the first year of life and also increases more rapidly than airway calibre during this time, a finding which is consistent with the concept of dysanaptic lung growth, i.e. a dissociation between the growth of the lung parenchyma and the airways. Most of the alveoli have been formed by two years of age, and subsequent lung growth primarily results from an increase in the size of individual alveoli. Forced vital capacity is reported to be the same in male and female infants and very young children (Jones et al 2000), which is consistent with post mortem morphometric measurements. By the second year of life the rate of increase in forced vital capacity is similar to that reported in older children.

During childhood, lung volumes and flow rates increase linearly with height, with a greater intercept and more positive slope in boys compared to girls (Rosenthal et al 1993a & b). The linearity of these changes is interrupted by puberty, when important shape changes occur in the thorax, particularly in boys, and are mirrored by changes in the size of the underlying lung (and in particular the alveoli) as manifest by an abrupt increase in vital capacity, forced expired volume in one second, and total lung capacity. Thereafter, the change in lung size again proceeds in a linear fashion. High resolution computed tomographic scanning has been used to measure airway dimensions, although this technique should be used with caution because of the radiation exposure. Alveolar size can now be measured using hyperpolarized helium, using magnetic resonance imaging.

Normal postnatal pulmonary arterial development

Immediately after birth, dramatic remodelling of the pulmonary vasculature occurs to effect an abrupt reduction of pulmonary vascular resistance. This process continues at a rapid rate throughout the first 1–2 months, while the lungs adapt to extrauterine life, and then more slowly throughout childhood. Failure to remodel in the presence of an anatomically normal heart leads to persistent pulmonary hypertension. Normal postnatal pulmonary arterial development in the full-term neonate can be divided into three stages:

Stage one

lasts from birth to about postnatal day 4, and concerns the immediate adaptation to extrauterine life. At birth, the endothelial cells of the precapillary arteries are squat and have narrow bases on the subendothelium, a low surface : volume ratio and many surface projections. Five minutes after birth, the endothelial cells are thinner and gradually show less cell overlap, the surface : volume ratio increases, few cell projections are seen, the vessel wall becomes thinner and the lumen diameter increases (Fig. 59.23). The smooth muscle cells show a significant reduction in diameter during this time.

Fig. 59.23 En face views (left) and transverse sections (right) showing the changes in the endothelial and smooth muscle cells of small muscular pulmonary arteries accompanying terminal bronchi from the neonatal period to 3 weeks after birth.

Stage two

lasts from around day 4 to 3–4 weeks, and is the time when the cells deposit matrix around themselves to fix their new positions. At birth, the internal elastic lamina of the small muscular arteries consists only of amorphous elastin in a basal lamina-like matrix. By 3 weeks of age, a definitive elastic lamina is evident, although it is heavily fenestrated, permitting contact between the endothelial cells and the smooth muscle cells.

Stage three

continues into adulthood. The intrapulmonary arteries increase in size and their walls increase in thickness. However, the maturation of all of the pulmonary vascular smooth muscle cells, from the hilum to the precapillary bed, is not advanced until 2 years. As the distal airspaces expand, the capillary nets fuse from one alveolus to another, forming, for a period, an extensive double capillary net: this process can be seen from postnatal day 28, becomes more extensive by 1.5 years, and it is believed to be complete by 5 years.

CONGENITAL MALFORMATIONS OF THE TRACHEA, BRONCHI AND LUNGS

This is an enormous topic and only a small number of abnormalities can be mentioned here (for further information, see Bush 2001; Abel et al 2006). The concept of the lung as six 'trees' has been mentioned earlier: all but the systemic venous tree may contribute to a congenital thoracic malformation (CTM). In addition, congenital abnormalities of the heart and great vessels, and of the chest and abdominal walls, including neuromuscular disease, may impact on lung development. It is somewhat artificial to describe airway malformations in isolation, and the possibility of associated vascular abnormalities must always be considered. Moreover, descriptions of what is seen clinically should be kept separate from speculations about the embryological origins of the abnormality.

Disorders of the proximal airways

Tracheomalacia and bronchomalacia

Abnormalities in cartilage development lead to the affected airways being 'floppy', and collapsing during inspiration or expiration, depending on whether they are outside or inside the bony thorax, respectively: these abnormalities are termed tracheomalacia when the trachea is affected, and bronchomalacia when the bronchi are involved. The abnormality may involve a small, localized area, or may be more generalized (e.g. Williams–Campbell syndrome – congenital deficiency of the airway cartilage – in which there is diffuse bronchomalacia from the second to the seventh generation of bronchi). Tracheobronchomalacia usually presents in early infancy with cough, tachypnoea, stridor and wheeze; it may also be associated with cardiac or respiratory abnormalities, such as absent pulmonary valve syndrome, or tracheo-oesophageal fistula, respectively. Patients with significant obstruction and apnoea may be treated by the insertion of airway stents if the disease is localized; generalized disease may mandate respiratory support, either with non-invasive mask ventilation during sleep, or via a tracheostomy, depending on severity. Surgical treatment by aortopexy is controversial.

Tracheo-oesophageal fistulae

Tracheo-oesophageal fistulae are the most common abnormalities of the lower respiratory tract, and occur in about 1 in 3000 births. They usually present in the newborn with recurrent respiratory distress and choking spells, although late presentation in adult life has been described. The anomaly may be associated with oesophageal atresia. Normally, the oesophagus lengthens with the rapid elongation of the embryo up to 7 weeks. The rapid proliferation of the oesophageal lumen partially obliterates the mucosa and recanalization is not complete until 8 weeks. The cellular processes that lead to separation of the trachea and oesophagus occasionally produce oesophageal atresia. Tracheo-oesophageal atresia is rare, with an incidence of 1 in 3000 to 1 in 4500 births. Five types of tracheo-oesophageal fistulae may be recognized (Fig. 59.24). In almost all cases, the oesophagus ends blindly and the stomach is connected to the lower end of the trachea. Because of this connection, the abdomen becomes rapidly distended with air once the baby is delivered and starts breathing. Prenatally, polyhydramnios may be a clinical feature, but may not be apparent until the third trimester. In two of the five types of tracheo-oesophageal fistulae there is no communication between the stomach and the upper gut. Such cases are identifiable on ultrasound, because the stomach should always be visible at a 20-week examination, and its absence on ultrasound should prompt further evaluation.

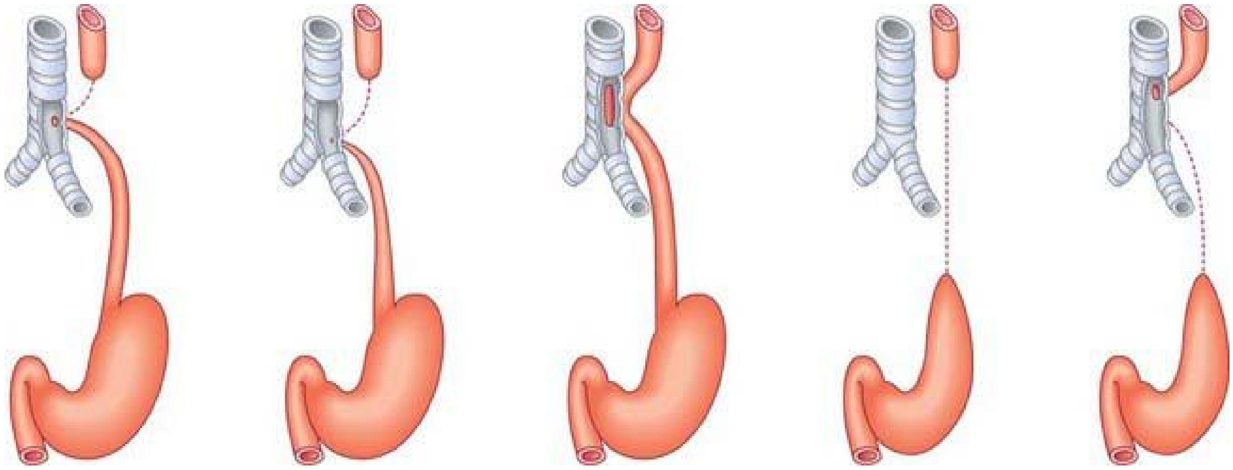

Fig. 59.24 Examples of tracheo-oesophageal fistulae and oesophageal atresia.

Tracheo-oesophageal fistula is commonly associated with other congenital anomalies, including cardiovascular defects (30%), anorectal (15%) and genitourinary anomalies (15%). These defects may be combined in the VATER syndrome, which involves vertebral, anorectal, cardiac and oesophageal anomalies, together with radial aplasia and the presence of a single umbilical artery.

Complete cartilage rings

The normal large airway cartilages are horseshoe shaped. Complete cartilage rings may develop in the trachea and large airways, and the posterior membranous part of the airway may be absent in a single cartilage or in long segments of the airway. This abnormality may be associated with vascular abnormalities such as pulmonary artery sling (where the left pulmonary artery originates from the right pulmonary artery, and not from the main pulmonary trunk). Extensive severe disease may present with neonatal respiratory distress; later presentations include apparently steroid-resistant asthma. Tracheal transplantation has been used to treat long segment tracheal stenosis.

Disorders of the distal airways

Agenesis and aplasia of the lungs

Agenesis/aplasia of the lungs are extremely rare congenital abnormalities, in which there may be unilateral or bilateral absence of the lung. In agenesis, the airway stump is absent, i.e. the trachea is absent in bilateral disease, or the primary bronchus is absent in unilateral disease. In aplasia, there is a rudimentary airway stump, but no distal lung; the contralateral lung is enlarged, with a greater number of alveoli, but has a normal bronchial pattern. Individuals with aplasia may present with recurrent infection, dyspnoea and reduced exercise capacity, and there may be pooling of bronchial secretions, with secondary infection and overspill of infected secretions into the contralateral normal lung.

Bronchogenic and other cysts

Cysts of various types, by order of frequency, may be found in the carinal (51%), right para-tracheal (19%), para-oesophageal (14%), hilar (9%) and pericardial, retrosternal and para-vertebral (7%) regions. Clinically they are part of the spectrum of congenital thoracic malformations, and can only be classified in more detail pathologically when the wall of the cyst is examined; they may have a systemic blood supply and venous drainage. Multicystic abnormalities, described as various types of congenital cystic adenomatous malformations (CCAM) and sequestrations (intra- and extra-pulmonary), are best considered generically as CTM spectrum, at least until examined pathologically. Presentation may be with a range of problems, from intractable newborn respiratory distress to a chance finding in adult life. Treatment is usually surgical if feasible, for all but the tiniest malformations.

Bronchial atresia

Bronchial atresia is a congenital condition in which a major bronchus or segmental airway ends blindly or with a thin membrane. Pulmonary development normally occurs distally, and over time this tissue becomes distended with debris and mucus (bronchocele), with adjacent over-inflated lung tissue. It characteristically affects the left upper lobe (64% of cases) and the chest radiographic findings are of a perihilar ovoid density with strands projecting into a localized area of hyperlucent lung. The left lower lobe is affected in 14% of cases and the right lower and right middle lobe in 8% of cases. The majority of cases are asymptomatic and are revealed as incidental findings on chest radiographs. However, many eventually become the seat of recurrent infection, and require operative removal. Some infants may show a congenital large hyperlucent pulmonary lobe (CLHL). This condition is termed ‘congenital lobar emphysema’ although it has nothing to do with adult emphysema. Presentation in severe cases is with newborn respiratory distress, in which case early surgery is required, otherwise, it may be a chance radiographic finding later in life, in which case no action is needed.

Section 8

ABDOMEN AND PELVIS

CHAPTER 60

Abdomen and pelvis: overview and surface anatomy

GENERAL STRUCTURE AND FUNCTION OF THE ABDOMINOPELVIC CAVITY

Although often considered separately, the abdomen and pelvis form the largest effectively continuous visceral cavity of the body. They act together to provide multiple vital functions including: support and protection of the digestive and urinary tracts and internal reproductive organs and their associated neurovascular supplies; transmission of the neurovascular supply to and from the thorax and the lower limb; provision of support and attachment to the external genitalia and access to and from the internal reproductive and urinary organs; provision of accessory muscles of physiological actions such as respiration, defecation, and micturition; support for the spinal column in weight bearing and movement.

MUSCULOSKELETAL FRAMEWORK OF THE ABDOMEN AND PELVIS

The walls of the abdominopelvic cavity consist of five lumbar vertebrae and their intervening intervertebral discs (lying in the posterior midline); three layers of skeletal muscles (transversus abdominis, internal oblique and external oblique) with associated fasciae and skin (lying lateral and anterolateral); a single muscular layer (rectus abdominis) with its associated fascial coverings (lying anterior); the bony ‘bowl’ formed by the walls of the true and false pelvis (ilium, ischium and pubis on each side); the muscles of the pelvic floor and perineum (lying inferiorly); the diaphragm (lying superiorly) (Fig. 60.1).

Fig. 60.1 The bony and muscular structures making up the abdominopelvic ‘cavity’. The anterolateral abdominal muscles have been removed for clarity.

The bony protection of the cavity is restricted to the pelvis (true and false) and the upper abdomen, which is partly enclosed by the anterolateral portions of the lower six ribs and their cartilages even though these structures are technically part of the thoracic wall. Between these two zones, the anterolateral abdominal wall is entirely musculofascial but of sufficient thickness and strength that it provides adequate protection for the viscera such that even direct blows can be resisted.

The abdominal wall and retroperitoneal structures play an important role in the function of the spinal column in both movement of the thorax in relation to the pelvis and in aiding support of the spine in weight bearing. The anterolateral muscles provide assistance with flexion and rotation of the thorax in relation to the pelvis (or vice versa if the thorax is fixed).

In the upright position, the pelvis lies at an angle such that the pelvic canal slopes posteriorly at an angle of 45° to the main abdominal visceral cavity. The main abdominal cavity is shaped by the spinal column and the posterior abdominal wall muscles. Although less pronounced than in the thorax, due to the presence of quadratus lumborum and psoas major, its prominence within the abdominal cavity produces two distinct paravertebral gutters on either side of the vertebral column. The lordosis of the lumbar spine in combination with the angle between the fifth lumbar vertebra and the sacrum produces the parabola shape of the sagittal section of each paravertebral gutter.

Thoracoabdominal interface

The thoracic and abdominal cavities interface with each other across the diaphragm. Six principle communications exist between the two cavities: the inferior vena cava, as it crosses between its short supra-hepatic portion and the intrathoracic portion below the right atrium, through the caval opening of the diaphragm (Ch. 62); the oesophagus passing inferiorly through the oesophageal opening of the diaphragm (Ch. 65); the aorta between the descending thoracic and abdominal portions, posterior to the median arcuate ligament of the diaphragm (Ch. 62); the lymphatics of the abdomen draining upwards to the thorax, mainly posterior to the median arcuate ligament via the thoracic duct lying posterolateral to the aorta, but also via peri-caval lymphatics and small vessels draining directly through and at the peripheral insertions of the diaphragm; the azygos and hemiazygos veins ascending behind the median arcuate ligament of the diaphragm into the thoracic azygos system (Ch. 62); the autonomic nervous system, both sympathetic and parasympathetic (see below) which cross between the two cavities behind the medial arcuate ligaments of the diaphragm, via the various diaphragmatic openings, and directly through the substance of the diaphragm itself (Ch. 54). Cutaneous neurovascular structures also cross between the thorax into the abdominal wall structures.

Pelvis–lower limb interface

The pelvis forms an integral part of the bony structure of both the abdominopelvic cavity and the lower limb. It transmits the weight of the upright body from the femoral heads to the lumbar spine as well as providing a stable platform about which movement of the hip joint can occur. Its bony surfaces give rise to extensive muscular attachments for the muscles of the buttock and thigh (Ch. 67) as well as for the muscles of the pelvic floor and perineal diaphragm (Ch. 63). The pelvis also transmits or gives origin to the neuro-lympho-vascular structures which supply the lower limb. The principle structures are as follows. The venous drainage includes the common femoral vein passing under the inguinal ligament to become the external iliac vein; the obturator veins passing through the obturator foramen; the superior and inferior gluteal veins draining from the buttock into the internal iliac vein via the greater and lesser sciatic foramina; multiple smaller venous channels. The arterial supply includes the external iliac artery passing under the inguinal ligament to become the common femoral artery; the obturator artery passing into the thigh via the obturator foramen; the superior and inferior gluteal arteries from the posterior division of the internal iliac artery passing out of the pelvis via the greater and lesser sciatic foramina. The lymphatic drainage principally passes under the inguinal ligament, via the femoral and obturator canals and via the sciatic foramina, to drain into the pelvic lymphatic chains (Ch. 63). The somatic neural structures include the femoral, obturator and sciatic nerves and other minor branches of the lumbosacral plexus (Ch. 62). The autonomic neural structures include those running with the arterial supply and with the branches of the lumbosacral plexus. Cutaneous neurovascular structures also cross between the lower abdomen and pelvis into the skin and superficial tissues of the lower limb.

GENERAL ARRANGEMENT OF ABDOMINOPELVIC NEUROVASCULAR STRUCTURES

It is useful to review here the overall arrangement of the neurovascular systems which cover several regions or multiple viscera of the abdominopelvic region. Descriptions of the neurovascular supply to individual organs are given in the relevant chapters.

AUTONOMIC SUPPLY

The autonomic supply to the abdominal and pelvic viscera is via the abdominopelvic part of the sympathetic chain and the greater, lesser and least splanchnic nerves (sympathetic), and the vagus and pelvic parasympathetic nerves (parasympathetic). Considerable ramification occurs between plexuses and ganglia, particularly in the major plexuses around the abdominal aorta, hence the descriptions tend to be simplifications based on the ‘main’ supply to each organ (Fig. 60.2). The details of the terminations of these fibres are given on page 1050.

Inferior hypogastric nerve
Inferior hypogastric plexus

Fig. 60.2 The overall arrangement of the autonomic plexuses of the abdominal and pelvic viscera.

Sympathetic innervation

The cell bodies of neurones of the sympathetic supply of the abdomen and pelvis lie in the intermediolateral grey matter of the first to 12th thoracic and first two lumbar spinal segments. These neurones give rise to myelinated axons which travel in the ventral ramus of the spinal nerve of the same level, leaving it via the white ramus communicans to enter a thoracic or lumbar paravertebral ganglion. Visceral branches may exit at the same level or ascend or descend several levels before exiting but leave the ganglia without synapsing in medial (visceral) branches. These give rise to the greater, lesser and least splanchnic nerves, and the lumbar and sacral splanchnic nerves. Axons destined for supply to somatic structures always synapse in the ganglion of the same level and post-ganglionic, unmyelinated axons leave the ganglion via the grey ramus communicans to enter the spinal nerve of the same level.

Greater splanchnic nerve

The greater splanchnic nerve is derived from the medial, visceral branches of the fifth to ninth thoracic ganglia. It enters the abdomen running through the fibres of the ipsilateral crus of the diaphragm and lies on the crus as it runs anteroinferiorly. The main trunk of the nerve enters the superior aspect of the coeliac ganglion.

Lesser splanchnic nerve

The lesser splanchnic nerve is derived from the medial, visceral branches of the 10th and 11th thoracic ganglia. It enters the abdomen running through the lowermost fibres of the ipsilateral crus of the diaphragm or under the medial arcuate ligament and lies on the crus as it runs anteroinferiorly. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It occasionally joins the greater and least splanchnic nerves as a single splanchnic nerve.

Least splanchnic nerve

The least splanchnic nerve is derived from the medial, visceral branches of the 12th thoracic ganglia. It enters the abdomen running with the sympathetic chain under the medial arcuate ligament and runs inferiorly to enter the renal plexus. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It is sometimes part of the lesser splanchnic nerve, when it forms a twig which enters the renal plexus just below the aorticorenal ganglion.

Lumbar sympathetic system

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia. The trunk runs in the extraperitoneal connective tissue anterior to the vertebral column and along the medial margin of psoas major. Superiorly, it is continuous with the thoracic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac artery and is continuous with the pelvic sympathetic trunk. On the right side, it lies posterior to inferior vena cava, and on the left it is posterior to the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels, but may pass behind some lumbar veins.

The first, second and sometimes third lumbar ventral spinal rami send white rami communicantes to the corresponding ganglia. Grey rami communicantes pass from all four lumbar ganglia to the lumbar spinal nerves. They are long, and accompany the lumbar arteries round the sides of the vertebral bodies, medial to the fibrous arches to which psoas major is attached. They supply the sympathetic innervation to the lumbar somatomes via these arteries. Four lumbar splanchnic nerves pass as medial branches from the ganglia to join the coeliac, inferior mesenteric (or occasionally abdominal aortic) and superior hypogastric plexuses. The first lumbar splanchnic nerve, from the first ganglion, gives branches to the coeliac, renal and inferior mesenteric plexuses. The second nerve joins the inferior part of the intermesenteric or inferior mesenteric plexus. The third nerve arises from the third or fourth ganglion and passes anterior to the common iliac vessels to join the superior hypogastric plexus. The fourth lumbar splanchnic nerve from the lowest ganglion passes above the common iliac vessels to join the lower part of the superior hypogastric plexus, or the inferior hypogastric ‘nerve’.

Vascular branches

Vascular branches from all the lumbar ganglia join the abdominal aortic plexus. Fibres of the lower lumbar splanchnic nerves pass to the common iliac arteries and form a plexus which extends along the internal and external iliac arteries. Many postganglionic fibres travel in the muscular, cutaneous and saphenous branches of the femoral nerve, supplying vasoconstrictor nerves to the femoral artery and its branches in the thigh. Other postganglionic fibres travel via the obturator nerve to the obturator artery. Considerable uncertainty persists regarding the exact path of the sympathetic nerve supply to the lower limb (Pick 1970). Sympathetic denervation of vessels in the lower limb can be effected by removing or ablating the upper three lumbar ganglia and the intervening parts of the sympathetic trunk; very rarely, this procedure is useful in treating vascular insufficiency of the lower limb.

Pelvic sympathetic system

The pelvic sympathetic trunk lies in the extraperitoneal tissue anterior to the sacrum beneath the presacral fascia. It lies medial or anterior to the anterior sacral foramina and has four or five interconnected sacral ganglia (they often merge to a greater or lesser extent). Above, it is continuous with the lumbar sympathetic trunk and receives preganglionic fibres descending via the lumbar chain from the lower lumbar spinal segments. Below the lowest ganglia, the two trunks converge to unite in the small ganglion impar anterior to the coccyx. Grey rami communicantes pass from the ganglia to the sacral and coccygeal spinal nerves but there are no white rami communicantes. Medial branches connect across the midline and twigs from the first two ganglia, referred to as sacral splanchnic nerves, join the inferior hypogastric plexus or the hypogastric ‘nerve’ to be distributed to the pelvic viscera via a fine network of pelvic nerves (the ‘pelvic plexus’). Small branches form a plexus on the median sacral artery.

Vascular branches

Postganglionic fibres pass through the grey rami communicantes to the roots of the sacral plexus. Those forming the tibial nerve are conveyed to the popliteal artery and its branches in the leg and foot whilst those in the pudendal and superior and inferior gluteal nerves accompany the same named arteries to the gluteal and perineal tissues. Branches may also supply the pelvic lymph nodes.

Preganglionic fibres for the rest of the lower limb are derived from the lower three thoracic and upper two or three lumbar spinal segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia.

Parasympathetic innervation

The parasympathetic neurones innervating the abdomen and pelvis lie either in the dorsal motor nucleus of the vagus nerve or in the intermediolateral grey matter of the second, third and fourth sacral spinal segments. The vagus nerves supply parasympathetic innervation to the abdominal viscera with the exception of the colon distal to the mid descending colon, rectum and upper anal canal. The nerves are derived from the oesophageal plexus and enter the abdomen via the oesophageal opening, closely related to the anterior and posterior walls of the abdominal oesophagus, from which they are separated by loose connective tissue. The anterior vagus is mostly derived from the left vagus and the posterior from the right vagus. The nerves supply the intra-abdominal oesophagus and stomach directly. The anterior nerve supplies branches to the hepatic plexus, which innervates the liver parenchyma and vasculature, the biliary tree including the gallbladder, and the structures in the free edge of the lesser omentum. The posterior nerve supplies branches to the coeliac plexus. These fibres frequently constitute the largest portion of the fibres derived from the plexus: they arise directly from the nerve and from the greater posterior gastric nerve and run beneath the peritoneum, deep to the posterior wall of the lesser sac, at the upper limit of the lesser omentum to reach the coeliac plexus. Their synaptic relays with postganglionic neurones are situated in the myenteric (Auerbach’s) and submucosal (Meissner’s) plexuses (see below).

Pelvic splanchnic nerves

Pelvic splanchnic nerves to the pelvic viscera travel in anterior rami of the second, third and fourth sacral spinal nerves. They leave the nerves as they exit the anterior sacral foramina and pass in the presacral tissue as a fine network of branches which are distributed to three locations. Most pass anterolaterally into the network which forms the inferior hypogastric plexus, whence most are distributed as a fine network of nerves (the ‘pelvic plexus’) to the pelvic viscera (alongside the sympathetic pelvic supply). Some join directly with the fibres forming the inferior hypogastric nerves and hence ascend out of the pelvis, some as far as the superior hypogastric plexus. A few run superolaterally in the presacral tissue, over the pelvic brim anterior to the iliac vessels. They pass directly into the tissue of the retroperitoneum and into the posterior aspect of the mesentery of the sigmoid and descending colon.

The pelvic splanchnic nerves are motor to the smooth muscle of the rectum, anus and bladder wall but inhibitory to the vesical sphincter. They supply vasodilator fibres to the erectile tissue of the penis and clitoris and are probably also vasodilator to the testes, ovaries, uterine tubes and uterus. They are visceromotor to the sigmoid and descending colon as far as the splenic flexure and distal transverse colon.

Abdominopelvic autonomic plexuses and ganglia

The abdominopelvic autonomic plexuses are somewhat variable and often fuse or are closely inter-related. The following descriptions recognize their main features (Figs 60.3, 60.4).

Coeliac plexus

The coeliac plexus is the largest major autonomic plexus, sited at the level of the twelfth thoracic and first lumbar vertebrae. It is a dense network uniting two large coeliac ganglia and surrounds the coeliac artery and the root of the superior mesenteric artery. It is posterior to the stomach and lesser sac, anterior to the crura of the diaphragm and the beginning of the abdominal aorta, and lies between the suprarenal glands. The plexus and ganglia are joined by the greater and lesser splanchnic nerves and branches from the vagus and phrenic nerves. The plexus extends as numerous secondary plexuses along adjacent arteries. The coeliac plexus is connected to, or gives rise to, the phrenic, splenic, hepatic, superior mesenteric, suprarenal, renal and gonadal plexuses (Fig. 60.5).

Aortic plexus

Fig. 60.5 Distribution of the upper abdominal autonomic plexuses.

Coeliac and aorticorenal ganglia

The coeliac ganglia are irregular masses on each side of the coeliac trunk adjacent to the suprarenal glands and anterior to the crura of the diaphragm. The right ganglion is posterior to the inferior vena cava, the left ganglion posterior to the origin of the splenic artery. The ipsilateral greater splanchnic nerve joins the upper part of each ganglion. The lower part of each ganglion forms a distinct subdivision, usually termed the aorticorenal ganglion, which receives the ipsilateral lesser splanchnic nerve and gives origin to the majority of the renal plexus (which most commonly lies anterior to the origin of the renal artery).

Phrenic plexus

The phrenic plexus lies around the inferior phrenic arteries on the crura of the diaphragm. It arises as a superior extension of the coeliac ganglion and often receives one or two sensory branches from the phrenic nerve. The left phrenic plexus is usually larger than the right. On the left it supplies branches to the left suprarenal gland and the cardiac orifice of the stomach. The right phrenic plexus joins the phrenic nerve, forming a small phrenic ganglion which distributes branches to the inferior vena cava, suprarenal gland and hepatic plexus.

Superior mesenteric plexus and ganglion

The superior mesenteric plexus lies in the preaortic connective tissue posterior to the pancreas, around the origin of the superior mesenteric artery. It is an inferior continuation of the coeliac plexus, and includes branches from the posterior vagus nerve and the coeliac plexus. Its branches accompany the superior mesenteric artery and divide into secondary plexuses which are distributed along the branches of the artery. The superior mesenteric ganglion lies superiorly in the plexus, usually above the origin of the superior mesenteric artery.

Abdominal aortic plexus (intermesenteric plexus)

The abdominal aortic plexus lies on the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. It consists of 4–12 intermesenteric nerves, connected by oblique branches. It is continuous above with the superior mesenteric plexus and below with the superior hypogastric plexus, and is formed by parasympathetic and sympathetic branches from the coeliac plexus. It receives rami from the first and second lumbar splanchnic nerves (which contain sympathetic fibres). The abdominal aortic plexus is connected to the gonadal, inferior mesenteric, iliac and superior hypogastric plexuses.

Inferior mesenteric plexus

The inferior mesenteric plexus lies around the origin of the inferior mesenteric artery and is distributed along its branches. It is formed predominantly from the aortic plexus and the first and second lumbar splanchnic nerves (sympathetic fibres), but it also receives connections from the superior hypogastric plexus (sympathetic and parasympathetic fibres). Disruption of the intermesenteric and inferior mesenteric plexuses rarely causes clinically significant disturbances of autonomic function.

Superior hypogastric plexus

The superior hypogastric plexus lies anterior to the aortic bifurcation, the left common iliac vein, medial sacral vessels, fifth lumbar vertebral body and sacral promontory, and between the common iliac arteries. It is occasionally termed the presacral nerve, but is seldom a single nerve and it is prelumbar rather than presacral. Most frequently found to the left side of the midline, it lies in extraperitoneal connective tissue from which the parietal peritoneum can easily be stripped. The breadth and condensation of its constituent nerves vary. The attachment of the sigmoid mesocolon and upper limit of the mesorectum containing the superior rectal vessels are anterior and to the left of the lower part of the plexus, and separated from it only by a thin sheet of loose connective tissue. The plexus is formed by branches from the aortic plexus and the third and fourth lumbar splanchnic nerves (which are mainly sympathetic). It may also contain parasympathetic fibres from the pelvic splanchnic nerves, which ascend from the two inferior hypogastric plexuses, via a series of filaments which are sometimes identified as the right and left hypogastric ‘nerves’. The latter lie in loose connective tissue just posterolateral to the start of the mesorectum and pass over the pelvic brim medial to the internal iliac vessels. The superior hypogastric plexus supplies fibres to the inferior mesenteric plexus and to the ureteric, gonadal and common iliac plexuses as well as small branches which turn abruptly forward into the upper mesorectum to supply the plexus around the superior rectal artery.

Inferior hypogastric plexus, pelvic plexus and nerves

The inferior hypogastric plexus lies in the thin extraperitoneal connective tissue on the pelvic side-wall anterolateral to the mesorectal fascia. It is directly related to the internal iliac vessels and the attachments of levator ani, coccygeus and obturator internus which lie laterally and the superior vesical and obliterated umbilical arteries superiorly. In males, the inferior hypogastric plexus lies posterolaterally on either side of the seminal vesicles, prostate and the posterior part of the urinary bladder. In females, each plexus lies lateral to the uterine cervix, vaginal fornix and the posterior part of the urinary bladder, and often extends into the broad ligaments of the uterus.

The inferior hypogastric plexus is formed mainly from the sacral splanchnic (sympathetic) and pelvic splanchnic (parasympathetic) branches; a small contribution is made from some sympathetic fibres (from the lower lumbar ganglia) which descend into the plexus via the inferior hypogastric nerves from the superior hypogastric plexus. It gives origin to a complex network of tiny pelvic branches, often referred to as the ‘pelvic plexus’, which supply the pelvic viscera either directly or via periarterial plexuses. The branches of the pelvic plexus supply the vas deferens, seminal vesicles, prostate, accessory glands and penis in males, the ovary, fallopian tubes, uterus, uterine cervix and vagina in females, and the urinary bladder and distal ureter in both sexes. The plexus also gives rise to the long branches of the parasympathetic pelvic splanchnic nerves.

Inferior hypogastric nerves

The inferior hypogastric ‘nerves’ are often double, multiple or form an extended plexus on each side. They contain mainly sympathetic and a few parasympathetic fibres. Most of these fibres are ascending from the inferior hypogastric plexus and so it is better to describe them running up out of the pelvis than down into it.

Other plexuses

Separate plexuses exist for organs within the abdomen and pelvis, for example, the hepatic, splenic and gonadal plexuses. Each tends to lie around the main arterial supply to the organ and is supplied with both sympathetic and parasympathetic fibres from one or more of the main plexuses.

Para-aortic bodies

The para-aortic bodies are condensations of chromaffin tissue which are found in close relation to the aortic autonomic plexuses and lumbar sympathetic chains. They are largest in the fetus, become relatively smaller in childhood and have largely disappeared by adulthood. They are most commonly found as a pair of bodies lying anterolateral to the aorta in the region of the intermesenteric, inferior mesenteric and superior hypogastric plexuses. They may lie as high as the coeliac plexus, as low as the inferior hypogastric plexus in the pelvis, or may be closely applied to the sympathetic ganglia of the lumbar chain. Scattered cells which persist into adulthood may, rarely, be the sites of development of a tumour of chromaffin tissue (phaeochromocytoma); these are much more commonly found arising from the cells of the suprarenal medulla. The wide variation in the site of persistent para-aortic body tissue accounts for the range of locations of such tumours.

MAJOR ABDOMINOPELVIC ARTERIAL AND VENOUS ARRANGEMENTS

The major vessels which occupy the abdomen and pelvis not only supply the viscera, retroperitoneal structures and much of the bony and soft tissue walls of the cavities, they also course through the cavities en route to supply the lower limbs. Both the arterial and systemic venous trees of the abdomen and pelvis lie predominantly posteriorly in the abdomen and postero-laterally in the pelvis; from the caval and aortic orifices in the diaphragm and the other points where smaller vessels cross the abdominothoracic interface, they follow the general parabolic shape of the lumbar spine. The pelvic divisions follow the contours of the brim and side wall of the true pelvis (Figs 60.6, 60.7). The individual parts of the aorto-iliac and iliocaval systems are described in the appropriate chapters.

Arterial supply to the gastrointestinal tract

The arterial supply to the gastrointestinal tract is derived from the anterior midline visceral branches of the aorta. There are usually three anterior branches, the coeliac trunk and the superior and inferior mesenteric arteries. Variants in the origin of the arteries are very rare. The most common is a joint origin of the upper two branches as either a coeliacomesenteric trunk or a lienohepaticomesenteric trunk with a separate left gastric artery. Accessory or replaced branches to the upper abdominal viscera are more common (see Chs 65, 66, 67 and 68). Accessory anastomotic vessels between the origin of the coeliac trunk and superior mesenteric artery are rare. The inferior mesenteric artery always arises separately, however, replaced, accessory or anastomotic vessels occasionally arise from the proximal superior mesenteric artery or its branches and contribute to the arterial supply to the proximal territory of the inferior mesenteric artery.

The coeliac trunk and its branches supplies the gastrointestinal tract from the distal third of the oesophagus to the mid part of the duodenum and all derived adenexae (liver, biliary tree, spleen, dorsal pancreas, greater omentum and lesser omentum). The superior mesenteric artery supplies the tract from the mid second part of the duodenum to the distal third of the transverse colon (jejunum, ileum, caecum, appendix, ascending colon and ileal mesentery). The inferior mesenteric artery supplies the tract from the distal transverse colon to the upper anal canal. Other than accessory arteries, numerous medium calibre arteries form anastomoses between the vascular territories. The most profuse occurs around the head of the pancreas and the duodenum, where anastomoses form between the anterior and posterior superior pancreaticoduodenal arteries and the inferior pancreaticoduodenal arteries; the posterior superior pancreaticoduodenal artery and jejunal arteries; the greater pancreatic artery and jejunal arteries. The anastomoses between the territories of the superior and inferior mesenteric arteries are less pronounced and more variable: the most reliable is the pericolic marginal artery, which runs along the transverse colon. Additional anastomotic arcades may exist in the colic mesentery between the transverse and descending colon.

Portal venous system

The (hepatic) portal system, like all portal venous systems, connects two capillary beds: that of the abdominal part of the digestive tube, with the exception of the lower anal canal but including the abdominal part of the oesophagus, and all organs, except the liver, derived from it (i.e. the spleen, pancreas and gallbladder) and the hepatic sinusoidal ‘capillary’ bed. The intrahepatic portal vein ramifies like an artery, and ends in sinusoids from which vessels again converge to reach the inferior vena cava via the hepatic veins. In adults, the portal vein and its tributaries have no valves. In fetal life and for a short postnatal period, valves are demonstrable in its tributaries, but they usually atrophy; although some occasionally persist in an atrophic form into adulthood.

Portal vein

The portal vein begins at the level of the second lumbar vertebra and is formed from the convergence of the superior mesenteric and splenic veins (see Fig. 70.8). It is approximately 8 cm long and lies anterior to the inferior vena cava, posterior to the neck of the pancreas (Fig. 60.8) and obliquely to the right. It ascends behind the first part of the duodenum, the common bile duct and gastroduodenal artery. At this point it is directly anterior to the inferior vena cava. It enters the right border of the lesser omentum, ascends anterior to the epiploic foramen to reach the right end of the porta hepatis, and then divides into right and left main branches which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum it lies posterior to both the common bile duct and hepatic artery. The portal vein is surrounded by the hepatic nerve plexus and accompanied by many lymph vessels and some lymph nodes.

Fig. 60.8 The overall arrangement of the portal venous system draining the abdominal viscera.

Tributaries of the portal vein

The right branch of the portal vein usually receives the cystic vein and then enters the right lobe of the liver. The left branch receives only the obliterated umbilical vein via the ligamentum teres which connects to its vertical portion. The main extrahepatic tributaries of the main portal vein are the coronary or the left gastric vein which ends in the left margin of the portal vein, and the posterior superior pancreaticoduodenal vein nearer to the head of the pancreas.

GENERAL MICROSTRUCTURE OF THE GUT WALL

The gut wall displays a common structural plan which is modified regionally to take account of local functional differences. The general microstructure is best appreciated by reference to the development of the gut (Ch. 73). Much of the alimentary canal originates as a tube of endoderm enclosed in splanchnopleuric mesoderm. Its external surface faces the embryonic coelom, and the endodermal lining forms the epithelium of the canal and also the secretory and ductal cells of various glands which secrete into the lumen, including the pancreas and liver. The splanchnopleuric mesoderm forms the connective tissue, muscle layers, blood vessels and lymphatics of the wall, and its external surface becomes the visceral mesothelium or serosa. There is no serosa surrounding the cervical and thoracic portions of the gut, or where the hindgut traverses the pelvic floor: in these sites the gut tube is surrounded by a connective tissue adventitia. Neural elements invade the gut from neural crest tissue (Ch. 24). The smooth muscle of the muscularis externa layers of the alimentary canal is supplemented with striated muscle both cranially (from the branchial arches) and caudally. The mature gut wall has four main layers, namely mucosa, submucosa, muscularis externa and serosa (Fig. 60.9). The mucosa (mucous membrane) is the innermost layer and is subdivided into a lining epithelium, an underlying lamina propria (a layer of loose connective tissue, where many of the glands are also found) and a thin layer of smooth muscle, the muscularis mucosae. The submucosa is a strong and highly vascularized layer of connective tissue. The muscularis externa consists of inner circular and outer longitudinal layers which are present throughout the gut wall: a partial oblique layer is present only in the stomach. The external surface is bounded by a serosa or adventitia, depending on its position within the body.

Mucosa

Epithelium

The epithelium is a protective barrier and the site of secretion and absorption. Its protective function (against mechanical, thermal and chemical injury) is particularly evident in the oesophagus and in the terminal part of the rectum, where it is thick, stratified, and covered in mucus, which serves as a protective lubricant. Other than in these sites, the epithelium lining the gut wall is single-layered, and either cuboidal (in glands) or columnar. It contains cells modified for absorption as well as various types of secretory cell.

The barrier function and selectivity of absorption depend on tight junctions over the entire epithelium. The surface area of the lumen available for secretion or absorption is increased by the presence of mucosal folds, pits, crypts, villi and glands (Fig. 60.9). Microvilli on the surfaces of individual absorptive cells amplify the area of apical plasma membrane in contact with the contents of the gut. Some glands lie in the lamina propria, some in the submucosa, and others (the liver and pancreas) are totally external to the wall of the gut. All of these glands drain into the lumen of the gut through individual ducts. The epithelium also contains scattered neuroendocrine (enteroendocrine) cells.

Lamina propria

The lamina propria consists of compact connective tissue, often rich in elastin fibres, which supports the surface epithelium and provides nutrient vessels and lymphatics. Lymphoid follicles are present in many regions of the gut, most notably in Peyer’s patches. Cells within the lamina propria are the source of growth factors which regulate cell turnover, differentiation and repair in the overlying epithelium.

Muscularis mucosae

The muscularis mucosae is well developed in the oesophagus and in the large intestine, especially in the terminal part of the rectum. In addition, single muscle cells originating from the muscularis mucosae are found inside the villi or between the tubular glands of the stomach and large intestine. By its contraction, the muscularis mucosae can alter the surface configuration of the mucosa locally, allowing it to adapt to the shapes and mechanical forces imposed by the contents of the lumen, and in the intestinal villi, promoting vascular exchange and lymphatic drainage.

Submucosa

The submucosa contains large bundles of collagen and is the strongest layer of the gut wall. However, it is also pliable and deformable and can therefore adjust to changes in the length and diameter of the gut. It contains the largest arterial network of the wall, which supplies both the mucosa and the muscle coat. The submucosa invades the folds which project into the lumen of the oesophagus and rectum, the rugae of the gastric wall, and the plicae circulares of the small intestine, but does not enter the villi.

Muscularis externa

The muscularis externa usually consists of distinct inner circular and outer longitudinal layers whose antagonistic activities create waves of peristalsis responsible for the movement of ingested material through the lumen of the gut. In the stomach, where movements are more complex, there is a partial oblique layer, internal to the other two layers. The layer of circular muscle is invariably thicker than the longitudinal muscle, except in the colon, where the longitudinal muscle is gathered into three cords (taenia coli).

The muscularis externa is composed almost exclusively of smooth muscle, except in the upper oesophagus, where smooth muscle blends with striated muscle. Although the oesophageal musculature resembles that of the pharynx, it is entirely under involuntary control. For most of its length, the smooth muscle of the gut wall consists of ill-defined bundles of cells, typically visceral in type, and somewhat larger than vascular smooth muscle cells. They are approximately 500 µm long, regardless of body size, and are electrically and mechanically coupled. Their fasciculi lack a perimysium, but have sharp boundaries.

The arrangement of the musculature means that a segment of gut can change extensively in diameter (to virtual occlusion of the lumen) and also in length, although elongation is limited by the presence of mesenteries. The co-ordinated activity of the two muscle layers produces a characteristic motor behaviour which is mainly propulsive and directed anally (peristalsis), combined with a non-propulsive motor activity which either mixes the luminal contents, as occurs in the stomach, or partitions them, as occurs at the pyloric sphincter. The muscle maintains constant volume, so that shortening of a segment of the gut wall is accompanied by an increase in muscle layer circumference.

Intestinal smooth muscle exhibits variable and changing degrees of contraction on which rhythmic (or phasic) contractions are superimposed. Slow waves of rhythmic electrical activity, driven by changes in membrane potential in pacemaker cells (interstitial cells), spread throughout the thickness of the circular and longitudinal smooth muscle coats. After spreading circumferentially, slow waves can move in either oral or anal directions, causing segmental contraction. The distances of propagation and the patterns of this spontaneous activity vary between areas of the intestine. Neural regulation of slow and phasic contractions involves excitatory and inhibitory transmitters which are released from the myenteric plexus. This motor control is closely co-ordinated with mucosal absorption and secretion and is mediated via intrinsic nerves in the submucous plexus. The peristaltic reflex occurs during passage of luminal contents down the intestine. It involves ascending contraction and descending relaxation: the sensory limb is mediated by sensory neurones that respond to either mucosal stimulation (intrinsic primary afferents) or muscle stretch (extrinsic afferents).

Interstitial cells

Interstitial cells (of Cajal) are thought to act as pacemakers for the myogenic contraction of muscularis externa, establishing the rhythm of bowel contractions through their influence on electrical slow wave activity. They receive modulatory inputs from the enteric nervous system and from the extrinsic innervation of the gut.

Interstitial cells are thin, flat, and branched. They resemble smooth muscle cells because they contain actin and myosin filaments, and are linked by gap junctions to typical smooth muscle cells. However, they are phenotypically distinct from muscle cells because their intermediate filaments are vimentin rather than desmin, (which is typical of muscle cells). They lie in close apposition to varicose nerve endings of at least two types; one contains small, round clear vesicles (50 nm diameter), the other contains flat, discoidal vesicles (70 nm diameter).

The positions of the interstitial cell layers vary regionally. In general, they lie in the same layers as the enteric plexuses. They are scattered among the cells of the circular muscle layer in the oesophagus and stomach, lie between the inner and outer layers of circular smooth muscle in the small intestine, and colocalize with the myenteric plexus and the single layer of the submucosal plexus on the luminal side of the circular component of the muscularis externa, in the large intestine.

Serosa and adventitia

A layer of connective tissue, of variable thickness, lies external to the muscularis externa. In many places it contains adipose tissue. Where the gut is covered by visceral peritoneum, the external layer is a serosa, which consists of a thin connective tissue layer and an external coat of mesothelium. Elsewhere the connective tissue blends with that of the surrounding fasciae and is referred to as an adventitia. Where the alimentary tract is retroperitoneal, the surface facing the abdominal cavity is covered by serosa, and the other parts are covered by adventitia.

Vascular plexuses

Vascular plexuses are present at various levels of the wall, especially in the submucosa and mucosa: they connect with plexuses of vessels which supply the surrounding tissues or those entering through the mesentery, and accompany the ducts of outlying glands.

Innervation

The gut is densely innervated by the autonomic and enteric nervous systems, and is under extrinsic and intrinsic neuronal control. Neuronal cell bodies of the enteric nervous system lie between the circular and longitudinal components of the muscularis externa (myenteric plexus) and within the submucosa (submucosal plexus). They provide the intrinsic sensory and motor supply of the gut wall and connect with extrinsic sensory, motor and sensorimotor nerves of cranial or spinal origin.

Extrinsic innervation

The extrinsic innervation is derived from neurones outside the gut, and contains functional components from the sympathetic, parasympathetic and visceral sensory divisions of the peripheral nervous system (see p. 1041). Visceral sensory endings respond to excessive muscular contraction or distension: their cell bodies are situated in the nodose ganglion of the vagus nerve and in thoracic and lumbar spinal or dorsal root ganglia. The cell bodies of parasympathetic efferent axons lie in the vagal dorsal motor nucleus in the medulla oblongata. Sympathetic efferent fibres arise from the thoracic and lumbar spinal cord and relay in prevertebral sympathetic ganglia (coeliac, mesenteric and pelvic).

A subserosal plexus, which sometimes contains neuronal cell bodies, connects the extrinsic nerve fibres with the myenteric plexus and is particularly prominent near the mesentery. Fibres from this plexus run through the longitudinal muscle layer to reach the myenteric plexus.

Intrinsic innervation

The intrinsic innervation of the gut wall is derived from neurones which are located entirely within the wall in intramural ganglionated plexuses. The myenteric (Auerbach’s) plexus is a network of fine bundles of axons and small ganglia which lies within the muscularis externa, between the circular and longitudinal layers. It is often associated with secondary and tertiary plexuses of nerve fibres which sometimes contain isolated neuronal cell bodies. There are two or more submucosal plexuses, the most superficial of which is Meissner’s plexus.

Non-ganglionated nerve plexuses lie at various levels in the wall, notably in the lamina propria (mucosal plexus); at the interface between the submucosa and muscularis externa; between the circular and longitudinal muscles (the non-ganglionated part of the myenteric plexus); and within the serosa. An additional non-ganglionated plexus lies between the internal and external components of the circular muscle of the small intestine. All parts of the myenteric plexus are continuous not only with each other, but also with the nerve fibre bundles in the circular muscle. The latter are connected to the ganglionated and non-ganglionated plexuses of the submucosa, and these in turn are connected with the mucosal plexus by fibres which pass through the muscularis mucosa.

SURFACE AND DIAGNOSTIC ANATOMY OF THE ABDOMEN AND PELVIS

ABDOMINAL PLANES AND REGIONS

For descriptive purposes, the abdomen can be divided by a number of imaginary horizontal and vertical lines drawn using the skeletal landmarks of the thorax and abdomen (Fig.). Projection of these lines into the sagittal or transverse planes can then be used to define certain abdominal ‘planes’. Apart from dividing the abdomen into different regions for descriptive purposes, these planes are also of value in defining approximate vertebral levels and the positions of some relatively fixed intra-abdominal structures.

Vertical planes

In addition to the midline, which passes through the xiphisternal process and the pubic symphysis, there are two paramedian planes which are projected from the midclavicular line (also sometimes called the lateral or the mammary line). This line passes through the midpoint of the clavicle, crosses the costal margin just lateral to the tip of the ninth costal cartilage, and passes through a point mid way between the anterior superior iliac spine and the symphysis pubis. It approximates to, but does not exactly correspond to, the lateral border of rectus abdominis.

Horizontal planes

Several horizontal planes have been defined, but only the subcostal and transtubercular planes are in common clinical use.

The xiphisternal plane runs horizontally through the xiphoid processes at the level of the ninth thoracic vertebra. It demarcates the level of the cardiac plateau on the central part of the upper border of the liver.

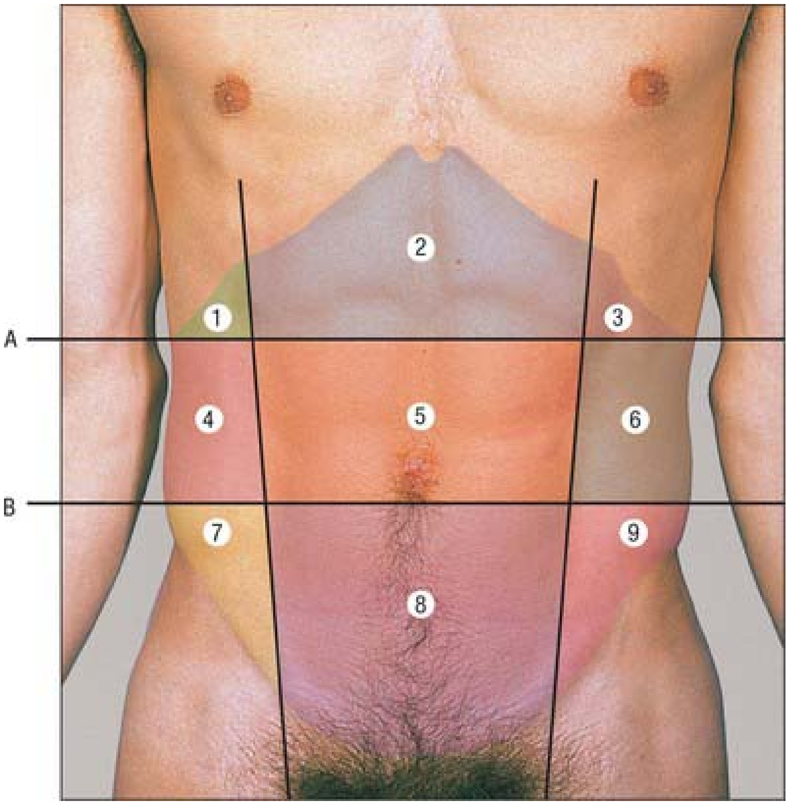

Fig. 60.10 Planes and regions of the abdomen. Key for planes: **A**, Subcostal plane. **B**, Transtubercular plane. Key for nine regions of the abdomen: **1**. Right hypochondrium. **2**. Epigastric. **3**. Left hypochondrium. **4**. Right lumbar. **5**. Central/umbilical. **6**. Left lumbar. **7**. Right iliac fossa. **8**. Suprapubic/hypogastrium. **9**. Left iliac fossa.

(Photograph by permission from Lumley JSP 2002 Surface Anatomy, 3rd edn. Edinburgh: Churchill Livingstone.)

The transpyloric plane lies midway between the suprasternal notch of the manubrium and the upper border of the pubic symphysis. It usually lies at the level of the body of the first lumbar vertebra near its lower border and meets the costal margins at the tips of the ninth costal cartilages, where a distinct ‘step’ may be felt at the costal margin. The linea semilunaris crosses the costal margin on the transpyloric plane. The hilum of both kidneys, the origin of the superior mesenteric artery, the termination of the spinal cord, the neck, adjacent body and head of the pancreas, and the confluence of the superior mesenteric and splenic veins as they form the hepatic portal vein may all lie in this plane. The pylorus may be found in the transpyloric plane, but is not a constant feature.

The subcostal plane is a line joining the lowest point of the costal margins, formed by the tenth costal cartilage on each side. It usually lies at the level of the body of the third lumbar vertebra, the origin of the inferior mesenteric artery from the aorta, and the third part of the duodenum, although this varies with posture.

The supracristal plane joins the highest point of the iliac crest on each side. It usually lies at the level of the body of the fourth lumbar vertebra, and marks the level of bifurcation of the abdominal aorta. On the posterior abdominal surface, it is a common level for the identification of the fourth lumbar vertebra, and is used to perform lumbar puncture at the L4–5 or L5–S1 intervertebral level, which is safely below the termination of the spinal cord.

The transtubercular plane joins the tubercles of the iliac crests and usually lies at the level of the body of the fifth lumbar vertebra near its upper border. It indicates, or is just above, the confluence of the common iliac veins and marks the origin of the inferior vena cava.

The interspinous plane joins the centres of the anterior superior spines of the iliac crests. It passes through either the lumbosacral disc, or the sacral promontory, or just below them, depending on the degree of lumbar lordosis, sacral inclination and curvature.

The plane of the pubic crest lies at the level of the inferior end of the sacrum or part of the coccyx, depending on the degree of lumbar lordosis, sacral inclination and curvature.

Abdominal regions

The abdomen can be divided into nine arbitrary regions by the subcostal and transtubercular planes and the two midclavicular planes projected onto the surface of the body. These regions are used in practice for descriptive localization of the position of a mass or the localization of a patient’s pain, and may also be used in the description of the location of the abdominal viscera. The nine regions thus formed are: epigastrium; right and left hypochondrium; central or umbilical; right and left lumbar; hypogastrium or suprapubic; right and left iliac fossa.

ANTERIOR ABDOMINAL WALL

Skeletal landmarks

The superior boundary of the anterior abdominal wall is formed by several clear landmarks (Fig. 60.11). In the midline superiorly lies the xiphoid process. From this point, the costal margins extend to either side from the seventh costal cartilage at the xiphisternal joint to the tip of the twelfth rib (the latter is often difficult to feel in the obese or if it is short). The lowest part of the costal margin lies in the midaxillary line and is formed by the inferior margin of the tenth costal cartilage. The tip of the lower border of the ninth costal cartilage can usually be defined as a distinct 'step' along the costal margin.

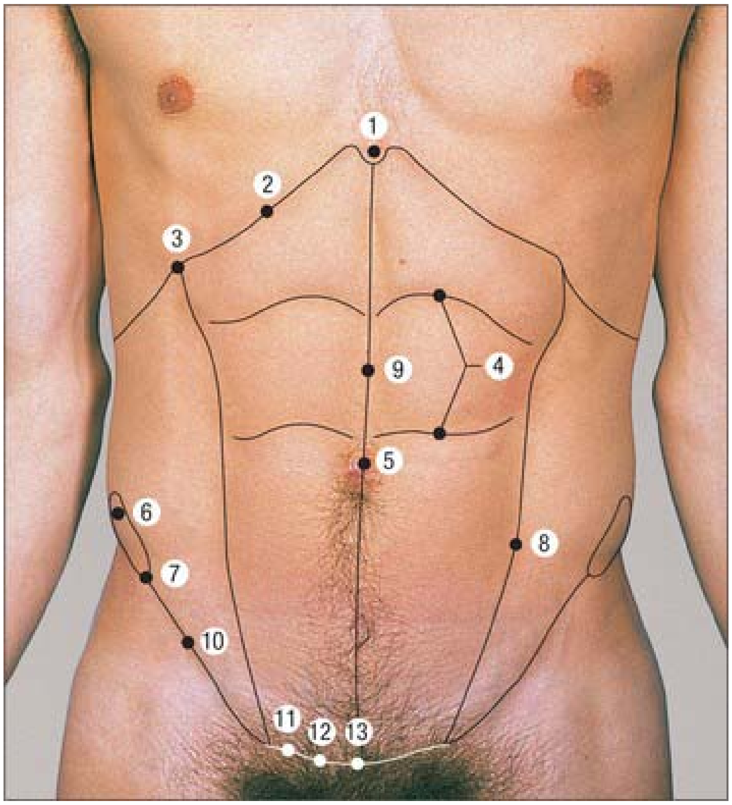

Fig. 60.11 Anterior abdominal wall landmarks. **1**. Xiphoid process. **2**. Costal margin. **3**. Tip of the ninth costal cartilage. **4**. Tendinous intersections. **5**. Umbilicus. **6**. Iliac crest. **7**. Anterior superior iliac spine. **8**.

Linea semilunaris. **9**. Linea alba. **10**. Inguinal ligament. **11**. Pubic tubercule. **12**. Pubic crest. **13**. Pubic symphysis.

(Photograph by permission from Lumley JSP 2002 Surface Anatomy, 3rd edn. Edinburgh: Churchill Livingstone.)

The inferior boundary of the anterior abdominal wall is formed, in order, by the iliac crest, which descends from the tubercle of the iliac crest to the anterior superior iliac spine; the inguinal ligament, which runs downwards and forwards to the pubic tubercle; and the pubic crest, which runs from the pubic tubercle laterally to the pubic symphysis in the midline. The pubic tubercle can be identified by direct palpation in thin individuals and can be detected, even in the obese, by palpation of the tendon of adductor longus, which runs up to its attachment on the pubis directly below the pubic tubercle. The tendon is best felt in tension with the hip flexed, abducted and externally rotated.

The posterolateral boundary is defined by the midaxillary line.

Soft tissue landmarks

Umbilicus

The umbilicus is an obvious but very inconstant landmark. In the supine adult, it usually lies at the level of the disc between the third and fourth lumbar vertebrae. The bifurcation of the abdominal aorta then lies about 2 cm caudal to the umbilicus. In the erect position, in children and in the obese, or in individuals with a pendulous abdomen, the umbilicus may lie at a lower level.

Rectus abdominis

In a thin and muscular individual, the tendinous intersections of rectus abdominis may be visible when the muscle is tensed by lifting the head against resistance or by sitting up: the intersections are usually situated at the level of the umbilicus, the level of the xiphoid process and mid way between these two points.

Linea alba

The linea alba is usually only visible in thin muscular individuals. It is wide and obvious above the umbilicus, but is almost linear and invisible below this level.

Linea semilunaris

The linea semilunaris lies along the lateral margin of the rectus sheath and is visible as a shallow curved groove in muscular individuals when the abdominal muscles are tensed, e.g. by sitting up from the lying position.

Inguinal region

The two commonly described surface markings in the inguinal region are the mid-inguinal point and the midpoint of the inguinal ligament.

Mid-inguinal point

The mid-inguinal point lies at the midpoint of the line between the symphysis pubis and the anterior superior iliac spine. It is superior to the point of palpation of the pulse of the femoral artery as it emerges from beneath the inguinal ligament. The approximate surface marking of the deep inguinal ring lies immediately above the mid-inguinal point, and is a useful landmark for palpation of the origin of an indirect inguinal herniae sac.

Midpoint of the inguinal ligament

The midpoint of the inguinal ligament lies halfway between the pubic tubercle and the anterior superior iliac spine, and is directly lateral to the origin of the inferior epigastric vessels as they lie on the posterior wall of the inguinal canal.

INTRA-ABDOMINAL VISCERA

The surface markings of the intra-abdominal viscera are variable and depend on age, body habitus, nutritional state, phase of ventilation and body position. The use of radiological imaging of the abdominal viscera means that the location of viscera by surface markings is almost obsolete in modern clinical practice. The following descriptions are at best regarded as the most common or approximate markings in a healthy supine individual (Fig. 60.12).

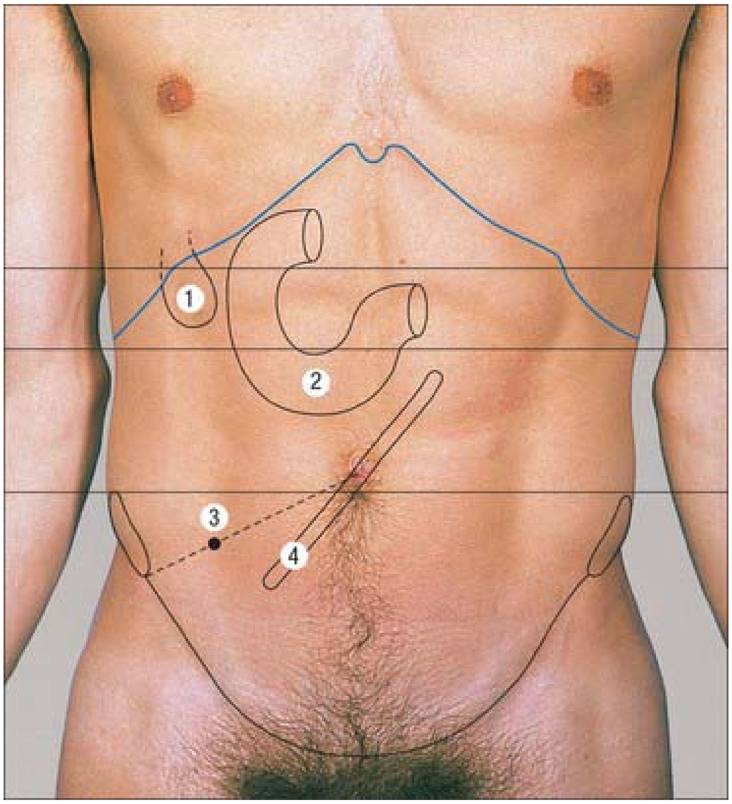

Fig. 60.12 Intra-abdominal visceral landmarks. **1**. Gallbladder. **2**. Duodenum. **3**. Appendix. **4**. Root of small bowel mesentery.

(Photograph by permission from Lumley JSP 2002 Surface Anatomy, 3rd edn. Edinburgh: Churchill Livingstone.)

Stomach

The stomach lies in a curve within the left hypochondrium and epigastrium although, when distended and pendulous, it may lie as far down as the central or hypogastric regions. The epigastrium is the usual place to auscultate for a ‘succussion splash’ caused by chronic gastric stasis in upper intestinal obstruction.

Duodenum

The first part of the duodenum sometimes lies just above the trans-pyloric plane, depending on its mobility and length. The second part usually lies in the transpyloric plane just to the right of the midline, and the third part usually lies in the subcostal plane across the midline. The fourth part often lies in the transpyloric plane to the left of the midline, although its position varies according to the length of its mesentery.

Small bowel and its mesentery

The small bowel is usually referred to as lying in the central umbilical region, but often occupies part of both iliac fossae, both lumbar regions and the hypogastrium. The small bowel mesentery runs obliquely in a line from a point 2 cm to the left of the body of the second lumbar vertebra above the subcostal plane, to a point just anterior to the right sacroiliac joint just below the interspinous plane.

Appendix

The appendix is highly variable both in its length and in its position. Its base is commonly referred to as lying beneath a point marked two-thirds of the way along a line joining the umbilicus to the anterior superior iliac spine.

Liver

The inferior border of the liver extends along a line that passes from the right 10th costal cartilage to the left fifth rib in the midclavicular line. The upper border of the liver follows a line that passes from the fifth rib in the midclavicular line on the right to the equivalent point on the left. This upper border curves slightly downwards at its centre and crosses the midline behind the xiphoid. The right border of the liver is curved to the right and joins the upper and lower right limits. The outline of the liver may be defined by the dull note it gives on percussion when compared with the resonance of the lungs above and the hollow abdominal viscera below.

The lower edge of a normal liver cannot usually be palpated, even in women and children, in whom the liver is at a slightly lower level. What is often mistaken for the liver in abdominal palpation is the bulge of rectus abdominis above its upper tendinous intersection.

Gallbladder

The fundus of the gallbladder is very variable in location. It is commonly identified with the tip of the ninth costal cartilage (in the transpyloric plane), near the junction of the linea semilunaris with the costal margin.

Spleen

The spleen lies beneath the ninth, 10th and 11th ribs on the left side. Its surface markings can be delineated on the lower posterior thoracic wall by defining its axis, which extends from a point 5 cm to the left of the midline at the level of the 10th thoracic spine, and passes laterally along the line of the tenth rib to the midaxillary line.

RETROPERITONEAL VISCERA

The surface projections of the retroperitoneal viscera are fairly reliable but have little clinical use since most interventions and procedures are guided by radiological imaging.

Pancreas

The surface projection of the head of the pancreas lies within the duodenal curve. The neck lies in the transpyloric plane, behind the pylorus in the midline. The body passes obliquely up and to the left for approximately 10 cm, its left part lying a little above the transpyloric plane. The tail lies a little above and to the left of the intersection of the transpyloric and left lateral planes.

Kidney

The anterior and posterior surface projections of the kidneys are related to anterior and posterior abdominal wall landmarks. In the description that follows, all measurements are approximate. The right kidney lies 1.25 cm lower than the left. On the anterior surface, the centre of the hilum lies in the transpyloric plane 5 cm from the midline and slightly medial to the tip of the ninth costal cartilage. From the hilum, the outline of the anterior surface can be drawn 11 cm long and 4.5 cm broad, the upper pole being 2.5 cm, and the lower 7.5 cm, from the midline: since the transverse axis is oblique, the width thus shown is 1.5 cm less than the actual width of the kidney. On the posterior surface, the centre of the hilum lies opposite the lower border of the spinous process of the first lumbar vertebra and 5 cm from the midline. The outline of the posterior surface can be traced similarly to the anterior surface. The lower pole is 2.5 cm above the summit of the iliac crest. The kidneys are 2.5 cm lower in the standing than in the supine individual; they ascend and descend a little with respiration, which is of particular importance in endoscopic renal surgery. The lower pole of the normal right kidney may occasionally be felt in the thin individual, especially the female, by bimanual palpation on full inspiration.

Ureter

The ureter starts on either side approximately at the transpyloric plane (the left higher than the right), approximately 5 cm from the midline. Each passes downwards and somewhat medially to enter the bladder at a point marked superficially by the position of the pubic tubercle.

Abdominal aorta

The abdominal aorta starts just to the left of the midline, at the level of the body of the 12th thoracic vertebra. It continues downwards for 10 cm as a band 2 cm wide, and bifurcates at the level of the fourth lumbar vertebra (which is marked by the transtubercular plane), 1.5 cm below and to the left of the umbilicus. The pulsations of the aorta can be felt in a thin individual in the supine position by pressing firmly in the midline backwards onto the vertebral column. An easily palpable aorta in an obese person should raise the suspicion of an aneurysm, to be checked by radiological imaging.

Visceral arteries

The coeliac trunk arises from the aorta immediately after it enters the abdomen at the level of the 12th thoracic vertebra. The origin of the superior mesenteric artery usually lies above the transpyloric plane, and that of the inferior mesenteric artery lies at the level of the body of the third lumbar vertebra, in the subcostal plane.

Renal arteries

The renal arteries can be projected as broad lines running laterally for 4 cm from the aorta just inferior to the transpyloric plane; the left inclines across the plane.

Iliac arteries

The surface projection of the common iliac artery corresponds to the superior one-third of a broad line, which is laterally slightly convex, from the aortic bifurcation to a point mid-way between the anterior superior iliac spine and the pubic symphysis. The external iliac artery corresponds to the inferior two-thirds of this line.

Superior gluteal artery

The surface marking of the exit of the superior gluteal artery from the pelvis corresponds to the junction of the upper and middle thirds of a line joining the posterior superior iliac spine to the apex of the greater trochanter.

Inferior gluteal artery

The surface marking of the exit of the inferior gluteal artery from the pelvis lies near the midpoint of a line joining the posterior superior iliac spine and the ischial tuberosity.

Inferior vena cava

The inferior vena cava starts at the level of the body of the fifth lumbar vertebra, usually in the transtubercular plane (2.5 cm below the supracristal plane). From this level it can be represented by a band, running vertically and 2.5 cm to the right of the midline. The inferior vena cava leaves the abdomen by traversing the diaphragm at the level of the eighth thoracic vertebra, directly behind the sternal extremity of the right sixth costal cartilage.

CLINICAL PROCEDURES

Pneumoperitoneum for laparoscopy

The establishment of a pneumoperitoneum is frequently performed by accessing the peritoneal cavity at the level of the umbilicus. Most commonly done just below the umbilicus, the incision through the linea alba allows access to the peritoneum at a point where there is relatively little extraperitoneal fat present and where the linea alba is relatively wide.

Surgical incisions

Most surgical incisions are performed according to surgical imperatives rather than anatomical constraints. The paramedian incision has been used to decrease the risk of incisional hernia. The skin and anterior fascial incision is made over the belly of rectus abdominis, at the level required. The muscle is displaced laterally, in order not to interfere with its neurovascular supply (which enters laterally), and the posterior rectus sheath is then incised in the paramedian plane. This approach allows rectus abdominis to lie between the two fascial incisions once the wound is closed.

Intestinal stomas (ileostomy, colostomy, caecostomy)

Where possible, intestinal stomas are usually formed through trans-rectus incisions. A cruciate incision is made in the anterior rectus sheath and the muscle fibres parted until the posterior sheath is reached. The latter is then incised without injury to the epigastric vessels (inferior or superior, depending on the level). This incision offers the advantage that fibres of rectus abdominis act to support the stoma: they provide a dynamic, contractile surround that tends to reduce the risk of herniation occurring around the stoma.

Suprapubic catheterization

The urinary bladder is commonly accessed for short- or long-term catheterization through the anterior abdominal wall. As the bladder fills, the upper part of its dome comes to lie in the preperitoneal space in the suprapubic region, and it can be relatively easily accessed via transcutaneous puncture in the midline (because there are no major neurovascular structures at this level and the linea alba is relatively thin).

CHAPTER 61

Anterior abdominal wall

The anterior abdominal wall extends from the costal margins and xiphoid process superiorly to the iliac crests, pubis and pubic symphysis inferiorly. It overlaps and is connected to both the posterior abdominal wall and paravertebral tissues. It forms a continuous but flexible sheet of tissue across the anterior and lateral aspects of the abdomen. The anterior abdominal wall is composed of the integument, muscles and connective tissue lining the peritoneal cavity (Figs 61.1-61.5). It has an important role in maintaining the form of the abdomen and is involved in many physiological activities. Anterior abdominal wall tissues form the inguinal canal that connects the abdominal cavity to the scrotum in men or labia majora in women, and also form the umbilicus; both of these sites are of considerable clinical importance.

SKIN AND SOFT TISSUE

The integument of the anterior abdominal wall comprises skin, soft tissues, lymphatic and vascular structures, and segmental nerves. The outer layer is formed from the skin and subcutaneous fat. The skin is non-specialized and variably hirsute, depending on the sex and race. All post-pubertal individuals have some extension of the pubic hair onto the anterior abdominal wall skin, although this is commonly most pronounced in males, in whom the hair may extend almost up to the umbilicus in a triangular pattern. The subcutaneous fat of the abdominal wall is highly variable in thickness and is one of the areas where excess fat is stored during periods of obesity, particularly in males.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The anterior abdominal wall receives its blood supply from paired superior and inferior epigastric arteries running vertically through the tissues, and from paired posterior intercostal, subcostal and lumbar vessels running obliquely around the anterolateral aspects of the abdomen.

Superior epigastric artery and veins

The superior epigastric artery is a terminal branch of the internal thoracic artery. It descends between the costal and xiphoid slips of the diaphragm, accompanied by two or more veins (Fig. 61.4). The vessels pass anterior to the lower fibres of transversus thoracis and the upper fibres of transversus abdominis. The artery enters the rectus sheath behind rectus abdominis and runs down to anastomose with the inferior epigastric artery usually above the level of the umbilicus. Branches supply rectus abdominis and perforate the sheath to supply the abdominal skin. A branch given off in the upper rectus sheath passes anterior to the xiphoid process of the sternum and anastomoses with the same contralateral branch. This vessel may give rise to troublesome bleeding during surgical incisions that extend up to and alongside the xiphoid process. The superior epigastric artery supplies small branches to the anterior part of the diaphragm. On the right, small branches reach the falciform ligament, where they anastomose with branches arising from the hepatic artery.

Inferior epigastric artery and veins

The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament (Fig. 61.6). Its accompanying veins, usually two, drain into the external iliac vein. It curves forwards in the anterior extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring. It lies posterior to the spermatic cord, but is separated from it by the transversalis fascia. It pierces the transversalis fascia which forms the flimsy posterior support of rectus abdominis, and ascends between the muscle and the fascia and overlying pre-peritoneal connective tissue. In this part of its course, it raises the parietal peritoneum of the anterior abdominal wall as the lateral umbilical fold but has little supporting tissue posteriorly. Disruption of the artery, by surgical incisions e.g. for laparoscopic ports or drains, is not uncommon and the resulting haematoma may expand to considerable size because of the lack of tissue against which the bleeding is effectively compressed. The artery divides into numerous branches. Those which anastomose with branches of the superior epigastric artery do so posterior to rectus abdominis at a variable height above the umbilicus. The inferior epigastric vessels are usually significantly larger than the superior vessels and provide the ‘dominant’ supply to rectus abdominis. Preparatory ligation of the inferior epigastric artery is often performed for myo(cutaneous) flaps using the mid or lower rectus abdominis based on the superior epigastric artery to allow expansion of the superior arterial flow to improve viability of the flap. Branches anastomose with terminal branches of the lower six posterior intercostal arteries posterior to rectus abdominis at the lateral border close to the sheath. The artery is an important inferomedial relation of the deep inguinal ring, and may be damaged during extensive medial dissection of the deep ring during hernia repair, particularly when this is performed in the preperitoneal plane. The vas deferens in the male, or round ligament in the female, wind laterally round it. It has the following branches: the cremasteric artery, a pubic branch, and muscular and cutaneous branches.

*(**B** From Drake, Vogl and Mitchell 2005.)*

The cremasteric artery accompanies the spermatic cord in males and supplies the cremaster and other coverings of the cord. It anastomoses with the testicular artery. In females it is small and accompanies the round ligament. A pubic branch, near the femoral ring, descends posterior to the pubis and anastomoses with the pubic branch of the obturator artery. Occasionally, the pubic branch of the inferior epigastric artery is larger than the main obturator artery origin, and it supplies the majority of flow into the obturator artery in the thigh. It is then referred to as the aberrant obturator artery. It lies close to the medial border of the femoral ring and may be damaged in medial dissection of the ring during femoral hernia repair. Muscular branches supply the abdominal muscles and peritoneum, and anastomose with the circumflex iliac and lumbar arteries. Cutaneous branches perforate the aponeurosis of external oblique, supply the skin and anastomose with branches of the superficial epigastric artery.

Sometimes the inferior epigastric artery arises from the femoral artery. It then ascends anterior to the femoral vein into the abdomen to follow its course as above. It occasionally arises from the external iliac artery, in common with an aberrant obturator artery and, rarely, from the obturator artery.

The superior and inferior epigastric arteries are important sources for a potential collateral circulation between the internal thoracic artery and the external iliac artery in situations where flow in the thoracic or abdominal aorta is compromised. Small tributaries of the inferior epigastric vein drain the skin around the umbilicus and anastomose with the terminal branches of the umbilical vein, draining the inner surface of the umbilicus via the falciform ligament. These anastomoses may open widely in cases of portal hypertension, when portal venous blood may drain into the systemic circulation via the inferior epigastric vessels. The radiating dilated veins seen under the umbilical skin are referred to as the 'caput medusae'.

Posterior intercostal, subcostal and lumbar arteries

The 10th and 11th posterior intercostal arteries and the subcostal artery emerge from under the subcostal groove of their respective ribs and pass into the tissues of the anterior abdominal wall. They run through the aponeurosis of transversus abdominis and lie deep to the fibres of internal oblique. The lumbar arteries also cross the aponeurosis of transversus abdominis and lie deep to internal oblique. The arteries on either side run forward, giving off muscular branches to the overlying internal and external oblique, before anastomosing with the lateral branches of the superior and inferior epigastric arteries at the lateral border of the rectus sheath (Fig. 61.7). Perforating cutaneous vessels run vertically through the muscles to supply the overlying skin and subcutaneous tissue. A small contribution to the supply of the lower abdominal muscles comes from branches of the deep circumflex iliac arteries.

Fig. 61.7 Arrangement of the anterolateral abdominal wall vessels at the level of the mid abdomen.

Lymphatic drainage

The lymphatic vessels of the anterior abdominal wall lie both superficial and deep to the deep fascia.

Superficial vessels

The superficial lymphatic vessels accompany the subcutaneous blood vessels. Vessels from the lumbar and gluteal regions run with the superficial circumflex iliac vessels. Those from the infra-umbilical skin run with the superficial epigastric vessels. Both drain into the superficial inguinal nodes. The supra-umbilical region is drained by vessels running obliquely up to the pectoral and subscapular axillary nodes, and there is some drainage to the parasternal nodes.

Deep vessels

The deep lymphatic vessels accompany the deep arteries. The vessels from the posterior portion of the abdominal wall pass with the lumbar arteries to drain into the lateral aortic and retro-aortic nodes. Vessels from the upper anterior abdominal wall run with the superior epigastric vessels to the parasternal nodes. Vessels of the lower abdominal wall drain into the circumflex iliac, inferior epigastric and external iliac nodes.

SEGMENTAL NERVES

The seventh to the 12th lower thoracic ventral rami continue anteriorly from the intercostal spaces into the abdominal wall (Fig. 61.3). Approaching the anterior ends of their respective spaces, the seventh and eighth nerves curve superomedially across the deep surface of the costal cartilages between the digitations of transverse abdominis. They reach the deep aspect of the posterior layer of the aponeurosis of internal oblique. Both the seventh and eighth nerves then run through this aponeurosis, pass posterior to rectus abdominis and supply branches to the upper portion of the muscle. They pass through the muscle near its lateral edge and pierce the anterior rectus sheath to supply the skin of the epigastrium.

The ninth to 11th intercostal nerves pass from their intercostal spaces between digitations of the diaphragm and transversus abdominis. They enter the layer between transversus abdominis and internal oblique. Here, the ninth nerve runs forwards almost horizontally, whereas the tenth and 11th pass inferomedially. At the lateral edge of rectus abdominis, the nerves pierce the posterior layer of the aponeurosis of internal oblique and pass behind the muscle to end, like the seventh and eighth intercostal nerves, with cutaneous branches. The ninth nerve supplies skin above the umbilicus, the tenth supplies skin, which includes the umbilicus, and the 11th supplies skin below the umbilicus (see Fig. 15.12 and Chapters 42, 45 and 79). The 12th thoracic nerve (subcostal nerve) connects with the first lumbar ventral ramus (dorsolumbar nerve). It accompanies the subcostal vessels along the inferior border of the 12th rib, passing behind the lateral arcuate ligament and kidney and anterior to the upper part of the quadratus lumborum. It perforates the transversus abdominis fascia, running deep to the internal oblique, to be distributed like the lower intercostal nerves. It supplies the anterior gluteal skin reaching down to the greater trochanter.

The seventh to 12th intercostal nerves supply the intercostal, subcostal and abdominal muscles. The tenth, 11th and 12th supply serratus posterior inferior. All six nerves also provide sensory fibres to the costal parts of the diaphragm and related parietal pleura and peritoneum. Like the upper intercostal nerves, they give off collateral and lateral cutaneous branches before they reach the costal angles. The collateral branch may rejoin its parent nerve but, if it does, it leaves it again near the lateral border of rectus abdominis. It then runs forward, through the muscle and its anterior sheath near the linea alba to supply the overlying skin. The lateral cutaneous branches pierce the intercostal muscles and external oblique and divide into anterior and posterior branches. These branches supply the skin of the abdomen and back. The anterior branches supply external oblique. The posterior branches pass back to supply the skin over latissimus dorsi. Each lateral cutaneous nerve descends as it pierces external oblique and the superficial fascia and reaches the skin on a level with the anterior and posterior cutaneous nerves of the segment.

Dermatomes

The dermatomes of the anterior abdominal wall are shown in Figure 15.12.

SOFT TISSUE

Superficial fascia

The superficial fascia of the abdominal wall consists mostly of a single layer that contains a variable amount of fat. It lies between the skin and muscles of the anterior abdominal wall. In the lower part, the fascia differentiates into superficial and deep layers between which lie superficial vessels and nerves and, in the region of the groin, superficial inguinal lymph nodes.

Superficial layer

Where present, the superficial layer is thick, areolar in texture and contains a variable amount of fat. It is often greatly thickened in obese individuals. Inferiorly, it lies superficial to the inguinal ligament and is continuous with the superficial fascia of the thigh. In the male, this layer continues over the penis and outer surface of the spermatic cord into the scrotum, where it changes its character. In this region it is generally thin, with very little adipose tissue present and is pale red in colour. In the scrotum it also contains smooth muscle fibres, which form the dartos muscle. From the scrotum it may be traced backwards into continuity with the superficial fascia of the perineum. In the female, it continues from the suprapubic skin of the abdomen into the labia majora and perineum.

Deep (membranous) layer

When present as a distinct entity, the deep layer of the fascia is more membranous than the superficial, and contains elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of external oblique, but in the midline it is intimately adherent to the linea alba and symphysis pubis. In the male, it extends onto the dorsum of the penis and forms part of the superficial ligament of the penis. Superiorly, it is continuous with the superficial fascia over the remainder of the trunk. Inferiorly, it lies superficial to the inguinal ligament and fuses with the overlying superficial layer and the underlying fascia lata in the inguinal flexure line or skin crease of the thigh.

In the male, the deep layer of the fascia continues inferiorly and medially over the penis and spermatic cord to the scrotum, where it becomes continuous with the membranous layer of the superficial fascia of the perineum. In the female, it continues into the labia majora and is continuous with the fascia of the perineum.

In the child, the testis can frequently be retracted out of the scrotum into the loose areolar tissue between external oblique and the deep layer of superficial fascia over the inguinal canal. This ‘space’ is sometimes called the superficial inguinal pouch.

Transversalis fascia

The transversalis fascia is a thin layer of connective tissue lying between the inner surface of transversus abdominis and the extraperitoneal fat. It is part of the general layer of fascia between the peritoneum and the abdominal wall. Posteriorly, it is continuous with the anterior layer of the thoracolumbar fascia, and it forms a continuous sheet anteriorly. Inferiorly, it is continuous with the iliac and pelvic fasciae, and superiorly it blends with the fascial covering of the inferior surface of the diaphragm. It is attached to the entire length of the iliac crest between the origins of transversus abdominis and iliacus and to the posterior margin of the inguinal ligament between the anterior superior iliac spine and the femoral vessels. In the inguinal region it is thick and dense, and augmented by the aponeurosis of transversus abdominis. Medial to the femoral vessels it is thin and fused to the pubis behind the conjoint tendon. Anterior to the femoral vessels, fascia extends down from the fascia transversalis to form the anterior part of the femoral sheath. The fascia is strengthened here by fibres, which arch transversely. Some fibres spread laterally towards the anterior superior iliac spine, some fibres run medially behind rectus abdominis, and some descend to the pubis behind the conjoint tendon. These arched fibres constitute the deep crural arch. The curved fibres of the deep crural arch thicken the inferomedial part of the rim of the deep inguinal ring. The spermatic cord in the male, or the round ligament of the uterus in the female, pass through the transversalis fascia at the deep inguinal ring. This opening is not visible during dissection through the skin because the transversalis fascia is prolonged on these structures as the internal spermatic fascia, but it can be seen from within the abdomen once the peritoneum has been stripped off. The internal spermatic fascia surrounds the testis and blends with the areolar tissue on the parietal layer of the tunica vaginalis: it may contain smooth muscle fibres.

Extraperitoneal connective tissue

The extraperitoneal connective tissue is a layer of areolar tissue lying between the peritoneum and the fasciae lining the abdominal and pelvic cavities. The amount of extraperitoneal tissue varies: it is especially abundant on the posterior wall of the abdomen, particularly around the kidneys, where it contains much adipose tissue; variable in thickness on the anterolateral wall, where it is thin in children and normal adults but often thickened in the obese, particularly in males; scanty in the suprapubic region, above the iliac crest and in the pelvis. Extraperitoneal tissue is continuous with the epimysium of the muscles of the abdominal wall.

MUSCLES

ANTEROLATERAL MUSCLES OF THE ABDOMEN

Rectus abdominis, pyramidalis, external oblique, internal oblique and transversus abdominis constitute the anterolateral muscles of the abdomen. They act together to perform a range of functions, some of which involve the generation of a positive pressure within one or more body cavities. Although many of these activities may occur with no ‘forced assistance’, activities such as expiration, defecation and micturition may be aided by the generation of a positive intra-abdominal pressure. Parturition, coughing and vomiting always require such a positive pressure. Under resting conditions, the tone developed within the muscles provides support for the abdominal viscera and retains the normal contour of the abdomen. The consequences of lack of muscular support can be seen in conditions such as ‘prune belly syndrome’, where there is congenital absence of these muscles.

Active contraction of the muscles provides an important role in the maintenance of abdominal wall tone when the intra-abdominal pressure is increased. The compression of the abdominal cavity required to increase the internal pressure is brought about mainly by the contraction of the diaphragm. The bony pelvis and lower thoracic cage provide an almost incompressible structure to part of the abdominal wall. During the generation of positive intra-abdominal pressure, the abdominal wall acts to hold the position of the wall fixed, rather than to generate pressure directly: because the majority of the abdominal wall is muscular, the anterolateral abdominal wall muscles must be synchronously contracted to prevent displacement of the viscera and the resultant loss of pressure. The oblique muscles, acting through the anterior aponeurosis and the rectus sheath, provide the majority of this tension, although transversus abdominis and rectus abdominis also contribute.

The lateral muscles, external oblique, internal oblique and transversus abdominis, have the greatest roles in these functions, tensing the rectus sheath and linea alba. The anterolateral abdominal muscles contribute little to the movements of the trunk during normal sitting and standing, which are movements controlled predominantly by the paravertebral and spinal muscles. However, movements of the trunk against resistance or when the individual is supine require the anterolateral abdominal muscles. Rectus abdominis is the most important in these situations, causing anterior flexion of the trunk. If the pelvic girdle is fixed, flexion of the thorax and pectoral girdle occurs. With a fixed thoracic cage, contraction of rectus abdominis causes the pelvis to lift and tilt to lie more nearly in a horizontal plane. Lateral flexion and rotation of the trunk against resistance is provided by unilateral contraction of the oblique muscles.

Rectus abdominis

Rectus abdominis is a long, strap-like muscle that extends along the entire length of the anterior abdominal wall. It is widest in the upper abdomen and lies just to the side of the midline. The paired recti are separated in the midline by the linea alba (Fig. 61.4).

The muscle fibres of rectus abdominis are interrupted by three fibrous bands or tendinous intersections. One is usually situated at the level of the umbilicus, another opposite the free end of the xiphoid process and a third about midway between the other two. These intersections pass transversely or obliquely across the muscle in a zigzag manner. They are rarely full-thickness and may extend only half-way through the body of the muscle. They usually fuse with the fibres of the anterior lamina of the sheath of the muscle. Sometimes, one or two incomplete intersections are present below the umbilicus. The intersections may occur during development or may represent the myosepta delineating the myotomes that form the muscle.

The medial border of rectus abdominis is closely related to the linea alba. Its lateral border may be visible on the surface of the anterior abdominal wall as a curved groove, the linea semilunaris, which extends from the tip of the ninth costal cartilage to the pubic tubercle. In a muscular individual it is readily visible, even when the muscle is not actively contracting, but in many normal and obese individuals it may be completely obscured.

Attachments

Rectus abdominis arises by two tendons. The larger, lateral tendon is attached to the crest of the pubis and may extend beyond the pubic tubercle to the pectineal line. The medial tendon interlaces with the contralateral muscle and blends with the ligamentous fibres covering the front of the symphysis pubis. Additional fibres may arise from the lower part of the linea alba. Superiorly, rectus abdominis is attached by three slips of muscle to the fifth, sixth and seventh costal cartilages. The most lateral fibres are usually attached to the anterior end of the fifth rib. Sometimes this slip is absent, and occasionally it may extend to the fourth and third ribs. The most medial fibres are occasionally connected to the costoxiphoid ligaments and the side of the xiphoid process. In males, the pubic attachment of rectus abdominis may run over the anterior surface of the symphysis pubis and become continuous with the attachment of the gracilis and the fascia lata to the pubis.

Vascular supply

Rectus abdominis is supplied principally by the superior and inferior epigastric arteries. The inferior epigastric artery tends to be larger in calibre than the superior. Small terminal branches from the lower three posterior intercostal arteries, the subcostal artery, the posterior lumbar arteries and the deep circumflex artery may provide some contribution, particularly to the lateral edges and the lower attachments, and they form small anastomoses with the lateral branches of the epigastric arteries. Rectus abdominis provides an excellent myocutaneous flap, either pedicled or free, because of the excellent vascularity provided by the epigastric vessels and because the muscle belly is separated from surrounding tissue within the rectus sheath. The upper half of the muscle may be used for breast reconstruction or augmentation of tissue loss on the anterior thorax. The lower half may be used in the region of the thigh and may be rotated on its lower attachments, passed through the pelvis and delivered into the perineum for reconstruction after radical pelvic and perineal resections.

Innervation

Rectus abdominis is innervated by the terminal branches of the ventral rami of the lower six or seven thoracic spinal nerves via the lower intercostal and subcostal nerves.

Actions

The recti contribute to the flexion of the trunk. They also contribute to the maintenance of abdominal wall tone required during straining.

Rectus sheath

Rectus abdominis on each side is enclosed by a fibrous sheath. The anterior portion of this sheath extends the entire length of the muscle and fuses with the periosteum of the muscle attachments. Posteriorly, the sheath is complete in the upper two-thirds of the muscle. In the lower one-third, the posterior layer of the sheath stops approximately midway between the umbilicus and the pubis. In most individuals this is a clearly defined line, although the transition may not always be clear-cut in others. The lower border of the posterior sheath is called the arcuate line. Below this level, rectus abdominis is enclosed posteriorly by the transversalis fascia and extraperitoneal connective tissue (Figs 61.8 and 61.9). The rectus sheath is formed from decussating fibres from all three lateral abdominal muscles. External oblique, internal oblique and transversus abdominis each forms a bilaminar aponeurosis at their medial borders. The fibres from all three anterior leaves run obliquely upwards, whereas the posterior leaves run obliquely downwards at right angles to the anterior leaves.

Fig. 61.9 Rectus sheath. Computed tomography scan (**A**) and diagram (**B**) of the anterior abdominal wall, demonstrating the formation of the rectus sheath above the umbilicus. The anterior rectus sheath is composed of both leaves of the aponeurosis of external oblique and the anterior leaf of the aponeurosis of internal oblique, fused together. The posterior rectus sheath is composed of the posterior leaf of the aponeurosis of internal oblique and both leaves of the aponeurosis of transversus abdominis.

The anterior rectus sheath is composed of both leaves of the aponeurosis of external oblique and the anterior leaf of the aponeurosis of internal oblique fused together. The posterior rectus sheath is composed of the posterior leaf of the aponeurosis of internal oblique and both leaves of the aponeurosis transversus abdominis (Fig. 61.10). Because of this arrangement, both the anterior and posterior layers of the rectus sheath consist of three layers of fibres with the middle layer running obliquely at right angles to the other two. At the midline, the anterior and posterior layers are closely approximated. Fibres of each layer decussate to the opposite side of the sheath, forming a continuous aponeurosis with the contralateral muscles (Fig. 61.11). Fibres also decussate anteroposteriorly, crossing from anterior sheath to posterior sheath. The dense fibrous line caused by this decussation is called the linea alba. The external oblique, internal oblique and transversus abdominis muscles can thus be regarded as paired, digastric muscles with a central tendon in the form of the linea alba. These decussating fibres maybe used to identify the midline during surgical incisions, since they can be seen as oblique fibres crossing at right angles. Below the level of the arcuate line, the fibres forming the posterior rectus sheath rapidly cease running behind the rectus and all leaves pass into the anterior rectus sheath.

Linea alba

The linea alba is a tendinous raphe extending from the xiphoid process to the symphysis pubis and pubic crest. It lies between the two recti and is formed by the interlacing and decussating aponeurotic fibres of external oblique, internal oblique and transversus abdominis. It is visible only in the lean and muscular, as a slight groove in the anterior abdominal wall. A fibrous cicatrix, the umbilicus, lies a little below the midpoint of the linea alba, and is covered by an adherent area of skin. Below the umbilicus, the linea alba narrows progressively as the rectus muscles lie closer together. Above the umbilicus, the rectus muscles diverge from one other and the linea alba is correspondingly broader. The linea alba has two attachments at its lower end: its superficial fibres are attached to the symphysis pubis, and its deeper fibres form a triangular lamella that is attached behind rectus abdominis to the posterior surface of the pubic crest on each side. This posterior attachment of linea alba is named the ‘adminiculum lineae albae’. The linea alba is crossed from side to side by a few minute vessels.

In the fetus, the umbilicus transmits the umbilical vessels, urachus and, up to the third month, the vitelline or yolk stalk. It closes a few days after birth, but the vestiges of the vessels and urachus remain attached to its deep surface. The remnant of the fetal left umbilical vein forms the round ligamentum of the liver. The obliterated umbilical arteries form the medial umbilical ligaments, enclosed in peritoneal folds of the same name. The partially obliterated remains of the urachus persist as the median umbilical ligament.

Divarication of the recti

Thinning and widening of the upper linea alba may occur, most commonly as a result of obesity or chronic straining. This process disrupts the arrangement of the fibres of the bilaminar aponeurosis. Contraction of the anterolateral abdominal muscles fails to be transmitted across the midline through the linea alba and increased intra-abdominal pressure causes the abdominal viscera to protrude beneath the thinned tissue as a broad midline bulge. The recti become widely separated or divaricated. This is not true herniation, as all the layers of the abdominal wall in that region are intact.

Umbilical hernia

There are three varieties of umbilical hernia. In true congenital herniation, a defect is present from birth. This is usually simply the result of failure of closure of the umbilicus after retraction of the umbilical gut loop. Less commonly, the gut loop does not retract and remains, in part, outside the abdominal cavity. An infantile umbilical hernia is caused by stretching of the umbilical scar tissue, associated with increased intra-abdominal pressure. An acquired umbilical or paraumbilical hernia actually occurs through small areas of weakness in the linea alba, above or below the umbilical scar.

Pyramidalis

Attachments

Pyramidalis is a triangular muscle that lies in front of the lower part of rectus abdominis within the rectus sheath. It is attached by tendinous fibres to the front of the pubis and to the ligamentous fibres in front of the symphysis. The muscle diminishes in size as it runs upwards, and ends in a pointed apex that is attached medially to the linea alba. This attachment usually lies midway between the umbilicus and pubis, but may occur higher. The muscle varies considerably in size. It may be larger on one side than on the other, absent on one or both sides, or even doubled.

Vascular supply

Pyramidalis is supplied by branches of the inferior epigastric artery, with some contribution from the deep circumflex iliac artery. A small artery frequently crosses the midline posterior to the belly of the muscle to anastomose with the contralateral vessel. This may cause troublesome bleeding during surgical incisions that run down as far as the lower rectus sheath above the symphysis pubis.

Innervation

Pyramidalis is supplied by the terminal branches of the subcostal nerve, which is the ventral ramus of the 12th thoracic spinal nerve.

Actions

Pyramidalis contributes to tensing the lower linea alba, but is of doubtful physiological significance.

External oblique

Attachments

External oblique is the largest and the most superficial of the three lateral abdominal muscles (Fig. 61.1). It curves around the lateral and anterior parts of the abdomen and is attached to the external surfaces and inferior borders of the lower eight ribs. The attachments rapidly become muscular and interdigitate with the lower attachment of serratus anterior and latissimus dorsi along an oblique line that extends downwards and backwards. The upper attachments are close to the cartilages of the corresponding ribs, the middle ones arise from the ribs at some distance from their cartilages and the lowest are close to the apex of the cartilage of the 12th rib. The fibres of external oblique diverge as they pass to their lower attachments. Those from the lower two ribs pass nearly vertically downwards and are attached to the anterior half or more of the outer lip of the anterior segment of the iliac crest. The middle and upper fibres pass downwards and forwards and end in the anterior aponeurosis, along a line drawn vertically from the ninth costal cartilage to a little below the level of the umbilicus. The muscle fibres rarely descend beyond a line from the anterior superior iliac spine to the umbilicus. The posterior border of the muscle is free.

The inguinal ligament is formed by the margin of the aponeurosis of external oblique extending between the anterior superior iliac spine and the pubic tubercle. The deep fibres of the aponeurosis of external oblique are not initially parallel to the long axis of the inguinal ligament: they approach the ligament obliquely at an angle of 10–20°. On reaching the ligament, fibres turns medially, and most run along the ligament to reach the pubic tubercle. The deepest fibres of the aponeurosis spread out posteromedially to insert into the pectineal line.

The upper and lower rib attachments of the muscle may be absent. Digitations or even the entire muscle may be reduplicated. The upper attachments of the muscle are sometimes continuous with pectoralis major or serratus anterior.

Vascular supply

External oblique is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex arteries and the posterior lumbar arteries.

Innervation

External oblique is innervated by the terminal branches of the lower five intercostal nerves and the subcostal nerve from the ventral rami of the lower six thoracic spinal nerves.

Actions

External oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure and lateral flexion of the trunk against resistance.

Inguinal ligament

The inguinal ligament is the thick, inrolled lower border of the aponeurosis of external oblique and stretches from the anterior superior iliac spine to the pubic tubercle. Its grooved abdominal surface forms the ‘floor’ of the inguinal canal. The ligament is not linear and has an inferior and an anterior convexity. At its lower border, it is continuous with the fascia lata. The lateral half is rounded and lies more obliquely than the medial half. The latter gradually widens towards its attachment to the pubis, where it becomes more horizontal and supports the spermatic cord. At the medial end, some fibres do not attach to the pubic tubercle but extend in two directions. Some expand posteriorly and laterally to attach to the pectineal line, forming the lacunar ligament complex. Other fibres pass upwards and medially behind the superficial inguinal ring and external oblique to join the rectus sheath and the linea alba. These constitute the reflected part of the inguinal ligament. Fibres from either side decussate in the linea alba, similarly to the aponeurosis of the abdominal muscles.

Internal oblique

Attachments

Internal oblique lies deep to external oblique for the majority of its course (Fig. 61.2). It is thinner and less bulky than external oblique. Its fibres arise from the lateral two-thirds of the grooved upper surface of the inguinal ligament, where they form a common attachment with the iliac fascia to the inguinal ligament. Laterally, internal oblique is also attached to the anterior two-thirds of the intermediate line of the anterior segment of the iliac crest, and posteriorly some fibres are attached to the thoracolumbar fascia. The fibres originating from the posterior end of the iliac attachment pass upwards and laterally and are attached to the inferior borders and tips of the lower three or four ribs and their cartilages. Here, the attachments merge with those of the internal intercostals. The uppermost of these fibres form a short, free superior border. The fibres attached to the anterior iliac crest diverge and end in the anterior aponeurosis, which gradually broadens from below upwards. The uppermost part of the aponeurosis is attached to the cartilages of the seventh, eighth and ninth ribs. The fibres that originate from the inguinal ligament arch downwards and medially across the spermatic cord in the male and the round ligament of the uterus in the female. They become tendinous, fuse with the corresponding part of the aponeurosis of transversus abdominis, and attach to the crest and medial part of the pectineal line, forming the conjoint tendon.

Vascular supply

Internal oblique is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex arteries and the posterior lumbar arteries.

Innervation

Internal oblique is innervated by the terminal branches of the lower five intercostal nerves and the subcostal nerve from the ventral rami of the lower six thoracic spinal nerves, in addition to a small contribution from the iliohypogastric and ilioinguinal nerves from the ventral ramus of the first lumbar spinal nerve.

Actions

Internal oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure, and enables lateral flexion of the trunk against resistance.

Cremaster

Attachments

Cremaster consists of loosely arranged muscle fasciculi lying along the spermatic cord. It is variable in thickness and is thickest in young men. It may form an incomplete coating around the cord, known as the cremasteric fascia, which extends around the testis but lies within the external spermatic fascia. The attachment of the muscle arises mainly from the inferomedial border of internal oblique and transversus abdominis. A separate tendinous attachment may also occur to the middle of the inguinal ligament, extending as far as the anterior superior iliac spine. The medial portion is attached to the pubic tubercle and lateral pubic crest. The fibres spread out over the lateral aspect of the spermatic cord as it approaches the superficial inguinal ring. The shortest and most superior fasciculi turn inwards in front of the cord to join the medial part. The longer, lateral fasciculi blend with the fascia over the cord and upper part of the tunica vaginalis. In the female, a few fibres descending on the round ligament of the uterus represent the lateral part of cremaster. The medial part of the muscle is variably developed, and may be absent. It is attached to the pubic tubercle and the lateral pubic crest, the conjoint tendon and lower border of transversus abdominis. These fasciculi loop on the posteromedial aspect of the cord, interlacing with those of the lateral part. The entire muscle appears to form continuous loops that pass from the middle of the inguinal ligament as far as the tunica vaginalis, and then return to attach to the pubic tubercle.

Vascular supply

Cremaster is supplied by the cremasteric artery, a branch of the inferior epigastric artery.

Innervation

Cremaster is innervated by the genital branch of the genitofemoral nerve, derived from the first and second lumbar spinal nerves.

Actions

Cremaster pulls the testis up towards the superficial inguinal ring. Although its fibres are striated, it is not usually under voluntary control. Stroking the skin of the medial side of the thigh evokes a reflex contraction of the muscle, the cremasteric reflex, which is most pronounced in children. It may represent a protective reflex, and the cremaster may also have a role in testicular thermoregulation.

Transversus abdominis

Attachments

Transversus abdominis is the deepest of the lateral abdominal muscles (Fig. 61.5). It is attached to the lateral one-third of the inguinal ligament and the associated iliac fascia, the anterior two-thirds of the inner lip of the anterior segment of the iliac crest, the thoracolumbar fascia between the iliac crest and the 12th rib, and the internal aspects of the lower six costal cartilages. The costal attachments interdigitate with the attachment of the diaphragm. The muscle ends in an anterior aponeurosis. The lower fibres curve downwards and medially, together with those of the aponeurosis of internal oblique, and insert into the pubic crest and pectineal line to form the conjoint tendon. A band of fibres, sometimes muscular, may run from the lower border of the muscle to the inguinal ligament and is called the inter-foveolar ligament. The remainder of the aponeurosis passes medially and the fibres decussate at, and blend with, the linea alba. The upper costal and anterior iliac fibres of transversus abdominis are short. The lower costal and posterior iliac fibres are longer, and the thoracolumbar fibres are longest. Near the xiphoid process, the aponeurosis is formed only 2–3 cm from the linea alba, so the muscular part of transversus abdominis extends behind rectus into the posterior layer of the rectus sheath. The medial edge of the muscle, at the start of the aponeurosis, curves first downwards and laterally, and is furthest from the lateral edge of the rectus sheath at the level of the umbilicus. It then curves downwards and medially towards the middle of the superior crus of the superficial inguinal ring.

Occasional defects filled with fascia may occur in the lower muscular and aponeurotic parts of both internal oblique and transversus abdominis. The two muscles are sometimes fused and, rarely, transversus abdominis may be absent.

Vascular supply

Transversus abdominis is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex arteries and the posterior lumbar arteries.

Innervation

Transversus abdominis is innervated by the terminal branches of the lower five intercostal nerves, the subcostal nerve and the iliohypogastric and ilioinguinal nerves. These arise from the ventral rami of the lower six thoracic and first lumbar spinal nerves.

Actions

Transversus abdominis contributes mainly to the maintenance of abdominal tone and increasing intra-abdominal pressure.

Conjoint tendon

The conjoint tendon is formed from the lower fibres of internal oblique and the lower part of the aponeurosis of transversus abdominis. It is attached to the pubic crest and pectineal line. It descends behind the superficial inguinal ring and acts to strengthen the medial portion of the posterior wall of the inguinal canal. The attachment to the pectineal line is frequently absent. Medially, the upper fibres of the tendon fuse with the anterior wall of the rectus sheath, and laterally some fibres may blend with the interfoveolar ligament.

Inguinal canal

The inguinal canal is a natural hiatus in the tissues of the anterior abdominal wall, and is formed from the various layers of the wall in the region of the groin (Figs 61.12, 61.13, 61.14, 61.15, and see Fig. 76.2). Its size and form vary with age, and although it is present in both sexes it is most well developed in the male. The canal is an oblique tunnel, with deep and superficial openings or rings. It contains the spermatic cord in males, the round ligament of the uterus in females, and the ilioinguinal nerve in both sexes.

Superficial inguinal ring

The superficial inguinal ring is a hiatus in the aponeurosis of external oblique, just above and lateral to the crest of the pubis. The ring is actually triangular, and its apex points along the line of the deep fibres of the aponeurosis. Although it varies in size, it does not usually extend laterally beyond the medial one-third of the inguinal ligament – the ring is smaller in the female. The base lies along the crest of the pubis and its sides are the crura of the opening in the aponeurosis. The lateral crus is the stronger and is reinforced by fibres of the inguinal ligament inserted into the pubic tubercle. The medial crus is thin. The fibres attach to the front of the symphysis pubis and interlace with fibres from the opposite side. In the external layer of the investing fascia of external oblique, some fibres arch above the apex of the superficial inguinal ring as intercrural fibres. In the male, the lateral crus is curved to form a groove, in which the spermatic cord rests. Fibres from the aponeurosis of external oblique and overlying fascia continue downwards from the crura of the ring, and form a delicate tubular prolongation of fibrous tissue around the spermatic cord and testis. This is the external spermatic fascia and constitutes the outermost covering of the cord. The superficial inguinal ring is only a distinct aperture when the continuity of this fascia with the aponeurosis is interrupted.

Deep inguinal ring

The deep inguinal ring is situated in the transversalis fascia, midway between the anterior superior iliac spine and the symphysis pubis approximately 1.25 cm above the inguinal ligament. It is oval, with an almost vertical long axis. Its size varies between individuals, and it is always much larger in the male. It is related above to the arched lower margin of transversus abdominis, and medially to the inferior epigastric vessels and the interfoveolar ligament, when that is present. Traction on the fascial ring exerted by internal oblique may constitute a valve-like safety mechanism when intra-abdominal pressure is increased.

Boundaries

The inguinal canal is a virtual space lying between the various layers formed from the lower tissues of the anterior abdominal wall. It lies obliquely and slants downwards and medially, parallel with and a little above the inguinal ligament. It extends from the deep to the superficial inguinal rings: the length depends on the age of the individual, but in the adult is between 3 and 5 cm long. The canal is bounded anteriorly by the skin, superficial fascia and aponeurosis of external oblique. In its lateral one-third, the anterior wall is reinforced by the muscular fibres of the internal oblique just above their origin from the inguinal ligament. Posteriorly lie the reflected inguinal ligament, the conjoint tendon and the transversalis fascia, which separate it from extraperitoneal connective tissue and peritoneum. Superiorly lie the arched fibres of internal oblique and transversus abdominis, forming the conjoint tendon, and inferiorly is the union of the transversalis fascia with the inguinal ligament and, at the medial end, the lacunar ligament.

In the newborn, the deep and superficial rings are nearly superimposed and the canal is extremely short. This creates an approximately oval defect in the abdominal wall. As the child grows, the anterior abdominal wall muscles grow rapidly, causing the positions of the rings to separate and the canal to lengthen. The defect thus becomes progressively more oblique until, in adulthood, the presence of separate anterior and posterior canal walls forms a ‘flap valve’ effect. Increases in intra-abdominal pressure transmitted through the posterior wall and the deep ring are supported by the presence of the thickest part of the overlying anterior wall. At the superficial ring and medial end of the anterior wall, where it is weakest, the posterior wall is strengthened by the conjoint tendon and the reflected inguinal ligament. The fibres of internal oblique and transversus abdominis, which form the conjoint tendon, are constantly active in standing; this activity increases during episodes of increased intra-abdominal pressure.

Relations

The inferior epigastric vessels are important posterior relations of the medial end of the canal (Fig. 61.16). They lie on the transversalis fascia as they ascend obliquely behind the conjoint tendon into the posterior portion of the rectus sheath.

Fig. 61.16 Deep structures of the inguinal canal. The aponeurosis of external oblique has been removed. For clarity, the fibres of internal oblique

and rectus abdominis have been divided and the structures passing posteroinferiorly to the inguinal ligament have been excluded.

The inguinal triangle lies in the posterior wall of the canal. It is bounded inferiorly by the medial half of the inguinal ligament, medially by the lower lateral border of rectus abdominis and laterally by the inferior epigastric artery, and overlies the medial inguinal fossa and, in part, the supravesical fossa.

Lacunar ligament

The lacunar ligament is a thick triangular band of tissue lying mainly posterior to the medial end of the inguinal ligament. It measures approximately 2 cm from base to apex and is a little larger in the male. It is formed from fibres of the medial end of the inguinal ligament and fibres from the fascia lata of the thigh, which join the medial end of the inguinal ligament from below. The inguinal fibres run posteriorly and laterally to the medial end of the pectineal line and are continuous with the pectineal fascia. They form a near horizontal, triangular sheet with a curved lateral border which forms the medial border of the femoral canal. The apex of the triangle is attached to the pubic tubercle. A strong fibrous band, the pectineal ligament of Astley Cooper, extends laterally along the pectineal line from the pectineal attachment. The fibres from the fascia lata join the inferior/posterior border of the inguinal ligament; the latter, in combination with fibres from the transversalis fascia, fuses with the pectineal fascia as it joins the thickened periosteum of the pectineal line. This portion of the lacunar ligament forms the lower extension of the medial border of the femoral canal and femoral sheath.

HERNIAS OF THE ANTERIOR ABDOMINAL WALL

INGUINAL HERNIA

Although the inguinal canal is arranged such that the weaknesses in the anterior abdominal wall caused by the deep and superficial inguinal rings are supported, the region remains a potential cause of herniation. An inguinal hernia involves the protrusion of a viscus through the tissues of the inguinal region of the abdominal wall.

Indirect inguinal hernia

An indirect hernia is defined as arising lateral to the inferior epigastric vessels. Many indirect hernias are related to the congenital abnormal persistence of the vaginal process, others are acquired as a result of progressive weakening of the lateral and posterior walls of the canal. The hernia may pass through the deep ring or may expand the deep ring such that it is no longer a clear entity. Small indirect hernias tend to lie below and lateral to the fibres of the conjoint tendon, but larger hernias often distort and thin the tendon superiorly. Small hernias, which do not protrude beyond the inguinal canal, are covered by the same inner layers as the spermatic cord, including the internal spermatic fascia and cremaster. If the hernia extends through the superficial inguinal ring it is additionally covered by external spermatic fascia.

In hernias related to a persistent fully patent vaginal process, the hernia contents descend in front of the testis into the tunica vaginalis (complete congenital hernia) and the vaginal process and tunica form part of the hernial sac. Where the vaginal process is sealed off from the tunica vaginalis, the hernia contents descend to the top of the testis (incomplete congenital hernia). Although both types are related to a congenital abnormality, actual herniation into the potential sac may not occur until adult life, when it may happen as a consequence of increased intra-abdominal pressure or sudden muscular strain.

Direct inguinal hernia

A direct inguinal hernia is defined as arising medial to the inferior epigastric vessels. Direct hernias are always caused by an acquired weakness of the inguinal triangle in the medial posterior wall of the canal, and frequently extend through the anterior wall of the canal or superficial ring. The hernia may protrude through the transversalis fascia, between the conjoint tendon and the inferior epigastric vessels, and enter the inguinal canal. It may closely resemble an indirect hernia, in that the coverings are similar. Its clinical presentation can also mimic an indirect inguinal hernia. Other direct hernias arise either between the fibres of the conjoint tendon or by eventration of the tendon such that it forms a thin covering to the hernia. In either case, a hernia enters the lower end of the canal, protruding through the superficial ring medial to the cord, and is covered by external spermatic fascia.

Clinical features of inguinal hernias

Indirect hernias often descend from lateral to medial in the same oblique angle as the canal, because of their origin in the lateral end of the inguinal canal. This is particularly true for congenital hernias. Direct hernias arise from the medial end of the canal and tend to protrude more directly anteriorly. With the patient in the supine position and the hernia reduced, pressure applied over the region of the deep inguinal ring may prevent appearance of an indirect hernia on standing or straining. This method of determining the type of hernia is fraught with difficulties. Indirect hernias may have a wide neck, and occlusion of the deep ring may not be possible with simple digital pressure. An acquired indirect hernia may arise medial to the deep ring. The angle of the descent of the hernia is also an unreliable guide, as it depends on the size of the defect in the posterior wall of the canal, the length of the canal and whether the hernia protrudes through the anterior wall. Direct hernias are more likely to have a wide-necked origin, making strangulation less likely.

FEMORAL HERNIA

A femoral hernia protrudes through the femoral ring. The femoral ring is normally closed by a femoral septum of modified extraperitoneal tissue, and is therefore a weak spot. In females, the ring is relatively large and subject to profound changes during pregnancy, which explains why femoral hernias are more common in women. When a section of intestine bulges through the ring, it pushes out a hernial sac of peritoneum. It is covered by extraperitoneal tissue (the femoral septum) and descends along the femoral canal to the saphenous opening. It is prevented from descending further along the femoral sheath by the narrow saphenous opening, by the vessels and by the close attachment of the superficial fascia and sheath to the lower part of the rim of the saphenous opening. The hernia hence turns forwards, distending the cribriform fascia and curving upwards over the inguinal ligament and the lower part of the aponeurosis of external oblique. While in the canal the hernia is usually small, because of the resistance of surrounding tissues, but it enlarges as it escape into the inguinal loose connective tissue. A femoral hernia first descends and then ascends forwards: pressure to reduce it should therefore be directed in the reverse order, with the thighs passively flexed for greatest relaxation.

The coverings of a femoral hernia are, from within outwards: the peritoneum, femoral septum, femoral sheath, cribriform fascia, superficial fascia and skin. A fibrous covering, the fascia propria, may lie outside the peritoneal sac and is frequently separated from it by adipose tissue. It represents a femoral septum which has been thickened to form a membranous sheet by hernial pressure. The fascia propria may easily be mistaken for the sac, and its contained extraperitoneal fat for omentum; the fat may resemble a lipoma, but dissection will reveal the true hernial sac in its centre. The intestine reaches only to the saphenous opening in incomplete femoral hernia, in contradistinction to complete hernia, in which it passes through the opening. The small size of an incomplete hernia renders it difficult to detect and therefore dangerous, especially in the corpulent. The site of strangulation varies: it may be at the neck of the hernial sac, more often it is at the junction of the falciform margin of the saphenous opening with the free edge of the pectineal part of the inguinal ligament, or it may be at the saphenous opening. The site of narrowing should be divided superomedially for a distance of 4–6 mm to avoid all normally positioned vessels and other important structures. Occasionally the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric artery descending almost vertically to the obturator foramen. This vessel sometimes curves along the edge of the lacunar part of the inguinal ligament, encircling the neck of a hernial sac, and may be inadvertently cut during enlargement of the femoral ring in reducing a femoral hernia.

The pubic tubercle is an important landmark in distinguishing inguinal from femoral hernias; the neck of the hernia is superomedial to it in inguinal hernia, but inferolateral in the femoral form.

LESIONS OF THE INTERCOSTAL NERVES

Lesions of individual intercostal nerves do not produce any appreciable clinical effects. The anterolateral muscles are innervated by a number of different nerves: injury to a single nerve will not reduce the tone of the muscle wall. The overlap between sequential dermatomes means that significant cutaneous anaesthesia is appreciated only after sectioning of at least two sequential nerves.

CHAPTER 62

Posterior abdominal wall and retroperitoneum

The posterior abdominal wall consists of fasciae, muscles and their vessels and spinal nerves; the overlying skin is continuous with that of the back. It is not easily defined, and is best described as that part of the abdominal wall lying between the two mid-dorsal lines, below the posterior attachments of the diaphragm and above the pelvis. It is continuous laterally with the anterolateral abdominal wall, superiorly with the posterior wall of the thorax behind the attachments of the diaphragm and inferiorly with the structures of the pelvis. The spinal column forms part of its structure and the muscles and fasciae of the back are closely related to it, especially posterolaterally.

The major vessels and lymphatic channels, in addition to the peripheral autonomic nervous systems of the abdomen, pelvis and lower limbs lie on the posterior abdominal wall. These structures, together with several viscera (including the kidneys [Ch. 74], suprarenal glands [Ch. 72], pancreas [Ch. 70], ureters [Ch. 74] and parts of the gut tube [Chs 66 and 67]), lie beneath the posterior parietal peritoneum. These tissues and their surrounding connective and fascial planes are collectively referred to as the retroperitoneum.

It has been suggested that the retroperitoneum can be divided into several spaces according to their relationships to the fascial layers that surround the kidneys and ureters. In this description, the layers of the perirenal fascia enclose a perirenal space containing the kidney, suprarenal gland, upper ureter and their neurovascular supply. The anterior layer of the perirenal fascia is continuous across the midline anterior to the main neurovascular structures of the retroperitoneum, and the right and left perirenal spaces communicate, although this channel is limited and contains many of the midline neurovascular structures of the retroperitoneum. Behind the posterior layer of the perirenal fascia lies the posterior pararenal space. Anterior to the anterior layer of the perirenal fascia lies the anterior pararenal space, in which lie several retroperitoneal parts of the gut tube, including the duodenum and pancreas. The anterior pararenal spaces are also continuous across the midline and are limited posteriorly by the anterior communicating layer of the perirenal fascia and anteriorly by the parietal peritoneum. This description helps to explain why moderate amounts of fluid, blood or pus collecting in the retroperitoneum tend to remain constrained within the space in which they are formed although, for pathological processes such as tumour invasion, the fascial planes provide a weak barrier to local spread (Figs 62.1, 62.2).

Several structures, such as the pancreas, are referred to as being retroperitoneal. Although they are derived embryologically from the gut tube, they are not readily separated from the other retroperitoneal structures. Several other structures, such as the descending colon, are also referred to as being retroperitoneal, but they remain separated from the other retroperitoneal structures by a clearly defined fascial plane, which corresponds with the plane of fusion of their mesentery during development. This is of relevance during surgical exposure of the retroperitoneal organs and in some pathological processes: those defined by clear fascial planes may be mobilized with little or no risk of bleeding, whereas mobilization of the pancreas, for example, is difficult and often very vascular.

SKIN AND SOFT TISSUES

The skin of the back in the region of the posterior abdominal wall is similar to that of the rest of the trunk. It is supplied by vessels from the musculocutaneous branches of the lumbar arteries and veins, and receives its innervation from the dorsal rami of the lumbar spinal and lower thoracic nerves.

The soft tissues of the posterior abdominal wall and retroperitoneum are composed of several distinct layers of fascia, which divide them into anatomically distinct compartments.

THORACOLUMBAR FASCIA

The thoracolumbar fascia in the lumbar region is in three layers (Figs 62.1, 62.2, 62.3). The posterior layer is attached to the spines of the lumbar and sacral vertebrae and to the supraspinous ligaments. The middle layer is attached medially to the tips of the transverse processes of the lumbar vertebrae and the intertransverse ligaments, inferiorly to the iliac crest, and superiorly to the lower border of the 12th rib and the lumbocostal ligament. The anterior layer covers quadratus lumborum and is attached medially to the anterior surfaces of the transverse processes of the lumbar vertebrae behind the lateral part of psoas major. Inferiorly, it is attached to the iliolumbar ligament and the adjoining part of the iliac crest. Superiorly, it is attached to the apex and inferior border of the 12th rib and then extends to the transverse process of the first lumbar vertebra, to form the lateral arcuate ligament of the diaphragm. The posterior and middle layers of the thoracolumbar fascia unite at the lateral margin of erector spinae. At the lateral border of quadratus lumborum they are joined by the anterior layer, to form the aponeurotic origin of transversus abdominis.

OTHER FASCIAL LAYERS

Psoas fascia

Psoas major is enclosed within a layer of fascia over its anterior surface. The medial border is continuous with the attachments of the muscle to the transverse processes of the lumbar vertebrae, the bodies of the lumbar vertebrae and the tendinous arches. Superiorly, the fascia forms part of the medial arcuate ligament. Laterally, the fascia blends with the fascia over quadratus lumborum in the upper part of the muscle and is continuous with the iliac fascia lower down. It separates the anterior mass of psoas major from the retroperitoneal structures lying on it. The fascia extends down into the thigh. Inflammatory collections arising from the paraspinal tissues or the retroperitoneal tissues that penetrate through the fascia tend to be confined by it, and they may track down the length of the muscle, to appear in the groin where the fascia is thinnest.

Iliac fascia

The iliac fascia is continuous with and indistinguishable from the psoas fascia. The fascia blends with the anterior layer of the thoracolumbar fascia over quadratus lumborum in the upper retroperitoneum. Lower down, it is attached firmly to the inner aspect of the iliac crest and medially to the periosteum of the ilium at the pelvic brim. It is also attached in the abdomen to the iliopectineal eminence.

Perirenal fascia

The perirenal fascia is a multilaminated fascial layer that surrounds the kidney, suprarenal glands, upper ureter and associated fat, which all lie in the perirenal space (see Ch. 74). Although described as having anterior and posterior layers, these are continuous with each other laterally, and give rise to the lateroconal fascia at this point (Figs 62.1-62.3). The posterior layer of the renal fascia is adherent to the fascia over psoas major, the iliac fascia and the anterior layers of the thoracolumbar fascia. In the obese, there may be some loose adipose tissue between these layers, but it is rarely thick. The anterior part of the renal fascia separates the kidney and the perirenal space from the overlying anterior pararenal space and its associated viscera (on the right the duodenum, ascending colon and right colonic mesentery and on the left the duodenum, descending colon and left colonic mesentery). Inferiorly, the perirenal fascia continues down and encloses the ureter. It becomes progressively thinner towards the brim of the pelvis, where it is no longer distinguishable from the loose general connective tissue of the retroperitoneum.

Lateroconal fascia

The lateroconal fascia is formed from the lateral aspect of the perirenal fascia and extends anterolaterally to fuse with the fascia over transversus abdominis. It divides the anterior and posterior pararenal spaces from each other, but is thinnest in the inferior part of the retroperitoneum.

POSTERIOR EXTRAPERITONEAL CONNECTIVE TISSUE

The retroperitoneum usually contains loose connective tissue between the fascial layers. This is particularly true around the renal fascia and anterior to the psoas and iliac fascia. In all but the thinnest individuals, there is some adipose tissue present in these areas, and in the obese it may be markedly thickened. The retroperitoneal arteries and veins lie within this tissue, but the branches of the lumbar plexus of nerves lie deep to it, beneath the iliac and psoas fascia.

BONES

The posterior abdominal wall is supported by the bony structures of the vertebral column and bony pelvis. These include the lower two ribs, the 12th thoracic and five lumbar vertebrae, and the sacrum and ilium, in addition to their interconnecting ligaments.

MUSCLES

The majority of the muscles of the posterior abdominal wall are functionally part of the lower limb or vertebral column. They provide the surface against which the neurovascular structures of the retroperitoneum lie, and they are supported and separated from the majority of the retroperitoneal structures by fascial layers (Figs 62.4, 62.5; see Fig. 62.14).

Quadratus lumborum

Quadratus lumborum is an irregularly shaped quadrilateral muscle, which is broader at its inferior attachment than superiorly.

Attachments

Quadratus lumborum is attached below by aponeurotic fibres to the iliolumbar ligament and the adjacent portion of the iliac crest for approximately 5 cm. The superior attachment is to the medial half of the lower border of the 12th rib, and by four small tendons to the apices of the transverse processes of the upper four lumbar vertebrae. Sometimes it is also attached to the transverse process or body of the 12th thoracic vertebra. Occasionally, a second layer of this muscle is found in front of the first, attached to the upper borders of the transverse processes of the lower three or four lumbar vertebrae and to the lower margin and the lower part of the anterior surface of the 12th rib.

Relations

Anteriorly are the colon (ascending on the right, descending on the left), kidney, psoas major and minor, and diaphragm. The subcostal, iliohypogastric and ilioinguinal nerves lie on the fascia anterior to the muscle, but are bound down to it by the medial continuation of the transversalis fascia.

Vascular supply

Quadratus lumborum is supplied by branches of the lumbar arteries, the arteria lumbalis ima, the lumbar branch of the iliolumbar artery and branches of the subcostal artery.

Innervation

Quadratus lumborum is innervated by the ventral rami of the 12th thoracic and upper three or four lumbar spinal nerves.

Actions

Quadratus lumborum fixes the last rib, and acts as a muscle of inspiration by helping to stabilize the lower attachments of the diaphragm. It has been suggested that this action might also provide a fixed base for controlled relaxation of the diaphragm in the precise adjustment of expiration needed for speech and singing. With the pelvis fixed, quadratus acts upon the vertebral column, flexing it to the same side. When both muscles contract, they probably help to extend the lumbar part of the vertebral column.

Psoas major

Psoas major has several sites of abdominal attachment. Posteriorly, the attachments are to the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae. The muscle arising from these attachments is referred to as the posterior mass. The muscle also has an anterior mass. It consists of two different sets of attachments. The first part is five slips of muscle attached to the bodies of two adjoining vertebrae and their intervertebral disc (from the 12th thoracic vertebra and the thoracolumbar disc to the body of the fifth lumbar vertebra). The second part is a series of tendinous arches extending across the narrow parts of the bodies of the five lumbar vertebrae between these slips. The upper four lumbar intervertebral foramina bear important relations to these attachments of the muscle. The foramina lie anterior to the transverse processes (the posterior attachments) and posterior to the vertebral bodies, discs and tendinous arches (anterior attachments). The roots of the lumbar plexus therefore enter the muscle directly between the two masses and the plexus is lodged within it. The branches then emerge from the borders and surfaces of psoas major.

Psoas minor

Psoas minor is often absent but, when present, lies anterior to psoas major. It arises from the sides of the bodies of the 12th thoracic and first lumbar vertebrae and from the disc between them, and ends in a long, flat tendon attached to the pectineal line and iliopectineal eminence and, laterally, to the iliac fascia.

Erector spinae

The muscles of the erector spinae group (see Ch. 42) do not form part of the posterior abdominal wall itself, but are closely associated with the fascial layers of the posterior wall.

Iliacus

Iliacus is a triangular sheet of muscle that arises from the superior two-thirds of the concavity of the iliac fossa, the inner lip of the iliac crest, the ventral sacroiliac and iliolumbar ligaments and the upper surface of the lateral part of the sacrum. It reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsule of the hip joint. Most of its fibres converge into the lateral side of the strong tendon of psoas major. It lines the posterior wall of the lesser pelvis formed by the ilium.

Posterior abdominal wall hernias

Herniation through the posterior abdominal wall is extremely rare because the fascial layers usually provide an excellent protection against protrusion of the posterior abdominal viscera, which are relatively immobile. However, the posterior free border of external oblique and the inferior free border of latissimus dorsi create an area of potential weakness, referred to as the lumbar triangle. Spontaneous hernias through this tissue are very rare in the absence of previous surgical access such as a nephrectomy.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ABDOMINAL AORTA

The abdominal aorta begins at the median, aortic hiatus of the diaphragm, anterior to the inferior border of the 12th thoracic vertebra and the thoracolumbar intervertebral disc (Figs 62.6, 62.7). It descends anterior to the lumbar vertebrae to end at the lower border of the fourth lumbar vertebra, a little to the left of the midline, by dividing into two common iliac arteries. It diminishes rapidly in calibre from above downward, because its branches are large; however, the diameter of the vessel at any given height tends to increase slightly with age. The cadaveric superior and inferior calibres are between 9–14 mm and 8–12 mm, respectively, with little difference between the sexes. The angle of the aortic bifurcation varies widely, particularly in the elderly. It has been suggested that the relationship between aortic size and shape is a possible causative factor in the development of abdominal aortic aneurysm (Newman et al 1971). The reflection of transmitted pressure waves at junctions between vessels (of which the abdominal aorta has many) may focally weaken the intimal lining, e.g. at the aortic bifurcation, pressure oscillations and possibly turbulence may be set up as a result of differences in the luminal diameters of the common iliac arteries, producing reflected waves that may injure the intima of the distal abdominal aorta. The role of the relative calibres of the iliac arteries remains uncertain (Shah et al 1978).

Relations

The upper abdominal aorta is related anteriorly to the coeliac trunk and its branches. The coeliac plexus and the lesser sac lie between it and the left lobe of the liver and lesser omentum. Below this, the superior mesenteric artery leaves the aorta, crossing anterior to the left renal vein. The body of the pancreas, with the splenic vein on its posterior surface, extends obliquely up and to the left across the abdominal aorta, separated from it by the superior mesenteric artery and left renal vein. Below the pancreas, the proximal parts of the gonadal arteries, and the third part of the duodenum, lie anteriorly. In its lowest part it is covered by the posterior parietal peritoneum and crossed obliquely by the origin of the small intestinal mesentery.

The thoracolumbar intervertebral discs, the upper four lumbar vertebrae, intervening intervertebral discs and the anterior longitudinal ligament are all posterior to the abdominal aorta. Lumbar arteries arise from its dorsal aspect and cross posterior to it. The third and fourth (and sometimes second) left lumbar veins also cross behind it to reach the inferior vena cava. The aorta may overlap the anterior border of the left psoas major.

On the right, the aorta is related above to the cisterna chyli and thoracic duct, the azygos vein and the right crus of the diaphragm, which overlaps and separates it from the inferior vena cava and right coeliac ganglion. Below the second lumbar vertebra, it is closely applied to the left side of the inferior vena cava. This close relationship occasionally allows the formation of an aorto-caval fistula, particularly after surgery for aneurysmal disease or trauma to the aorta.

On the left, the aorta is related above to the left crus of the diaphragm and left coeliac ganglion. Level with the second lumbar vertebra, it is related to the duodenojejunal flexure and the left sympathetic trunk, the fourth part of the duodenum and the inferior mesenteric vein.

Branches

The branches of the aorta are described as anterior, lateral and dorsal (Fig. 62.8). The anterior and lateral branches are distributed to the viscera and the dorsal branches supply the body wall, vertebral column, vertebral canal and its contents. The aorta terminates by dividing into the right and left common iliac arteries.

Anterior group

Coeliac trunk

The coeliac trunk is the first anterior branch and arises just below the aortic hiatus at the level of T12/L1 vertebral bodies (Fig. 62.9). It is 1.5–2 cm long and passes almost horizontally forwards and slightly right above the pancreas and splenic vein. It divides into the left gastric, common hepatic and splenic arteries. The coeliac trunk may also give off one or both of the inferior phrenic arteries. The superior mesenteric artery may arise with the coeliac trunk as a common origin. One or more of the superior mesenteric branches may arise from the coeliac trunk. Anterior to the coeliac trunk lies the lesser sac. The coeliac plexus surrounds the trunk, sending extensions along its branches. On the right lie the right coeliac ganglion, right crus of the diaphragm and the caudate lobe of the liver. To the left lie the left coeliac ganglion, left crus of the diaphragm and the cardiac end of the stomach. The right crus may compress the origin of the coeliac trunk, giving the appearance of a stricture. The body of the pancreas and the splenic vein are inferior to the coeliac trunk.

Superior mesenteric artery

The superior mesenteric artery originates from the aorta approximately 1 cm below the coeliac trunk, at the level of the L1/2 intervertebral disc (Fig. 62.9). It lies posterior to the splenic vein and the body of the pancreas, and is separated from the aorta by the left renal vein. It runs inferiorly and anteriorly, anterior to the uncinate process of the pancreas and the third part of the duodenum.

Inferior mesenteric artery

The inferior mesenteric artery is usually smaller in calibre than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the aorta at about the level of the third lumbar vertebra, 3 or 4 cm above the aortic bifurcation and posterior to the horizontal part of the duodenum (Figs 62.6, 62.9).

Lateral group

Suprarenal artery

The middle suprarenal artery arises from the lateral aspect of the abdominal aorta, level with the superior mesenteric artery. It ascends slightly, and runs over the crura of the diaphragm to the suprarenal glands, where it anastomoses with the suprarenal branches of the phrenic and renal arteries. The right middle suprarenal artery passes behind the inferior vena cava, near the right coeliac ganglion. The left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas.

Renal artery

The renal arteries are two of the largest branches of the abdominal aorta and arise laterally from the vessel just below the origin of the superior mesenteric artery. The right is longer and usually arises slightly higher than the left. It passes posterior to the inferior vena cava, right renal vein, head of the pancreas and second part of the duodenum. The left renal artery arises a little lower down and passes behind the left renal vein, the body of the pancreas and the splenic vein.

Gonadal artery

The gonadal arteries are two long, slender vessels that arise from the aorta a little inferior to the renal arteries. Each passes inferolaterally under the parietal peritoneum on psoas major.

Dorsal group

Inferior phrenic arteries

The inferior phrenic arteries usually arise from the aorta, just above the level of the coeliac trunk. Occasionally they arise from a common aortic origin with the coeliac trunk, from the coeliac trunk itself or from the renal artery. They contribute to the arterial supply of the diaphragm. Each artery ascends and runs laterally anterior to the crus of the diaphragm, near the medial border of the suprarenal gland. The left passes behind the oesophagus and forwards on the left side of its diaphragmatic opening. The right passes posterior to the inferior vena cava and then along the right of the diaphragmatic opening for the inferior vena cava. Near the posterior border of the central tendon of the diaphragm, each divides into medial and lateral branches (Fig. 62.6). The medial branch curves forwards to anastomose with its fellow in front of the central tendon and with the musculophrenic and pericardiacophrenic arteries. The lateral branch approaches the thoracic wall, and anastomoses with the lower posterior intercostal and musculophrenic arteries. The lateral branch of the right artery provides the arterial supply to the wall of the inferior vena cava, whereas the left sends ascending branches to the serosal surface of the abdominal oesophagus. Each inferior phrenic artery has two or three small suprarenal branches. The capsule of the liver and spleen may also receive a small supply from the arteries.

Lumbar arteries

There are usually four lumbar arteries on each side, in series with the posterior intercostal arteries. They arise from the posterolateral aspect of the aorta, opposite the lumbar vertebrae. A fifth, smaller, pair occasionally arise from the median sacral artery, but lumbar branches of the iliolumbar arteries usually take their place. The lumbar arteries run posterolaterally on the first to the fourth lumbar vertebral bodies, behind the sympathetic trunks, to intervals between the lumbar transverse processes. From here they continue into the muscles of the posterior abdominal wall. The right arteries pass posterior to the inferior vena cava. The upper two on the right side, and the first left lumbar arteries, lie posterior to the corresponding crus of the diaphragm. Arteries of both sides pass under tendinous arches, which span the lateral concavities of the vertebral bodies, and which form the attachment of psoas major. The arteries run posterior to the muscle and the lumbar plexus, then cross the anterior surface of quadratus lumborum. At the lateral border of quadratus lumborum they pierce the posterior aponeurosis of transversus abdominis, and run forwards between it and internal oblique. They anastomose with one another and the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

Dorsal branches

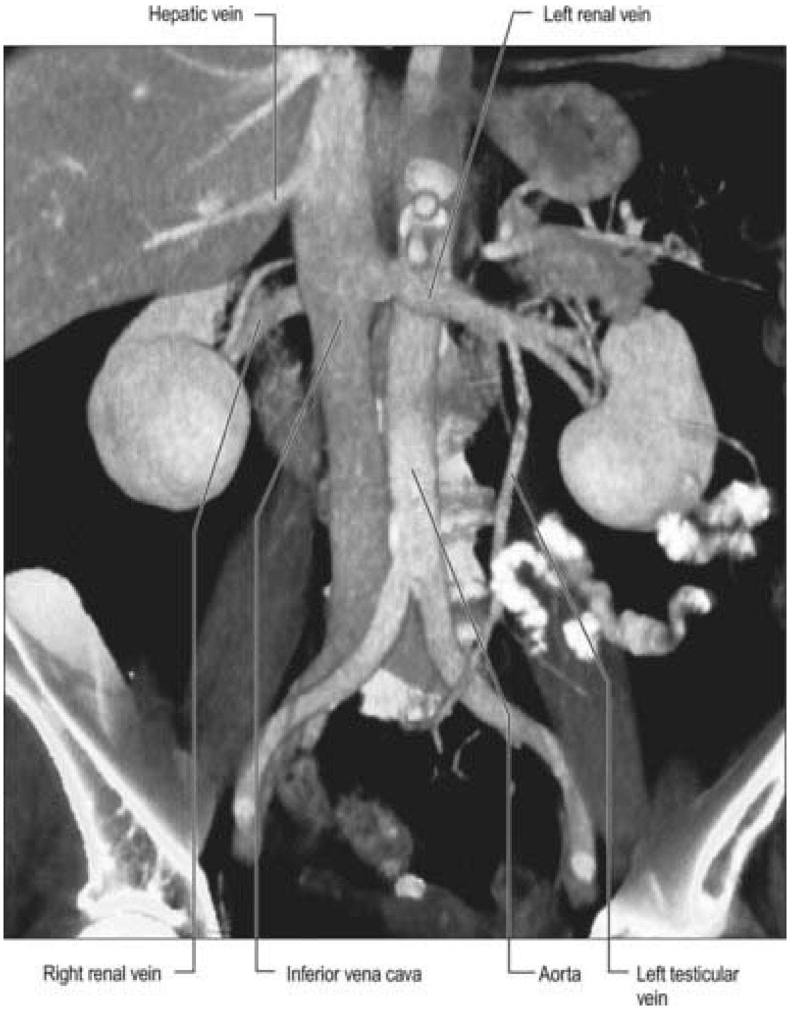
Each lumbar artery has a dorsal branch, which passes backwards between the adjacent transverse vertebral processes to supply the dorsal muscles of the back, the joints and skin of the back. This branch also has a spinal branch which enters the vertebral canal to supply its contents and adjacent vertebra, anastomosing with the arteries above and below it and across the midline (see Fig. 43.9). The spinal branch of the first lumbar artery supplies the terminal part of the spinal cord proper and the remainder supply the cauda equina, meninges and vertebral canal. Occlusion of all or most of these arteries by dissection or aneurysm of the abdominal aorta may cause ischaemia of the cauda equina, producing the so-called ‘cauda equina syndrome’. This is rare, however, even after infrarenal aortic graft surgery, because of the relatively good collateral circulation of the spinal cord arteries from the descending thoracic aorta. Branches of the lumbar arteries and their dorsal branches supply the adjacent muscles, fasciae, bones, haemopoeitic marrow, ligaments and joints of the vertebral column.

Median sacral artery

The median sacral artery is a small branch that arises from the posterior aspect of the aorta a little above its bifurcation. It descends in the midline, anterior to the fourth and fifth lumbar vertebrae, sacrum and coccyx, and ends in the coccygeal body. At the level of the fifth lumbar vertebra, it is crossed by the left common iliac vein and often gives off a small lumbar artery (arteria lumbalis ima), small branches of which reach the anorectum via the anococcygeal ligament. Anterior to the fifth lumbar vertebra the median sacral artery anastomoses with a lumbar branch of the iliolumbar artery. Anterior to the sacrum it anastomoses with the lateral sacral arteries and sends branches into the anterior sacral foramina.

INFERIOR VENA CAVA

The inferior vena cava conveys blood to the right atrium from all structures below the diaphragm (Fig. 62.10). The majority of its course is within the abdomen, but a small section lies within the fibrous pericardium in the thorax.



Hepatic vein
Left renal vein
Right renal vein
Inferior vena cava
Aorta
Left testicular vein

Fig. 62.10 Multislice computed tomography three-dimensional surface-shaded angiogram of the abdominal aorta and inferior vena cava.

The inferior vena cava is formed by the junction of the common iliac veins anterior to the fifth lumbar vertebral body, a little to its right. It ascends anterior to the vertebral column, to the right of the aorta, and is contained in a deep groove on the posterior surface of the liver, or sometimes in a tunnel completed by a band of liver tissue. It next crosses the tendinous part of the diaphragm between its median and right ‘leaves’, inclines slightly anteromedially and passes through the fibrous pericardium and a posterior inflexion of the serous pericardium to open into the inferoposterior part of the right atrium. The abdominal portion of the inferior vena cava is devoid of valves.

Relations of the abdominal part of the inferior vena cava

Anteriorly, the inferior vena cava is related to the right common iliac artery at its origin. It is crossed obliquely by the root of the mesentery and its contained vessels and nerves, and by the right gonadal artery. It lies behind the peritoneum of the posterior abdominal wall and the third part of the duodenum, and ascends behind the head of the pancreas and then the first part of the duodenum, separated from these structures by the common bile duct and portal vein. Above the duodenum it is again covered by the peritoneum of the posterior abdominal wall, which forms the posterior wall of the epiploic foramen and which separates the inferior vena cava from the right free border of the lesser omentum and its contents. Above this it is intimately related to the liver anteriorly.

The lower three lumbar vertebral bodies and their intervertebral discs, the anterior longitudinal ligament, right psoas major, sympathetic trunk and third and fourth lumbar arteries, are all posterior to the inferior vena cava. Superior to these structures, the inferior vena cava is related posteriorly to the right crus of the diaphragm, the medial part of the right suprarenal gland, the right coeliac ganglion and the right renal, middle suprarenal and inferior phrenic arteries.

The right ureter, the second part of the duodenum, medial border of the right kidney and the right lobe of the liver are all lateral to the right side of the inferior vena cava. The aorta, the right crus of the diaphragm and the caudate lobe of the liver are all lateral to the left side.

Numerous anomalies may occur in the anatomy of the inferior vena cava, mostly related to its complex formation. It is sometimes replaced, below the level of the renal veins, by two more or less symmetric vessels (Fig. 62.11), often associated with the failure of interconnection between the common iliac veins, and persistence on the left of a longitudinal channel (usually the supracardinal or subcardinal vein) that normally disappears in early fetal life. In complete visceral transposition, the inferior vena cava lies to the left of the aorta.

Tributaries

The abdominal inferior vena cava usually receives the common iliac veins at its origin and the lumbar, right gonadal, renal, right suprarenal, inferior phrenic and hepatic veins during its course (Figs 62.6, 62.12).

Lumbar veins

Four pairs of lumbar veins collect blood by dorsal tributaries from the lumbar muscles and skin. These branches anastomose with tributaries of the lumbar origin of the azygos and hemiazygos veins. The abdominal tributaries to the lumbar veins drain blood from the posterior, lateral and anterior abdominal walls, including the parietal peritoneum. Anteriorly, the abdominal tributaries anastomose with branches of the inferior and superior epigastric veins. These anastomoses provide routes of continued venous drainage from the pelvis and lower limb to the heart in the event of inferior vena caval obstruction. The abdominal tributaries drain into the superior epigastric veins and hence via the internal thoracic veins to the superior vena cava, whereas the dorsal tributaries carry blood into the azygos and hemiazygos system and hence into the superior vena cava. Near the vertebral column, the lumbar veins drain the vertebral plexuses and are connected by the ascending lumbar vein, which is a vessel running longitudinally anterior to the roots of the transverse processes of the lumbar vertebrae. The third and fourth lumbar veins are fairly consistent in their course, and usually pass forward on the sides of the corresponding vertebral bodies to enter the posterior aspect of the inferior vena cava. The left lumbar veins pass behind the abdominal aorta and are therefore longer. First and second lumbar veins are much more variable; they may drain into the inferior vena cava, ascending lumbar vein, or lumbar azygos veins, and are often connected to each other. The first lumbar vein does not usually enter the inferior vena cava directly, but either turns down to join the second lumbar vein or, less commonly, may drain directly into the ascending lumbar vein or pass forward over the first lumbar vertebral body to join the lumbar azygos vein. The second lumbar vein may join the inferior vena cava at or near the level of the renal veins, or, less commonly, join the third lumbar or ascending lumbar vein.

Ascending lumbar vein

The ascending lumbar vein connects the common iliac, iliolumbar and lumbar veins. It lies between psoas major and the roots of the lumbar transverse processes. There is considerable variability in the course of this vein and the related lumbar azygos and first lumbar veins. Superiorly, it commonly joins the subcostal vein to form the azygos vein on the right and the hemiazygos on the left. These veins run forward over the 12th thoracic vertebral body, and pass deep to the crura of the diaphragm and into the thorax. The ascending lumbar vein is usually joined by a small vessel from the back of the inferior vena cava or left renal vein on the left. This little vein represents the azygos line and is referred to as the lumbar azygos vein. Sometimes the ascending lumbar vein ends in the first lumbar vein, which then skirts the first lumbar vertebra with the first lumbar artery, to join the lumbar azygos vein. In this circumstance the subcostal veins join the azygos vein on the right and the hemiazygos vein on the left.

Gonadal veins

Only the right gonadal vein joins the inferior vena cava directly. It opens into its right anterolateral aspect at an acute angle just inferior to the level of the left renal vein. It is often double all the way to the level of entry into the inferior vena cava.

Renal veins

The renal veins are large calibre vessels, which lie anterior to the renal arteries and open into the inferior vena cava almost at right angles (Fig. 62.10). The left is three times longer than the right in length (7.5 cm and 2.5 cm, respectively). The left vein lies on the posterior abdominal wall posterior to the splenic vein and body of the pancreas. Close to its opening into the inferior vena cava, it lies anterior to the aorta with the superior mesenteric artery just above it. The right renal vein lies posterior to the second part of the duodenum and sometimes the lateral part of the head of the pancreas.

Suprarenal vein

The right suprarenal vein drains directly into the inferior vena cava at the level of the 12th thoracic vertebra.

Inferior phrenic veins

The inferior phrenic veins run on the inferior surface of the central tendon of the diaphragm. They drain into the posterolateral aspect of the inferior vena cava around the level of the tenth thoracic vertebra. The left vein tends to drain at a slightly higher level than the right, and runs above the level of the oesophageal opening in the diaphragm. It may be double, with a branch draining into the left renal or suprarenal vein.

Collaterals in inferior vena caval occlusion

Occlusion of the inferior vena cava may follow thrombosis resulting from hypercoagulable conditions, or embolism from lower limb or pelvic thromboses. Collateral venous circulation is established through a wide range of anastomoses between branches that drain ultimately to the superior vena cava. The lumbar veins connect to branches of the superior and inferior epigastric, circumflex iliac, lateral thoracic, subcostal and posterior intercostal veins. They also anastomose with tributaries of the azygos, hemiazygos and lumbar azygos veins. The interconnecting vertebral venous plexuses provide an additional route of collateral circulation between the vena cavae.

Inferior vena caval filters

Recurrent embolization of clot from the pelvic or lower limbs veins may be a serious threat to life. In an effort to prevent life-threatening pulmonary embolism, a fenestrated filter may be placed within the inferior vena cava in an effort to trap the clot. These are most commonly inserted by radiological guidance via the internal jugular vein and superior vena cava and placed at a level below the origin of the renal veins. Progressive occlusion of the filter by clot may lead to symptoms of vena caval obstruction. Rarely, damage to the medial wall of the vena cava from the retaining hooks of the filter may lead to the development of an aorto-caval fistula as a result of the close proximity of the aorta at this level.

LYMPHATIC DRAINAGE

The lymphatic drainage of the muscles, deep tissues and integument of the posterior abdominal wall is broadly divided into four regions. The small upper left and upper right regions drain to the lateral aortic nodes and the ipsilateral axillary lymph nodes. The larger lower left and lower right portions drain to the lateral and retro-aortic lymph nodes, although some drainage also occurs to the left and right superficial inguinal nodes.

The lymphatic drainage of the abdominal viscera occurs almost exclusively through the cisterna chyli and the thoracic duct. Some lymphatic drainage may occur across the diaphragm from the bare area of the liver and the uppermost retroperitoneal tissues, but this is probably of little clinical consequence other than during obstruction of the thoracic duct. The lymph nodes of the retroperitoneum lie around the abdominal aorta and form pre-aortic, lateral aortic and retro-aortic groups (Fig. 62.13). Collectively, they are referred to as the para-aortic lymph nodes and clinically it is difficult to distinguish between them, either at operation or on cross-sectional imaging.

Cisterna chyli and abdominal lymph trunks

The abdominal origin of the thoracic duct lies to the right of the midline at the level of the lower border of the 12th thoracic vertebral body or the thoracolumbar intervertebral disc. It receives all the lymph delivered by the four main abdominal lymph trunks, which converge to an elongated arrangement of channels, referred to as the abdominal confluence of lymph trunks. The confluence may be a simple duct-like structure or be duplicated, triplicated or plexiform. When it is wider than the thoracic duct, its interior is sometimes irregular and bilocular or trilocular, and it may surround intercalated lymph nodes. Occasionally the confluence is a simple, fusiform, saccular dilatation; the widely used name ‘cisterna chyli’ best describes these simpler forms.

The abdominal confluence of lymph trunks extends from the beginning of the thoracic duct, vertically downwards for 5–7 cm, and lies anterolateral to the right of the first and second lumbar vertebral bodies and their intervening discs. It lies immediately to the right of the abdominal aorta. Along its length it lies between the territories containing the upper right lateral aortic lymph nodes and right-sided members of the coeliac and superior mesenteric pre-aortic groups, branches from which may drain directly into the various trunks. The upper two right lumbar arteries and the right lumbar azygos vein are between the confluence and the vertebral column. The medial edge of the right crus of the diaphragm lies anterior to the abdominal confluence of lymph trunks. The confluence receives the right and left lumbar and intestinal lymph trunks, although rarely these may drain directly into the thoracic duct.

The lumbar lymph trunks are formed by vessels draining from the lateral aortic nodes. Thus, either directly, or after traversing intermediary groups, the trunks carry lymph from the lower limbs, the full thickness of the pelvic, perineal and infra-umbilical abdominal walls, the deep tissues of most of the supra-umbilical abdominal walls, most of the pelvic viscera, gonads, kidneys and suprarenal glands. The intestinal lymph trunks receive vessels draining from coeliac nodes and, via these nodes, the superior and inferior mesenteric nodes, which are collectively the pre-aortic nodes. Either directly or via intermediary groups, they drain the entire abdominal gastrointestinal tract down to the anus.

The intimate relationship of the cisterna chyli and abdominal lymph trunks to the abdominal aorta may lead to problems after aortic surgery, particularly dissections carried out around the aorta above the level of the coeliac axis. The large calibre of the trunks, coupled with the volume of lymph flowing through them, means that they do not readily self-seal after injury, and this may lead to problematic recurrent chylous (lymphatic) ascites.

The thoracic duct leaves the superior end of the cisterna chyli or the abdominal confluence and immediately passes through the aortic aperture of the diaphragm posterolateral to the aorta.

Pre-aortic group

The pre-aortic groups tend to lie around the origins of the anterior (visceral) arteries and receive lymph from the gastrointestinal tract and its accessory structures (liver, spleen and pancreas) from the abdominal oesophagus to the level of the anus. They give rise to lymphatic vessels, which drain upwards to form the intestinal trunks that enter the abdominal confluence of lymph trunks. They are divisible into coeliac, superior mesenteric and inferior mesenteric groups, being near the origins of these arteries.

Coeliac nodes

The coeliac nodes lie anterior to the abdominal aorta around the origin of the coeliac artery. They are a terminal group and receive lymph draining from the regional lymph nodes around the branches of the coeliac artery (left gastric, hepatic and pancreaticosplenic nodes) and from the lower pre-aortic groups (the superior mesenteric and inferior mesenteric). The coeliac nodes give rise to right and left intestinal lymph trunks.

Gastric

There are numerous gastric lymph node groups. They drain the stomach, upper duodenum, abdominal oesophagus and the greater omentum into the coeliac group.

Hepatic

The hepatic nodes extend in the lesser omentum along the hepatic arteries and bile duct. They vary in number and site, but almost always occur at the junction of the cystic and common hepatic ducts (the cystic node), alongside the upper common bile duct and in the anterior border of the epiploic foramen. Hepatic nodes drain the majority of the liver, gallbladder and bile ducts, but also receive drainage from some parts of the stomach, duodenum and pancreas. They drain into the coeliac nodes and thence to the intestinal trunks.

Pancreaticosplenic

The pancreaticosplenic nodes drain the spleen, pancreas and part of the stomach into the coeliac nodes.

Superior mesenteric and inferior mesenteric nodes

The superior and inferior mesenteric nodes lie anterior to the aorta near the origins of their respective arteries. The superior and inferior mesenteric nodes are preterminal groups for the alimentary canal from the duodenojejunal flexure to the upper anal canal. They collect from outlying groups, including the mesenteric, ileocolic, colonic and pararectal nodes and drain into the coeliac nodes.

Lateral aortic group

The lateral aortic nodes lie on either side of the abdominal aorta anterior to the medial margins of psoas major, diaphragmatic crura and sympathetic trunks. On the right, some nodes lie lateral and anterior to the inferior vena cava near the end of the right renal vein. Nodes rarely lie between the aorta and inferior vena cava where they are closely related. The lateral aortic nodes drain the viscera and other structures supplied by the lateral and dorsal aortic branches. The upper lateral groups receive the lymph drainage directly from the suprarenal glands, kidneys, ureters, gonads, uterine tubes and upper uterus. They also receive lymph directly from the deeper tissues of the posterior abdominal wall. Lymphatics from the pelvis, most of the pelvic viscera, the perineum and the anterolateral abdominal wall pass first to regional nodes largely related to the iliac arteries and their branches. These include the common iliac, external iliac, internal iliac and circumflex iliac nodes, in addition to the inferior epigastric and sacral nodes. Lymph from the lower limbs passes through the pelvic lymph nodes via the iliac groups.

The lateral aortic group drains into the two lumbar lymph trunks, one on each side, which terminate in the confluence of lymph trunks. A few vessels may pass to the pre-aortic and retro-aortic nodes and others cross the midline to flow into the contralateral nodes, forming a loose plexus.

Retro-aortic group

The retro-aortic group is the smallest of all the para-aortic lymph nodes and has no particular areas of drainage, although it may receive some lymph directly from the paraspinal posterior abdominal wall. Retro-aortic nodes are effectively peripheral nodes of the lateral aortic groups and provide interconnections between surrounding groups.

INNERVATION

The posterior abdominal wall contains the origin of the lumbar plexus and numerous autonomic plexuses and ganglia, which lie close to the abdominal aorta and its branches (Fig. 62.14).

The lumbar ventral rami descend laterally into psoas major, and increase in size from first to last. The first three and most of the fourth form the lumbar plexus; the smaller moiety of the fourth joins the fifth as a lumbosacral trunk, which joins the sacral plexus. The fourth ramus is often termed the nervus furcalis, because it is divided between the two plexuses. Occasionally the third ramus is the nervus furcalis, and both third and fourth ventral rami may be furcal nerves, in which case the plexus is termed prefixed. More frequently, the fifth ventral ramus is furcal, and the plexus is then termed postfixed. These variations modify the sacral plexus.

The first and second, and sometimes the third, lumbar ventral rami are each connected with the lumbar sympathetic trunk by a white ramus communicans. All lumbar ventral rami are joined near their origins by long slender grey rami communicantes from the four lumbar sympathetic ganglia. The rami communicantes accompany the lumbar arteries round the sides of the vertebral bodies, behind psoas major. Their arrangement is irregular: one ganglion may give rami to two lumbar ventral rami, or one lumbar ventral ramus may receive rami from two ganglia, or grey rami often leave the sympathetic trunk between ganglia.

LUMBAR PLEXUS

The lumbar plexus lies within the substance of the posterior part of psoas major, anterior to the transverse processes of the lumbar vertebrae and in ‘line’ with the intervertebral foramina (Fig. 62.15). It is formed by the first three, and most of the fourth, lumbar ventral rami, with a contribution from the 12th thoracic ventral ramus. Although there may be minor variations, the most common arrangement of the plexus is described here.

Fig. 62.15 The lumbar plexus and its branches.

The first lumbar ventral ramus, joined by a branch from the 12th thoracic ventral ramus, bifurcates, and the upper and larger part divides again into the iliohypogastric and ilioinguinal nerves. The smaller lower part unites with a branch from the second lumbar ventral ramus to form the genitofemoral nerve. The remainder of the second, third, and part of the fourth, lumbar ventral rami join the plexus and divide into ventral and dorsal branches. Ventral branches of the second to fourth rami join to form the obturator nerve. The main dorsal branches of the second to fourth rami join to form the femoral nerve. Small branches from the dorsal branches of the second and third rami join to form the lateral femoral cutaneous nerve. The accessory obturator nerve, when it exists, arises from the third and fourth ventral branches. The lumbar plexus is supplied by branches from the lumbar vessels which supply psoas major.

The branches of the lumbar plexus are:

Muscular	T12, L1–4
Iliohypogastric	L1
Ilioinguinal	L1
Genitofemoral	L1, L2
Lateral femoral cutaneous	L2, L3
Femoral	L2–4 dorsal divisions
Obturator	L2–4 ventral divisions
Accessory obturator	L2, L3

Division of constituent ventral rami into ventral and dorsal branches is not as clear in the lumbar and lumbosacral plexuses as it is in the brachial plexus. Anatomically, the obturator and tibial nerves (via the sciatic) arise from ventral divisions, and the femoral and fibular nerves (via the sciatic) from dorsal divisions. Lateral branches of the 12th thoracic and first lumbar ventral rami are drawn into the gluteal skin, but otherwise these nerves are typical. The second lumbar ramus is difficult to interpret. It not only contributes substantially to the femoral and obturator nerves, but also has an anterior terminal branch (the genital branch of the genitofemoral) and a lateral cutaneous branch (lateral femoral cutaneous nerve and the femoral branch of the genitofemoral). Anterior terminal branches of the third to fifth lumbar and first sacral rami are suppressed, but the corresponding parts of the second and third sacral rami supply the skin, etc. of the perineum.

Inflammatory processes may occur in the posterior abdominal wall in the tissues anterior to psoas major, such as retrocaecal appendicitis on the right and diverticular abscess on the left. This may cause irritation of one or more of the branches of the lumbar plexus and lead to presenting symptoms of pain or dysaesthesia in the distribution of the affected nerves such as in the thigh, hip or buttock skin.

Muscular branches

Small branches from all five lumbar roots.

Iliohypogastric nerve

Distribution

The iliohypogastric nerve originates from the L1 ventral ramus. It emerges from the upper lateral border of psoas major, crosses obliquely behind the lower renal pole and in front of quadratus lumborum. Above the iliac crest, it enters the posterior part of transversus abdominis. Between transversus abdominis and internal oblique, it divides into lateral and anterior cutaneous branches, and also supplies both muscles. The lateral cutaneous branch runs through internal and external oblique above the iliac crest, a little behind the iliac branch of the 12th thoracic nerve, and is distributed to the posterolateral gluteal skin. The anterior cutaneous branch runs between and supplies internal oblique and transversus abdominis. It runs through internal oblique approximately 2 cm medial to the anterior superior iliac spine, and through the external oblique aponeurosis approximately 3 cm above the superficial inguinal ring, and is then distributed to the suprapubic skin. The iliohypogastric nerve connects with the subcostal and ilioinguinal nerves (see Fig. 61.4). The nerve is occasionally injured during an oblique surgical approach to the appendix, but there is rarely any detectable sensory loss because the suprapubic skin is innervated from several sources. Division of the iliohypogastric nerve above the anterior superior iliac spine may weaken the posterior wall of the inguinal canal and predispose to formation of a direct hernia.

Motor

The iliohypogastric nerve supplies a small motor contribution to transversus abdominis and internal oblique, including the conjoint tendon.

Sensory

The iliohypogastric nerve supplies sensory fibres to transversus abdominis, internal oblique and external oblique, and innervates the posterolateral gluteal and suprapubic skin.

Ilioinguinal nerve

Distribution

The ilioinguinal nerve originates from the L1 ventral ramus. It is usually smaller than the iliohypogastric nerve and arises with it from the first lumbar ventral ramus, to emerge from the lateral border of psoas major, with or just inferior to the iliohypogastric nerve. It passes obliquely across quadratus lumborum and the upper part of iliacus and enters transversus abdominis near the anterior end of the iliac crest, where it sometimes connects with the iliohypogastric nerve. At this point it can readily be affected by a relatively small volume of local anaesthetic to help anaesthetize the inguinal canal for surgery. It pierces internal oblique a little lower down, supplies it and then traverses the inguinal canal below the spermatic cord. It emerges with the cord from the superficial inguinal ring and supplies the proximal medial skin of the thigh and the skin over the root of the penis and upper part of the scrotum in males, or the skin covering the mons pubis and the adjoining labium majus in females. The ilioinguinal and iliohypogastric nerves are reciprocal in size. The ilioinguinal is occasionally very small and ends by joining the iliohypogastric, a branch of which then takes its place. Occasionally, the ilioinguinal nerve is completely absent, in which case the iliohypogastric nerve supplies its territory. The nerve may be injured during inguinal surgery, particularly for hernia, which produces paraesthesia over the skin of the genitalia. Entrapment of the nerve during surgery may cause troublesome recurrent pain in this distribution.

Motor

The ilioinguinal nerve supplies motor nerves to transversus abdominis and internal oblique.

Sensory

The ilioinguinal nerve supplies sensory fibres to transversus abdominis and internal oblique. It innervates the medial skin of the thigh and the skin over the root of the penis and upper part of the scrotum in males or the skin covering the mons pubis and the adjoining labium majus in females.

Genitofemoral nerve

Distribution

The genitofemoral nerve originates from the L1 and L2 ventral rami and is formed within the substance of psoas major. It descends obliquely forwards through the muscle to emerge on its abdominal surface near the medial border, opposite the third or fourth lumbar vertebra. It then descends beneath the peritoneum on psoas major, crosses obliquely behind the ureter and divides above the inguinal ligament into genital and femoral branches; it often divides close to its origin, in which case its branches emerge separately from psoas major. The genital branch crosses the lower part of the external iliac artery, enters the inguinal canal by the deep ring and supplies cremaster and the skin of the scrotum in males. In females, it accompanies the round ligament and ends in the skin of the mons pubis and labium majus. The femoral branch descends lateral to the external iliac artery, and sends a few filaments round it before crossing the deep circumflex iliac artery, passing behind the inguinal ligament and entering the femoral sheath lateral to the femoral artery. It pierces the anterior layer of the femoral sheath and fascia lata and supplies the skin anterior to the upper part of the femoral triangle. It connects with the femoral intermediate cutaneous nerve and supplies the femoral artery. Like the ilioinguinal nerve, the genital branch may be injured during inguinal surgery.

Motor

The genitofemoral nerve innervates cremaster via the genital branch.

Cutaneous

The genitofemoral nerve innervates the skin of the scrotum in males or mons pubis and labium majus in females via the genital branch, and the anteromedial skin of the thigh via the femoral branch.

Femoral nerve

The femoral nerve descends through psoas major and emerges low on its lateral border. It passes between psoas major and iliacus deep to the iliac fascia and runs posterior to the inguinal ligament into the thigh. It gives off branches which supply iliacus and pectineus and sends sensory fibres to the femoral artery. Posterior to the inguinal ligament, it lies lateral to the femoral artery and is separated from it by a part of psoas major. The further course and distribution of the femoral nerve is described in Chapter 80.

Lateral femoral cutaneous nerve of the thigh

The lateral femoral cutaneous nerve of the thigh emerges from the lateral border of psoas major and crosses iliacus obliquely towards the anterior superior iliac spine. It supplies sensory fibres to the parietal peritoneum in the iliac fossa. The right nerve passes posterolateral to the caecum, separated from it by the iliac fascia and peritoneum. The left nerve passes behind the lower part of the descending colon. Both nerves pass behind or through the inguinal ligament approximately 1 cm medial to the anterior superior iliac spine and anterior to, or through, sartorius into the thigh. The further course and distribution of the lateral femoral cutaneous nerve is described in Chapter 80.

Obturator nerve

The obturator nerve descends within the substance of psoas major to emerge from its medial border at the level of the pelvic brim. It passes posterior to the common iliac vessels and lateral to the internal iliac vessels. It then descends on the lateral wall of the pelvis attached to the fascia over obturator internus and lies anterosuperior to the obturator vessels before running into the obturator foramen to enter the thigh. It has no branches in the abdomen or pelvis. The further course and distribution of the obturator nerve is described in Chapter 80.

Accessory obturator nerve

When present, the accessory obturator nerve emerges from the medial border of psoas major and runs along this border over the posterior surface of the superior pubic ramus posterior to pectineus. It gives off branches here to supply pectineus and the hip joint, and it may join with the main obturator nerve.

LUMBOSACRAL PLEXUS

The lumbosacral plexus provides the nerve supply to the pelvis and lower limb, in addition to part of the autonomic supply to the pelvic viscera. It gives origin to the sciatic, inferior gluteal, superior gluteal and pudendal nerves and the nerves to quadratus femoris, obturator internus and the posterior cutaneous nerve of the thigh. The further course and distribution of these nerves is described in Chapter 80.

LUMBAR SYMPATHETIC SYSTEM

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia lying on the extraperitoneal connective tissue anterior to the vertebral column and along the medial margin of psoas major. Superiorly, it is continuous with the thoracic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac artery and is continuous with the pelvic sympathetic trunk. On the right side, it lies posterior to inferior vena cava, and on the left it is posterior to the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels, but may pass behind some lumbar veins.

LUMBAR PARASYMPATHETIC SYSTEM

The parasympathetic supply to the abdominal viscera is provided by the vagus nerve to the coeliac and superior mesenteric plexuses, and from the pelvic splanchnic nerves to the inferior mesenteric, superior hypogastric and inferior hypogastric plexuses.

PARA-AORTIC BODIES

The para-aortic bodies are condensations of chromaffin tissue that are found in close relation to the aortic autonomic plexuses and lumbar sympathetic chains. They are largest in the fetus, become relatively smaller in childhood and have largely disappeared by adulthood. They are most commonly found as a pair of bodies lying anterolateral to the aorta in the region of the intermesenteric, inferior mesenteric and superior hypogastric plexuses. They may lie as high as the coeliac plexus, as low as the inferior hypogastric plexus in the pelvis, or may be closely applied to the sympathetic ganglia of the lumbar chain. Scattered cells that persist into adulthood may, rarely, be the sites of development of tumours of the chromaffin tissue (phaeochromocytoma), although these are much more commonly found arising from the cells of the suprarenal medulla. The wide variation in site of persistent para-aortic body tissue accounts for the range of locations of such tumours.

CHAPTER 63

True pelvis, pelvic floor and perineum

TRUE PELVIS AND PELVIC FLOOR

The true pelvis is a bowl-shaped structure formed from the sacrum, pubis, ilium, ischium, the ligaments which interconnect these bones and the muscles which line their inner surfaces. The true pelvis is considered to start at the level of the plane passing through the promontory of the sacrum, the arcuate line on the ilium, the iliopectineal line and the posterior surface of the pubic crest. This plane, or 'inlet' lies at an angle of between 35 and 50° up from the horizontal and above this the bony structures are sometimes referred to as the false pelvis. They form part of the walls of the lower abdomen. The floor or 'outlet' of the true pelvis is formed by the muscles of levator ani. Although the floor is gutter shaped, it generally lies in a plane between 5 and 15° up from the horizontal. This difference between the planes of the inlet and outlet is the reason why the true pelvis is said to have an axis (lying perpendicular to the plane of both inlet and outlet) which progressively changes through the pelvis from above downwards. The details of the topography of the bony and ligamentous pelvis are considered fully on page 1358.

MUSCLES AND FASCIAE OF THE PELVIS

Pelvic muscles

The muscles arising within the pelvis form two groups. Piriformis and obturator internus, although forming part of the walls of the pelvis, are considered as primarily muscles of the lower limb (Fig. 63.1). Levator ani and coccygeus form the pelvic diaphragm and delineate the lower limit of the true pelvis (Fig. 63.2). The fasciae investing the muscles are continuous with visceral pelvic fascia above, perineal fascia below and obturator fascia laterally.

Piriformis

The complete description of piriformis is in Chapter 80.

Piriformis (see p. 1371) forms part of the posterolateral wall of the true pelvis and is attached to the anterior surface of the sacrum, the gluteal surface of the ilium near the posterior inferior iliac spine, the capsule of the adjacent sacroiliac joint and sometimes to the upper part of the pelvic surface of the sacrotuberous ligament. It passes out of the pelvis through the greater sciatic foramen. Within the pelvis, the anterior surface of piriformis is related to the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels. The posterior surface lies against the sacrum.

Obturator internus

Obturator internus (see p. 1371) and the fascia over its upper inner (pelvic) surface form part of the anterolateral wall of the true pelvis. It is attached to the structures surrounding the obturator foramen, the inferior ramus of the pubis, the ischial ramus, the pelvic surface of the hip bone below and behind the pelvic brim, and the upper part of the greater sciatic foramen. It also attaches to the medial part of the pelvic surface of the obturator membrane. The muscle is covered by a thick fascial layer and the fibres themselves cannot be seen directly from within the pelvis. This fascia gives attachment to some of the fibres of levator ani and thus only the upper portion of the muscle lies lateral to the contents of the true pelvis, whilst the lower portion forms part of the boundaries of the ischio-anal fossa. In the male, the upper portion lies lateral to the bladder, the obturator and vesical vessels, and the obturator nerve. In the female, the attachments of the broad ligament of the uterus, the ovarian end of the uterine tubes, and the uterine vessels, also lie medial to obturator internus and its fascia.

Levator ani (ischiococcygeus, iliococcygeus, pubococcygeus)

Levator ani is a broad muscular sheet of variable thickness which is attached to the internal surface of the true pelvis and forms a large portion of the pelvic floor (Fig. 63.3). The muscle is subdivided into named portions according to their attachments and the pelvic viscera to which they are related. These parts are often referred to as separate muscles, but the boundaries between each part cannot be easily distinguished and they perform many similar physiological functions. The separate parts are referred to as ischiococcygeus, iliococcygeus and pubococcygeus. Pubococcygeus is often subdivided into separate parts according to the pelvic viscera to which they relate (puboperinealis, puboprostaticus or pubovaginalis, puboanalis, puborectalis). Levator ani arises from each side of the walls of the pelvis along the condensation of the obturator fascia (the tendinous arch of levator ani; see below). Fibres from ischiococcygeus attach to the sacrum and coccyx but the remaining parts of the muscle converge in the midline. The fibres of iliococcygeus join by a partly fibrous intersection and form a raphe posterior to the anorectal junction. Closer to the anorectal junction and elsewhere in the pelvic floor, the fibres are more nearly continuous with those of the opposite side and the muscle forms a sling (puborectalis and pubovaginalis or pubourethralis).

Attachments

The attachments for the ischiococcygeus, iliococcygeus and pubococcygeus parts are as follows.

Ischiococcygeus

The ischiococcygeal part may be referred to as a separate muscle, sometimes named coccygeus. It lies as the most posterosuperior portion of levator ani and arises as a triangular musculotendinous sheet with its apex attached to the pelvic surface and tip of the ischial spine. The base of the muscle is attached to the lateral margins of the coccyx and the fifth sacral segment. Ischiococcygeus is rarely absent, but may be nearly completely tendinous rather than muscular. It lies on the pelvic aspect of the sacrospinous ligament and may be fused with it, particularly if it is mostly tendinous. The sacrospinous ligament may represent a degenerate part or an aponeurosis of the muscle since the muscle and ligament are coextensive.

Iliococcygeus

The iliococcygeal part is attached to the inner surface of the ischial spine below and anterior to the attachment of ischiococcygeus and to the tendinous arch as far forward as the obturator canal (Fig. 63.2). The most posterior fibres are attached to the tip of the sacrum and coccyx but most join with fibres from the opposite side to form a raphe. This raphe is effectively continuous with the fibroelastic anococcygeal ligament, which is closely applied to its inferior surface and some muscle fibres may attach into the ligament. The raphe provides a strong attachment for the pelvic floor posteriorly and must be divided to allow wide excisions of the anorectal canal during abdominoperineal excisions for malignancy. An accessory slip may arise from the most posterior part and is sometimes referred to as iliosacralis.

Pubococcygeus

The pubococcygeal part is attached to the back of the body of the pubis and passes back almost horizontally. The most medial fibres run directly lateral to the urethra and its sphincter as it passes through the pelvic floor; here the muscle is correctly called the puboperinealis, although due to its close relationship to the upper half of the urethra in both sexes it is often referred to as pubourethralis. The muscle fibres from both sides form part of the urethral sphincter complex together with the intrinsic striated and smooth musculature of the urethra; fibres decussate across the midline directly behind the urethra. In males some of these fibres lie lateral and inferior to the prostate and are referred to as puboprostaticus (levator prostatae). In females, some fibres form the pubourethralis, others run further back to form a sling around the posterior wall of the vagina where they are referred to as pubovaginalis. In both sexes, fibres from this part of pubococcygeus attach to the perineal body; a few elements also attach to the anorectal junction. Some of these fibres, sometimes called puboanalis, decussate and blend with the longitudinal rectal muscle and fascial elements to contribute to the conjoint longitudinal coat of the anal canal. Behind the rectum, some fibres of pubococcygeus form a tendinous intersection as part of the levator raphe, and a thick muscular sling, puborectalis, wraps around the anorectal junction. Some fibres blend with those of the external anal sphincter. Pubourethralis, pubovaginalis/puboprostaticus and puboanalis are sometimes collectively referred to as ‘pubovisceralis’.

Relations

The superior, pelvic surface of levator ani is separated only by fascia (superior pelvic diaphragmatic, visceral and extraperitoneal) from the urinary bladder, prostate or uterus and vagina, rectum and peritoneum. Its inferior, perineal, surface forms the medial wall of the ischio-anal fossa and the superior wall of the anterior recess of the fossa, both being covered by inferior pelvic diaphragmatic fascia. The posterior border is separated from the coccyx by areolar tissue. The medial borders of the two levator muscles are separated by the visceral outlet, through which pass the urethra, vagina, and anorectum.

Vascular supply

Levator ani is supplied by branches of the inferior gluteal, inferior vesical and pudendal arteries.

Innervation

Fibres which originate mainly in the second, third and fourth sacral spinal segments reach levator ani from below and above by a variety of routes (Wendell-Smith & Wilson 1991). Most commonly, pubococcygeus is supplied by second and third sacral spinal segments via the pudendal nerve, and ischiococcygeus and iliococcygeus by direct branches of the sacral plexus from the third and fourth sacral spinal segments.

Actions

Pubococcygeus is a lateral compressor of the various visceral canals which cross the pelvic floor. Puborectalis also reinforces the external anal sphincter, helps to create the anorectal angle, and reduces the anteroposterior dimension of the ano-urogenital hiatus. Iliococcygeus and, to a lesser extent, the less muscular ischiococcygeus, assist puborectalis in contributing to anorectal and urinary continence.

Levator ani must relax appropriately to permit expulsion of urine and particularly faeces, and it contracts with abdominal muscles and the abdominothoracic diaphragm to raise intra-abdominal pressure. It forms much of the basin-shaped muscular pelvic diaphragm, which supports the pelvic viscera. Like the abdominothoracic diaphragm, but unlike abdominal muscles, levator ani is also active in the inspiratory phase of quiet respiration. In the pregnant female, the shape of the pelvic floor may help to direct the fetal head into the anteroposterior diameter of the pelvic outlet.

Pelvic fasciae

The pelvic fasciae may be conveniently divided into the parietal pelvic fascia, which mainly forms the coverings of the pelvic muscles, and the visceral pelvic fascia, which forms the coverings of the pelvic viscera and their vessels and nerves (Fig. 63.4).

The parietal pelvic fascia is shown in black, the mesorectal fascia in brown, the fascial boundaries of the deep perineal space/pouch in green, the peritoneum in blue, the deep abdominal fascia in purple and the subcutaneous abdominal and perineal fascia in red. The visceral perietal fasciae have been omitted for clarity.

Parietal pelvic fascia

The parietal pelvic fascia consists of the obturator fascia, the fasciae over piriformis, and over levator ani (the pelvic diaphragm), and the presacral fascia.

Obturator fascia

The parietal pelvic fascia on the pelvic (medial) surface of obturator internus is well differentiated. Although in humans it is derived from the degenerate upper portion of the attachment of levator ani, it is usually referred to as the obturator fascia. Above, it is connected to the posterior part of the arcuate line of the ilium, and is continuous with iliac fascia. Anterior to this, as it follows the line of origin of obturator internus, it is gradually separated from the attachment of the iliac fascia and a portion of the periosteum of the ilium and pubis spans between them. It arches below the obturator vessels and nerve, investing the obturator canal, and is attached anteriorly to the back of the pubis. Behind the obturator canal, the fascia is markedly aponeurotic and gives a firm attachment to levator ani, usually called the tendinous arch of levator ani (arcus tendineus musculi levatoris ani) (see Figs 63.3, 63.13, 63.14). Below the attachment of levator ani, the fascia is thin and is effectively composed only of the epimysium of the muscle and overlying connective tissue; posteriorly it forms part of the lateral wall of the ischio-anal fossa in the perineum, and anteriorly it merges with the fasciae of the muscles of the deep perineal space (see Fig. 63.14), which is continuous with the ischio-anal fossa. The obturator fascia is continuous with the pelvic periosteum and thus the fascia over piriformis.

The parietal pelvic fascia is shown in black, fascial boundaries of the deep perineal space/pouch in green, the deep perineal fascia in purple and the superficial perineal fascia in red. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the 'pelvic' aspect of the deep transverse perinei is very thin and does not form a distinct layer as such in places blending with the parietal pelvic fascia over the inferior aspect of levator ani.

Fascia over piriformis

The fascia over the inner aspect of piriformis is very thin, and fuses with the periosteum on the front of the sacrum at the margins of the anterior sacral foramina. It ensheathes the sacral anterior primary rami which emerge from these foramina: the nerves are often described as lying behind the fascia. The internal iliac vessels lie in front of the fascia over piriformis; their branches draw out sheaths of the fascia and extraperitoneal tissue into the gluteal region, above and below piriformis.

Fascia over levator ani (pelvic diaphragm)

The fascia over levator ani covers both of the surfaces of the pelvic diaphragm. On the lower surface, the thin inferior fascia is continuous with the obturator fascia below the tendinous arch of levator ani laterally. It covers the medial wall of the ischio-anal fossa and blends below with fasciae on the urethral sphincter and the external anal sphincter. On the upper surface, the superior fascia of the pelvic diaphragm is markedly thicker than that over the inferior surface. It is attached anteriorly to the back of the body of the pubis, approximately 2 cm above its lower border, and extends laterally across the superior ramus of the pubis, blending with the obturator fascia and continuing along an irregular line to the spine of the ischium. It is continuous posteriorly with the fascia over piriformis and the anterior sacrococcygeal ligament. Medially, the superior fascia of the pelvic diaphragm blends with the visceral pelvic fascia forming part of the endopelvic fascia.

Arcus tendineus fascia pelvis/white line of the parietal pelvic fascia

Low on the superomedial aspect of the upper fascia over levator ani, a thick white band of condensed connective tissue extends from the lower part of the symphysis pubis to the inferior margin of the spine of the ischium (see Figs 63.4, 63.13, 63.14). Although often referred to as the tendinous arch of the pelvic fascia (arcus tendineus fasciae pelvis), it is really the remnant of the degenerate tendon of iliococcygeus in humans and is best referred to as the white line of the parietal pelvic fascia (Smith 1908). It provides attachment for the condensations of visceral pelvic fascia which provide support to the urethra, bladder and vagina in females (see below).

Presacral fascia

The presacral fascia forms a hammock-like structure posterior to the posterior portion of the mesorectal fascia. Laterally it extends to the origin of the fascia over piriformis and the fascia over levator ani (superior pelvic diaphragmatic fascia) with which it blends, and more inferiorly it extends between the white line of the parietal pelvic fascia on either side. Inferiorly, it extends to the anorectal junction, where it fuses with the posterior aspect of the mesorectal fascia and the anococcygeal ligament at the level of the anorectal junction. Superiorly, it can be traced to the origin of the superior hypogastric plexus, where it becomes progressively thinner over the promontory of the sacrum and becomes continuous with the retroperitoneal tissues. The right and left hypogastric nerves and inferior hypogastric plexuses lie on its surface and the presacral veins lie immediately posterior to it. It forms a distinct layer which can be seen both on magnetic resonance images of the pelvis and during surgery. The presacral fascia provides an important landmark because extension of rectal tumours through it significantly reduces the possibility of curative resectional surgery. Dissection in the plane posterior to the fascia may result in bleeding from the presacral veins: because the adventitia of the veins is partly attached to the posterior surface of the fascia, the haemorrhage may be severe (since the veins are unable to contract properly).

Visceral pelvic fascia

The visceral pelvic fascia is formed from condensations of connective tissue which are closely associated with the pelvic viscera to which it relates and with the neurovascular structures supplying or running near those organs. In its most inferior and lateral extent, the visceral pelvic fascia is closely related to, and effectively derived from, the superior fascia over the attachment of levator ani (see below), whereas more superiorly and posteriorly, it is derived from part of the fascia over piriformis. The condensations where these fasciae meet are sometimes collectively referred to as the ‘endopelvic fascia’. Further accounts are given of the paravisceral portions of the visceral pelvic fascia (e.g. parametrium, paracolpium) in the chapters describing the organs to which the fascia relates.

Several different condensations of endopelvic fascia are recognized both at operation and by MRI imaging. They provide important support to the pelvic viscera and play a role in continence in both sexes.

In the female, pubourethral ligaments form from periurethral connective tissue and attach to the white line of the parietal pelvic fascia close to its pubic end. A little more laterally, similar tissue exists which may be termed the urethropelvic ligaments, and which insert into the white line over levator ani. These condensations are effectively continuous with connective tissue which runs from the paravaginal tissue to the white line, and is sometimes referred to as the vaginolevator support or attachment. Since the normal angle of the urethra during standing is nearly 45° to the vertical, these two structures combined can be viewed as providing a ‘hammock-like’ support to the midurethra (DeLancey 1994); some fibres may even decussate across the midline between the urethra and the anterior vaginal wall. The upper portion of the pubourethral ligament blends with the pubovesical and vesicopelvic ligaments (connective tissue around the neck of the urinary bladder), and may contain cholinergically innervated smooth muscle fibres, sometimes referred to as pubovesicalis. In males, pubourethral structures are augmented by the puboprostatic ligament/puboprostaticus. In both sexes, these muscles may have a role in opening the upper urethra and bladder neck during micturition.

There is much less condensation of connective tissue around the rectum, and no similar rectopelvic ligaments exist. The connective tissue over the longitudinal muscles of the rectum is thickened just above the anal hiatus in levator ani and it fuses with the endopelvic fascia and the anococcygeal ligament, sometimes referred to as a rectosacral ligament.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE PELVIS

The true pelvis contains the internal iliac arteries and veins and the lymphatics which drain the majority of the pelvic viscera. The common and external iliac vessels and the lymphatics which drain the lower limb lie along the pelvic brim and in the lower retroperitoneum, but are conveniently discussed together with the vessels of the true pelvis.

Arteries of the pelvis

Common iliac arteries

The abdominal aorta bifurcates into the right and left common iliac arteries anterolateral to the left side of the fourth lumbar vertebral body. These arteries diverge as they descend and divide at the level of the sacroiliac joint into external and internal iliac arteries. The external iliac artery is the principal artery of the lower limb. The internal iliac artery provides the principal supply to the walls and viscera of the pelvis, the perineum and the gluteal region.

Right common iliac artery

The right common iliac artery is approximately 5 cm long. It passes obliquely across part of the fourth and the fifth lumbar vertebral bodies, and is crossed anteriorly by the sympathetic rami to the pelvic plexus and, at its division into internal and external iliac arteries, by the ureter. It is covered by the parietal peritoneum, which separates it from the coils of the small intestine. Posteriorly, it is separated from the fourth and fifth lumbar vertebral bodies and their intervening disc by the right sympathetic trunk, the terminal parts of the common iliac veins and the start of the inferior vena cava, the obturator nerve, lumbosacral trunk and iliolumbar artery. Laterally, the inferior vena cava and the right common iliac vein lie superiorly and the right psoas major lies inferiorly. The left common iliac vein is medial to the upper part of the right common iliac artery.

Left common iliac artery

The left common iliac artery is shorter than the right and is approximately 4 cm long. Lying anterior to it are the sympathetic rami to the pelvic plexus, the superior rectal artery and, at its terminal bifurcation, the ureter. The sympathetic trunk, the fourth and fifth lumbar vertebral bodies and intervening disc, the obturator nerve, lumbosacral trunk and iliolumbar artery are all posterior. The left common iliac vein is posteromedial, and the left psoas major lateral, to the left common iliac artery.

Branches

In addition to the external iliac and internal iliac branches, each common iliac artery also gives small branches to the peritoneum, psoas major, ureter, adjacent nerves and surrounding areolar tissue. The common iliac artery occasionally gives rise to the iliolumbar artery and accessory or replaced renal arteries if the kidney is low lying.

Internal iliac arteries

Each internal iliac artery, approximately 4 cm long, begins at the common iliac bifurcation, level with the lumbosacral intervertebral disc and anterior to the sacroiliac joint. It descends posteriorly to the superior margin of the greater sciatic foramen where it divides into an anterior trunk, which continues in the same line towards the ischial spine, and a posterior trunk, which passes back to the greater sciatic foramen. Anterior to the artery are the ureter and, in females, the ovary and fimbriated end of the uterine tube. The internal iliac vein, lumbosacral trunk and sacroiliac joint are posterior. Lateral is the external iliac vein, between the artery and psoas major, and the obturator nerve lying inferior to the vein. The parietal peritoneum is medial, separating it from the terminal ileum on the right and the sigmoid colon on the left. Tributaries of the internal iliac vein are also medial (Fig. 63.5).

Inferior gluteal artery
Obturator artery
Obliterated right umbilical artery
Middle rectal artery
Inferior vesical artery

Fig. 63.5 Arteries of the male pelvis.

In the fetus, the internal iliac artery is twice the size of the external iliac artery and is the direct continuation of the common iliac artery. The main trunk ascends on the anterior abdominal wall to the umbilicus, converging on the contralateral artery, and the two arteries run through the umbilicus to enter the umbilical cord as the umbilical arteries. At birth, when placental circulation ceases, only the pelvic segment remains patent as the internal iliac artery and part of the superior vesical artery; the remainder becomes a fibrous medial umbilical ligament. In males, the patent part (usually the superior vesical artery) usually gives off an artery to the vas deferens.

Posterior trunk branches

The branches of the posterior trunk of the internal iliac artery are the iliolumbar, lateral sacral and superior gluteal arteries.

Iliolumbar artery

The iliolumbar artery is the first branch of the posterior trunk and ascends laterally anterior to the sacroiliac joint and lumbosacral nerve trunk. It lies posterior to the obturator nerve and external iliac vessels and reaches the medial border of psoas major, dividing behind it into the lumbar and iliac branches. The lumbar branch supplies psoas major and quadratus lumborum and anastomoses with the fourth lumbar artery. It sends a small spinal branch through the intervertebral foramen between the fifth lumbar and first sacral vertebrae, to supply the cauda equina. The iliac branch supplies iliacus; between the muscle and bone it anastomoses with the iliac branches of the obturator artery. A large nutrient branch enters an oblique canal in the ilium. Other branches runs around the iliac crest, contribute to the supply of the gluteal and abdominal muscles, and anastomose with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries.

Lateral sacral arteries

The lateral sacral arteries are usually double, or if single, divide rapidly into superior and inferior branches. The superior and larger artery passes medially into the first or second anterior sacral foramen, supplies the sacral vertebrae and contents of the sacral canal, and then leaves the sacrum via the corresponding dorsal foramen to supply the skin and muscles dorsal to the sacrum. The inferior or lateral sacral artery crosses obliquely anterior to piriformis and the sacral anterior spinal rami, then descends lateral to the sympathetic trunk to anastomose with its fellow and the median sacral artery anterior to the coccyx. Its branches enter the anterior sacral foramina and are distributed in the same way as the branches of the superior artery.

Superior gluteal artery

The superior gluteal artery is the largest branch of the internal iliac artery and effectively forms the main continuation of its posterior trunk. It runs posteriorly between the lumbosacral trunk and the first sacral ramus or between the first and second rami, then turns slightly inferiorly, leaving the pelvis by the greater sciatic foramen above piriformis and dividing into superficial and deep branches. In the pelvis it supplies piriformis, obturator internus and a nutrient artery to the ilium. The superficial branch enters the deep surface of gluteus maximus. Its numerous branches supply the muscle and anastomose with the inferior gluteal branches while others perforate the tendinous medial attachment of the muscle to supply the skin over the sacrum, where they anastomose with the posterior branches of the lateral sacral arteries. The deep branch of the superior gluteal artery passes between gluteus medius and the bone, soon dividing into superior and inferior branches. The superior branch skirts the superior border of gluteus minimus to the anterior superior iliac spine and anastomoses with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral artery. The inferior branch runs through gluteus minimus obliquely, supplies it and gluteus medius and anastomoses with the lateral circumflex femoral artery. A branch enters the trochanteric fossa to join the inferior gluteal artery and ascending branch of the medial circumflex femoral artery; other branches run through gluteus minimus to supply the hip joint.

The superior gluteal artery occasionally arises directly from the internal iliac artery with the inferior gluteal artery and sometimes from the internal pudendal artery.

Anterior trunk branches

The branches of the anterior trunk of the internal iliac artery are the superior and inferior vesical, middle rectal, vaginal, obturator, uterine, internal pudendal and inferior gluteal.

Superior vesical artery

The superior vesical arter is the first large branch of the anterior trunk. It lies on the lateral wall of the pelvis just below the brim and runs anteroinferiorly medial to the periosteum of the posterior surface of the pubis. It supplies the distal end of the ureter, the bladder, the proximal end of the vas deferens and the seminal vesicles. It also gives origin to the umbilical artery in the foetus, which remains as a fibrous cord, the medial umbilical ligament, in the adult. This vessel occasionally remains patent as a small artery supplying the umbilicus.

Inferior vesical artery

The inferior vesical artery may arise as a common branch with the middle rectal artery. In the female it is often replaced by the vaginal artery. It supplies the bladder, the prostate, the seminal vesicles and the vas deferens.

Middle rectal artery

The middle rectal artery is often multiple and may be small. It runs into the lateral fascial coverings of the mesorectum. It occasionally arises close to or in common with the origin of the inferior vesical artery in males.

Vaginal artery

In females the vaginal artery may replace the inferior vesical artery. It may arise from the uterine artery close to its origin (Fig. 63.6).

Fig. 63.6 Arteries of the female pelvis.

Obturator artery

The obturator artery runs anteroinferiorly from the anterior trunk on the lateral pelvic wall to the upper part of the obturator foramen. It leaves the pelvis via the obturator canal and divides into anterior and posterior branches. In the pelvis it is related laterally to the fascia over obturator internus and is crossed on its medial aspect by the ureter and, in the male, by the vas deferens. In the nulliparous female the ovary lies medial to it. The obturator nerve is above the artery, the obturator vein below it. In the pelvis, the obturator artery provides iliac branches to the iliac fossa which supply the bone and iliacus and anastomose with the iliolumbar artery. A vesical branch runs medially to the bladder and sometimes replaces the inferior vesical branch of the internal iliac artery. A pubic branch usually arises just before the obturator artery leaves the pelvis, and ascends over the pubis to anastomose with the contralateral artery and the pubic branch of the inferior epigastric artery.

Outside the pelvis, the anterior and posterior terminal branches encircle the foramen between obturator externus and the obturator membrane. The anterior branch curves anteriorly on the membrane and then inferiorly along its anterior margin to supply branches to obturator externus, pectineus, the femoral adductors and gracilis. It anastomoses with the posterior branch and the medial circumflex femoral artery. The posterior branch follows the posterior margin of the foramen and turns anteriorly on the ischial part to anastomose with the anterior branch. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. An acetabular branch enters the hip joint at the acetabular notch, ramifies in the fat of the acetabular fossa and sends a branch along the ligament of the femoral head.

Occasionally the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric artery which descends almost vertically to the obturator foramen. It usually lies near the external iliac vein, lateral to the femoral ring, and is rarely injured during inguinal or femoral hernia surgery. Sometimes it curves along the edge of the lacunar part of the inguinal ligament, partly encircling the neck of a hernial sac, and may be inadvertently cut during enlargement of the femoral ring in reducing a femoral hernia.

Uterine artery

The uterine artery is an additional branch in females. It is a large artery which arises below the obturator artery on the lateral wall of the pelvis and runs inferomedially into the broad ligament of the uterus.

Internal pudendal artery (in the pelvis)

The internal pudendal artery arises just below the origin of the obturator artery. It descends laterally to the inferior rim of the greater sciatic foramen, where it leaves the pelvis between piriformis and ischiococcygeus to enter the gluteal region. It then curves around the dorsum of the ischial spine to enter the perineum by the lesser sciatic foramen. This course effectively allows the nerve to wrap around the posterior limit of levator ani at its attachment to the ischial spine and so gain access to the perineum. In the pelvis the internal pudendal artery crosses anterior to piriformis, the sacral plexus and the inferior gluteal artery. Behind the ischial spine it is covered by gluteus maximus, with the pudendal nerve medial and the nerve to obturator internus lateral to it. The internal pudendal artery gives off several muscular branches in the pelvis and gluteal region which supply adjacent muscles and nerves.

Inferior gluteal artery

The inferior gluteal artery is the larger terminal branch of the anterior internal iliac trunk and principally supplies the buttock and thigh. It descends posteriorly, anterior to the sacral plexus and piriformis but posterior to the internal pudendal artery. It passes between the first and second, or second and third, sacral anterior spinal nerve rami, then between piriformis and ischiococcygeus and runs through the lower part of the greater sciatic foramen to reach the gluteal region. The artery runs inferiorly between the greater trochanter and ischial tuberosity with the sciatic and posterior femoral cutaneous nerves, deep to gluteus maximus. It continues down the thigh, supplying the skin and anastomosing with branches of the perforating arteries. The inferior gluteal and internal pudendal arteries often arise as a common stem from the internal iliac artery, sometimes with the superior gluteal artery. Inside the pelvis the inferior gluteal artery gives branches to piriformis, ischiococcygeus and iliococcygeus and occasionally contributes to the middle rectal arterial supply. In the male, it may supply vessels to the seminal vesicles and prostate.

External iliac arteries

The external iliac arteries are of larger calibre than the internal iliac arteries. Each artery descends laterally along the medial border of psoas major, from the common iliac bifurcation to a point midway between the anterior superior iliac spine and the symphysis pubis, and enters the thigh posterior to the inguinal ligament to become the femoral artery.

The parietal peritoneum and extraperitoneal tissue separate the right external iliac artery from the terminal ileum and, usually, the appendix, and the left external iliac artery from the sigmoid colon and coils of the small intestine anteromedially. At its origin, the external iliac artery may be crossed by the ureter and is also crossed by the gonadal vessels, the genital branch of the genitofemoral nerve, the deep circumflex iliac vein and the vas deferens (male) or round ligament (female). Posteriorly, the artery is separated from the medial border of psoas major by the iliac fascia. The external iliac vein lies partly posterior to its upper part, but is more medial below. Laterally, it is related to psoas major, which is covered by the iliac and psoas fascia. Numerous lymph vessels and nodes lie on its front and sides.

The external iliac artery is principally the artery of the lower limb and as such has few branches in the pelvis. Apart from very small vessels to psoas major and neighbouring lymph nodes, the artery has no branches until it gives off the deep circumflex iliac and inferior epigastric arteries, which arise near to the point at which it passes under the inguinal ligament.

Deep circumflex iliac artery

The deep circumflex iliac artery branches laterally from the external iliac artery almost opposite the origin of the inferior epigastric artery. It ascends and runs laterally to the anterior superior iliac spine behind the inguinal ligament in a sheath formed by the union of the transversalis and iliac fasciae. There it anastomoses with the ascending branch of the lateral circumflex femoral artery, pierces the transversalis fascia and skirts the internal lip of the iliac crest. About halfway along the iliac crest it runs through transversus abdominis and then between transversus abdominis and internal oblique to anastomose with the iliolumbar and superior gluteal arteries. It gives off a large ascending branch at the anterior superior iliac spine which runs between internal oblique and transversus abdominis, supplies both muscles, and anastomoses with the lumbar and inferior epigastric arteries.

Inferior epigastric artery

The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament. It curves forwards in the anterior extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring whence it continues as an artery of the anterior abdominal wall.

Veins of the pelvis

The true pelvis contains a large number of veins which drain the pelvic walls and most of the viscera contained within the pelvis, and which carry venous blood from the gluteal region, hip and thigh. The external iliac veins, which lie close to the brim of the pelvis, carry the venous drainage from most of the lower limb. There is considerable variation in the venous drainage of the pelvis: although the major veins frequently follow their named arterial counterparts, the small tributaries exhibit a great deal of variation between individuals.

Common iliac veins

The common iliac vein is formed by the union of the external and internal iliac veins, anterior to the sacroiliac joints. It ascends obliquely to end at the right side of the fifth lumbar vertebra, uniting at an acute angle with the contralateral vessel to form the inferior vena cava. The right common iliac vein is shorter and more nearly vertical, lying posterior and then lateral to its artery. The right obturator nerve passes posteriorly. The left common iliac vein is longer and more oblique, and lies first medial, then posterior, to its artery. It is crossed anteriorly by the attachment of the sigmoid mesocolon and superior rectal vessels. Each vein receives iliolumbar and sometimes lateral sacral veins. The left common iliac vein usually drains the median sacral vein. There are no valves in these veins.

The left common iliac vein occasionally ascends to the left of the aorta to the level of the kidney, where it receives the left renal vein and crosses anterior to the aorta to join the inferior vena cava: this vessel represents the persistent caudal half of the left postcardinal or supracardinal vein.

Median sacral veins

The right and left medial sacral veins accompany the corresponding arteries anterior to the sacrum, where they unite to form a single vein which usually ends in the left common iliac vein, but which sometimes ends at the common iliac junction.

Internal pudendal veins

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel which ends in the internal iliac vein. They receive veins from the inferior rectal veins and either the penile bulb and scrotum (males) or the clitoris and labia (females).

Internal iliac vein

The internal iliac vein is formed by the convergence of several veins above the greater sciatic foramen. It does not have the predictable trunks and branches of the internal iliac artery but its tributaries drain the same territories. It ascends posteromedial to the internal iliac artery to join the external iliac vein, forming the common iliac vein at the pelvic brim, anterior to the lower part of the sacroiliac joint. It is covered anteromedially by parietal peritoneum. Its tributaries are the gluteal, internal pudendal and obturator veins, which originate outside the pelvis; the lateral sacral veins, which run from the anterior surface of the sacrum; and the middle rectal, vesical, uterine and vaginal veins, which originate in the venous plexuses of the pelvic viscera (Fig. 63.7).

Fig. 63.7 Veins of the female pelvis.

The venous drainage of the leg may be blocked by thrombosis involving the external iliac systems and the inferior vena cava. Under these circumstances, the pelvic veins, particularly the internal iliac tributaries, enlarge and provide a major avenue of venous return from the femoral system. Surgical interference with these veins may seriously compromise venous drainage and precipitate oedema of one or both legs.

Superior gluteal veins

The superior gluteal veins are the venae comitantes of the superior gluteal artery. They receive tributaries which correspond to the branches of the superior gluteal artery and enter the pelvis via the greater sciatic foramen, above piriformis. They join the internal iliac vein, frequently as a single trunk.

Inferior gluteal veins

The inferior gluteal veins are venae comitantes of the inferior gluteal artery. They begin proximally and posterior in the thigh, where they anastomose with the medial circumflex femoral and first perforating veins, and enter the pelvis low in the greater sciatic foramen, joining to form a vessel opening into the distal (lower) part of the internal iliac vein. The inferior gluteal and superficial gluteal veins connect by perforating veins (Doyle 1970) which are analogous to the sural perforating veins. The gluteal veins probably have a venous ‘pumping’ role, and provide collaterals between the femoral and internal iliac veins.

Obturator vein

The obturator vein begins in the proximal adductor region and enters the pelvis via the obturator foramen. It runs posteriorly and superiorly on the lateral pelvic wall below the obturator artery and between the ureter and internal iliac artery and ends in the internal iliac vein. It is sometimes replaced by an enlarged pubic vein, which joins the external iliac vein.

Lateral sacral veins

The lateral sacral veins accompany the lateral sacral arteries, and are interconnected by a sacral venous plexus.

Middle rectal vein

The middle rectal vein begins in the rectal venous plexus and drains the rectum and mesorectum. Variable in size, it runs laterally on the pelvic surface of levator ani to end in the internal iliac vein. The middle rectal vein often receives tributaries from the bladder and either the prostate and seminal vesicle (males) or the posterior aspect of the vagina (females).

External iliac vein

The external iliac vein is the proximal continuation of the femoral vein. It begins posterior to the inguinal ligament, ascends along the pelvic brim and ends anterior to the sacroiliac joint by joining the internal iliac vein to form the common iliac vein. On the right it lies medial to the external iliac artery, gradually inclining behind it as it ascends. On the left it is wholly medial. Disease of the external iliac artery may cause it to adhere closely to the vein at the point where it is in contact, and, particularly on the right side, the walls of the vessels may become fused, making dissection hazardous. The external iliac vein is crossed medially by the ureter and internal iliac artery. In males it is crossed by the vas deferens, in females by the round ligament and ovarian vessels. Psoas major lies laterally, except where the artery intervenes. The vein is usually valveless, but may contain a single valve. It tributaries are the inferior epigastric, deep circumflex iliac and pubic veins.

Inferior epigastric vein

One or two inferior epigastric veins accompany the inferior epigastric artery and drain into the external iliac vein a little above the inguinal ligament.

Deep circumflex iliac vein

The deep circumflex vein is formed from venae comitantes of the corresponding artery. It joins the external iliac vein a little above the inferior epigastric vein after crossing anterior to the external iliac artery.

Pubic vein

The pubic vein connects the external iliac and obturator veins. It ascends on the pelvic surface of the pubis with the pubic branch of the inferior epigastric artery and sometimes replaces the normal obturator vein.

Lymphatic drainage of the pelvis

The lymph nodes in the pelvis are grouped around the common, external and internal iliac vessels, and are named accordingly.

Common iliac nodes

The common iliac nodes receive the entire lymphatic drainage of the lower limb because they drain both internal and external iliac nodes. They usually lie in medial, lateral and anterior chains around the common iliac artery, the lateral being the main route: one or two lie inferior to the aortic bifurcation and anterior to the fifth lumbar vertebra or sacral promontory. The common iliac nodes connect to the lateral aortic nodes.

External iliac nodes

The external iliac nodes usually form three subgroups which are lateral, medial and anterior to the external iliac vessels. The medial nodes are considered the main channel of drainage, collecting lymph from the lower limb via the inguinal nodes, the deeper layers of the infra-umbilical abdominal wall, the adductor region of the thigh, the glans penis or clitoris, the membranous urethra, prostate, fundus of the bladder, uterine cervix and upper vagina. Their efferents pass to the common iliac nodes.

Inferior epigastric and circumflex iliac nodes

The inferior epigastric and circumflex iliac nodes are associated with their similarly named vessels and drain the corresponding areas to the external iliac nodes.

Internal iliac nodes

The internal iliac nodes surround the branches of the internal iliac vessels. They receive afferents from most of the pelvic viscera (with the exception of the gonads and the majority of the rectum), the deeper parts of the perineum and the gluteal and posterior femoral muscles, and drain to the common iliac nodes. The individual groups are considered in the description of the viscera. There are frequent connections between the right and left groups particularly when they lie close to the anterior and posterior midlines (Fig. 63.8).

INNERVATION OF THE PELVIS

The pelvis contains the lumbosacral nerve trunk, the sacral and coccygeal plexuses and the pelvic parts of the sympathetic and parasympathetic systems. Collectively, these nerves carry the somatic and autonomic innervation to the majority of the pelvic visceral organs, the pelvic floor and perineum, the gluteal region and the lower limb.

The ventral rami of the sacral and coccygeal spinal nerves form the sacral and coccygeal plexuses (Fig. 63.9). The upper four sacral ventral rami enter the pelvis by the anterior sacral foramina, the fifth enters between the sacrum and coccyx, and the ventral ramus of the coccygeal nerve curves forwards below the rudimentary transverse process of the first coccygeal segment. The first and second sacral ventral rami are large, the third to fifth diminish progressively, and the coccygeal is the smallest. Each receives a grey ramus communicans from a corresponding sympathetic ganglion. Visceral efferent rami leave the second to fourth sacral rami as the pelvic splanchnic nerves, containing parasympathetic fibres to minute ganglia in the walls of the pelvic viscera.

Fig. 63.9 The lumbosacral plexus in the pelvis.

Lumbosacral trunk and sacral plexus

The sacral plexus is formed by the lumbosacral trunk, the first to third sacral ventral rami and part of the fourth sacral ventral ramus (the remainder of the fourth sacral ventral ramus joins the coccygeal plexus).

The lumbar part of the lumbosacral trunk contains part of the fourth and all the fifth lumbar ventral rami; it appears at the medial margin of psoas major, and descends over the pelvic brim anterior to the sacroiliac joint to join the first sacral ramus. The greater part of the second and third sacral rami converge on the inferomedial aspect of the lumbosacral trunk in the greater sciatic foramen to form the sciatic nerve. The ventral and dorsal divisions of the nerves do not separate physically from each other, but their fibres remain separate within the rami; the ventral and dorsal divisions of each contributing root join within the sciatic nerve. The fibres of the dorsal divisions will go on to form the common fibular nerve and the fibres of the ventral division form the tibial nerve. The sciatic nerve occasionally divides into common fibular and tibial nerves inside the pelvis. In these cases the common fibular nerve usually runs through piriformis.

The sacral plexus lies against the posterior pelvic wall anterior to piriformis, posterior to the internal iliac vessels and ureter, and behind the sigmoid colon on the left. The superior gluteal vessels run either between the lumbosacral trunk and first sacral ventral ramus or between the first and second sacral rami, while the inferior gluteal vessels lie between either the first and second or second and third sacral rami (Fig. 63.9).

The sacral plexus is not commonly involved in malignant tumours of the pelvis because it lies behind the relatively dense presacral fascia, which resists all but locally very advanced malignant infiltration. When it occurs, there is intractable pain in the distribution of the branches of the plexus which may be very difficult to treat. The plexus may also be involved in the reticuloses or be affected by plexiform neuromas.

Branches of the sacral plexus

The branches of the sacral plexus are:

	Ventral divisions	**Dorsal divisions**
Nerve to quadratus femoris and gemellus inferior	L4,5, S1	
Nerve to obturator internus and gemellus superior	L5, S1,2	
Nerve to piriformis		S2 (S1)
Superior gluteal nerve		L4,5, S1
Inferior gluteal nerve		L5, S1,2

Posterior femoral cutaneous nerve	S2,3	S1,2
Tibial (sciatic) nerve	L4,5, S1,2,3	
Common fibular (sciatic) nerve		L4,5, S1,2
Perforating cutaneous nerve		S2,3
Pudendal nerve	S2,3,4	
Nerves to levator ani and external anal sphincter	S4	
Pelvic splanchnic nerves		S2,3 (S4)

The course and distribution of most of the branches of the sacral plexus are covered fully on page 1384.

Pudendal nerve (in the pelvis)

The pudendal nerve arises from the ventral divisions of the second, third and fourth sacral ventral rami and is formed just above the superior border of the sacrotuberous ligament and the upper fibres of ischiococcygeus. It leaves the pelvis via the greater sciatic foramen between piriformis and ischiococcygeus, enters the gluteal region and crosses the sacrospinous ligament close to its attachment to the ischial spine, where it lies medial to the internal pudendal vessels. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal (Alcock’s) canal on the lateral wall of the ischio-anal fossa. In the posterior part of the canal it gives rise to the inferior rectal nerve, the perineal nerve and the dorsal nerve of the penis or clitoris.

Sacral visceral branches

Visceral branches, the pelvic splanchnic nerves, arise from the second to fourth sacral ventral rami and innervate the pelvic viscera.

Sacral muscular branches

Several muscular branches arise from the fourth sacral ventral ramus to supply the superior surface of levator ani and the upper part of the external anal sphincter. The branches to levator ani enter the superior (pelvic) surface of the muscle whilst the branch to the external anal sphincter (also referred to as the perineal branch of the fourth sacral nerve) reaches the ischio-anal fossa by running either through ischiococcygeus or between ischiococcygeus and iliococcygeus. It supplies the skin between the anus and coccyx via its cutaneous branches.

Coccygeal plexus

The coccygeal plexus is formed by a small descending branch from the fourth sacral ramus and by the fifth sacral and coccygeal ventral rami. The fifth sacral ventral ramus emerges from the sacral hiatus, curves round the lateral margin of the sacrum below its cornu and pierces ischiococcygeus from below to reach its upper, pelvic surface. Here it is joined by a descending branch of the fourth sacral ventral ramus; the small trunk so formed descends on the pelvic surface of ischiococcygeus and joins the minute coccygeal ventral ramus which emerges from the sacral hiatus and curves round the lateral coccygeal margin to pierce coccygeus to reach the pelvis. The small trunk that is formed in this way is the coccygeal plexus. Anococcygeal nerves arise from it and form a few fine filaments which pierce the sacrotuberous ligament to supply the adjacent skin.

Pelvic part of the sympathetic system

The pelvic sympathetic trunk lies in the extraperitoneal tissue anterior to the sacrum beneath the presacral fascia (Fig. 63.10). It lies medial or anterior to the anterior sacral foramina and has four or five interconnected ganglia. Above, it is continuous with the lumbar sympathetic trunk. The right and left trunks converge below the lowest ganglia and unite in the small ganglion impar anterior to the coccyx. Grey rami communicantes pass from the ganglia to sacral and coccygeal spinal nerves but there are no white rami communicantes. Medial branches connect across the midline and twigs from the first two ganglia join the inferior hypogastric plexus or the hypogastric ‘nerve’. Other branches form a plexus on the median sacral artery.

Vascular branches

Preganglionic fibres for the vessels supplying the pelvis and lower limb are derived from the lower three thoracic and upper two or three lumbar spinal segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia. Postganglionic fibres pass from these ganglia via grey rami communicantes to the femoral nerve which carries them to the femoral artery and its branches. Some fibres descend through the lumbar ganglia to synapse in the upper two or three sacral ganglia, from which postganglionic axons pass through grey rami communicantes to the roots of the sacral plexus. Those in the pudendal and superior and inferior gluteal nerves accompany the arteries of the same name to the gluteal and perineal tissues; branches may also supply the pelvic lymph nodes. Those joining the tibial nerve are carried to the popliteal artery and distributed via its branches to the leg and foot.

Sympathetic denervation of vessels in the lower limb can be effected by removing or ablating the upper three lumbar ganglia and the intervening parts of the sympathetic trunk, which is used rarely in treating vascular insufficiency of the lower limb.

PERINEUM

MUSCLES AND FASCIAE OF THE PERINEUM

The perineum is an approximately diamond-shaped region which lies below the pelvic floor, between the inner aspects of the thighs and anterior to the sacrum and coccyx. It is usually described as if from the position of an individual lying supine with the hip joints in abduction and partial flexion. The surface projection of the perineum and the form of the skin covering it varies considerably depending on the position of the thighs whereas the deep tissues themselves occupy relatively fixed positions. The perineum is bounded anteriorly by the pubic symphysis and its arcuate ligament, posteriorly by the coccyx, anterolaterally by the ischiopubic rami and the ischial tuberosities, and posterolaterally by the sacrotuberous ligaments. The deep limit of the perineum is the inferior surface of the pelvic diaphragm and its superficial limit is the skin which is continuous with that over the medial aspect of the thighs and the lower abdominal wall. An arbitrary line joining the ischial tuberosities (the interischial line) divides the perineum into an anterior urogenital triangle and a posterior anal triangle. The urogenital triangle faces downwards and forwards, whereas the anal triangle faces downwards and backwards.

The male urogenital triangle contains the bulb and attachments of the penis (Fig. 63.11) (Ch. 76) and the female urogenital triangle contains the mons pubis, the labia majora, the labia minora, the clitoris and the vaginal and urethral orifices (Ch. 77).

Fig. 63.11 Muscles and fasciae of the male perineum. On the left side the skin and superficial fascia of the perineum only have been removed. The posterior scrotal (perineal) artery has been shown as it runs forward into the scrotal tissues. On the right side, the corpora cavernosa and corpus spongiosum and their associated muscles, the superficial perineal muscles and perineal membrane have been removed to reveal the underlying deep muscles and arteries of the perineum. All veins and nerves have been omitted for clarity.

Anal triangle

The structure of the anal triangle is similar in males and females, the main difference reflecting the wider transverse dimension of the triangle in females as a result of the larger size of the pelvic outlet. The anal triangle contains the anal canal and its sphincters, and the ischio-anal fossa and its contained nerves and vessels. It is lined by superficial and deep fascia.

Superficial fascia of the anal triangle

The superficial fascia of the region is thin and is continuous with the superficial/subcutaneous fascia of the skin of the perineum, thighs and buttocks (see p. 1095).

Deep fascia of anal triangle

The deep fascia lines the inferior surface of levator ani and is continuous at its lateral origin with the fascia over obturator internus below the attachment of levator ani. It lines the deep portion of the ischio-anal fossa and its lateral walls.

Ischio-anal fossa

The ischio-anal fossa is an approximately horse-shoe shaped region filling the majority of the anal triangle: although often referred to as a space, it is filled with loose adipose tissue and occasional blood vessels. The ‘arms’ of the horseshoe are triangular in cross section because levator ani slopes downwards towards the anorectal junction (see Fig. 67.43). The anal canal and its sphincters lie in the centre of the horseshoe. Above them the deep medial limit of the fossa is formed by the deep fascia over levator ani. The outer boundary of the fossa is formed anterolaterally by the deep fascia over obturator internus deeply and the periosteum of the ischial tuberosities more superficially. Posterolaterally, the outer boundary is formed by the lower border of gluteus maximus and the sacrotuberous ligament. Anteriorly, the superficial boundary of the fossa is formed by the posterior aspect of the transverse perineal muscles and the deep perineal pouch. Deep to this there is no fascial boundary between the fossa and the tissues deep to the perineal membrane as far anteriorly as the posterior surface of the pubis below the attachment of levator ani. Posteriorly, the fossa contains the attachment of the external anal sphincter to the tip of the coccyx: above and below this, the adipose tissue of the fossa is uninterrupted across the midline. These continuations of the ischio-anal fossa mean that infections, tumours and fluid collections within may not only enlarge relatively freely to the side of the anal canal, but may also spread with little resistance to the opposite side and deep to the perineal membrane. The internal pudendal vessels and accompanying nerves lie in the lateral wall of the ischio-anal fossa, enclosed in fascia forming the pudendal canal. The inferior rectal vessels and nerves cross the fossa from the pudendal canal and often branch within it.

The ischio-anal fossa is an important surgical plane during resections of the anal canal and anorectal junction for malignancy. It provides an easy, relatively bloodless, plane of dissection which encompasses all of the muscular structures of the anal canal and leads to the inferior surface of levator ani through which the dissection is carried.

External anal sphincter

The external anal sphincter is an oval tube of striated muscle which surrounds the lowest part of the anal canal. The uppermost (deepest) fibres blend with the lowest fibres of puborectalis; the two are seen to be continuous on endoanal ultrasound and magnetic resonance imaging. Anteriorly, some of these upper fibres decussate into the superficial transverse perineal muscles. Posteriorly, some fibres are attached to the anococcygeal raphe. The majority of the middle fibres of the external anal sphincter surround the lower part of the internal sphincter and are attached anteriorly to the perineal body and posteriorly to the coccyx via the anococcygeal ligament. Some fibres from each side of the sphincter decussate in these areas to form a sort of commissure in the anterior and posterior midline. The anterior and posterior attachments of the external anal sphincter give the muscular tube an oval profile lying anteroposteriorly. The lower fibres lie below the level of the internal anal sphincter and are separated from the lowest anal epithelium only by submucosa.

Anococcygeal ligament

The anococcygeal ligament is a layered musculotendinous structure running between the middle portion of the external anal sphincter and the coccyx. The lowest portion of the presacral fascia lies above the deep part of the ligament and the most posterior fibres of the raphe of iliococcygeus lie between the two: these three structures together are sometimes referred to as the postanal plate. Division of the anococcygeal raphe may cause descent of the anal canal and a lowering of the posterior part of the anal triangle, but does not demonstrably interfere with the process of defecation.

Urogenital triangle

The urogenital triangle is bounded posteriorly by the inter-ischial line which usually overlies the posterior border of the transverse perineal muscles. Anteriorly and laterally it is bounded deeply by the symphysis pubis and ischiopubic rami. In males, the urogenital triangle extends superficially to encompass the scrotum and the root of the penis. In females, it extends to the lower limit of the labia and mons pubis. The urogenital triangle is divided into two parts by a strong perineal membrane: the deep perineal space lies above the membrane and the superficial perineal space lies below it.

The female urogenital triangle includes muscles, fasciae and spaces similar to those in the male. There are some differences in size and disposition caused by the presence of the vagina and female external genitalia.

Deep perineal pouch (space)

The deep perineal pouch was long regarded as an anatomical region between the urogenital diaphragm and the perineal membrane containing the urethra and urethral sphincter. However, the urogenital diaphragm does not exist and the urethral sphincter, previously thought to be the principle content of the deep perineal space (where it was described as surrounding the urethra), is now recognized to be contained within the urethra. The deep perineal pouch is bounded deeply by the endopelvic fascia of the pelvic floor and superficially by the perineal membrane. Between these two fascial layers lie the deep transverse perinei, superficial to the urethral sphincter mechanism and pubourethralis, and in females superficial to the compressor urethrae and sphincter urethrovaginalis. These muscles do not form a true diaphragmatic sheet as such because fibres from several parts extend through the visceral outlet in the pelvic floor into the lower reaches of the pelvic cavity.

Perineal membrane (previously the inferior fascia of the urogenital diaphragm)

The perineal membrane is a triangular membrane which stretches almost horizontally across the deep perineal pouch. It is attached laterally to the periosteum of the ischiopubic rami and its apex is attached to the arcuate ligament of the pubis. It is particularly thick in this area and is here referred to as the transverse perineal ligament. The posterior border is fused with the deep part of the perineal body and is continuous with the fascia over the deep transverse perinei.

In the male, the perineal membrane is crossed by the urethra, 2–3 cm behind the inferior border of the symphysis pubis; the vessels and nerves to the bulb of the penis; the ducts of the bulbourethral glands, posterolateral to the urethral orifice; the deep dorsal vessels and dorsal nerves of the penis, behind the pubic arch in the midline; and the posterior scrotal vessels and nerves, anterior to the transverse perinei.

In the female, the perineal membrane is less well defined than in the male. It is divided almost into two halves by the vagina and urethra such that it forms a triangle on each side of these structures; the pubourethral ligament (the female equivalent of the transverse perineal ligament in males) links the two sides anteriorly behind the pubic arch. It is crossed by the urethra, 2–3 cm behind the inferior border of the symphysis pubis; the vagina, centrally; the ducts of Bartholin’s glands, posterolateral to the urethral orifice; the deep dorsal vessels and dorsal nerves of the clitoris, behind the pubic arch in the midline; the posterior labial vessels and nerves, anterior to the transverse perinei.

Deep transverse perinei

The deep transverse perinei form an incomplete sheet of muscle extending across the deep perineal pouch from the medial aspects of the ischiopubic rami. Posteriorly the sheet is attached to the perineal body where its fibres decussate with those of the opposite side. Anteriorly, the muscles are deficient and the visceral structures pass across the endopelvic fascia and the perineal membrane. Some fibres pass to the deep part of the external anal sphincter posteriorly and sphincter urethrae anteriorly. Together with the superficial transverse perinei, the muscles act to tether the perineal body in the median plane and may help to support the visceral canals which pass through them. They are supplied by the perineal branches of the pudendal vessels and nerves.

Urethral sphincter mechanism

The urethral sphincter mechanism consists of the intrinsic striated and smooth muscle of the urethra and the puboperinealis (pubourethralis) component of levator ani which surrounds the urethra at the point of maximum concentration of those muscles. It surrounds the membranous urethra in the male and the middle and lower thirds of the urethra in the female. In the male, fibres also reach up to the lowest part of the neck of the bladder and, between the two, lie on the surface of the prostate. The bulk of the fibres surround the membranous urethra and some fibres are attached to the inner surface of the ischiopubic ramus. In the female, the sphincter mechanism surrounds more than the middle third of the urethra. It blends above with the smooth muscle of the bladder neck and below with the smooth muscle of the lower urethra and vagina.

Actions

The urethral sphincter mechanism compresses the urethra, particularly when the bladder contains fluid. Its location around the region of highest urethral closing pressure suggests that it plays an important role in the continence of urine. Like bulbospongiosus, it is relaxed during micturition, but it contracts to expel final drops of urine, or of semen in the male, from the bulbar urethra. It may be stimulated via a vaginal tampon electrode, as has been used in the treatment of stress incontinence of urine in females.

Innervation

The urethral sphincter mechanism extends from the perineum through the urogenital hiatus into the pelvic cavity. It probably receives innervation via the perineal branch of the pudendal nerve from below and direct branches from the sacral plexus and the pelvic splanchnic nerves from above (Wendell-Smith & Wilson 1991). All these nerves originate in the second, third and fourth sacral spinal segments.

Compressor urethrae

Compressor urethrae exists in females and arises from the ischiopubic rami of each side by a small tendon. Fibres pass anteriorly to meet their contralateral counterparts in a flat band which lies anterior to the urethra, below sphincter urethrae (Fig. 63.12). A variable number of fibres from the same origin fan medially to reach the lower walls of the vagina, and may rarely reach as far posteriorly as the perineal body.

On the left side, superficial perineal muscles and overlying fascia have been removed to show the deep perineal muscles. **B**, The continuity of the deep perineal muscles with sphincter urethrae.

Sphincter urethrovaginalis

Sphincter urethrovaginalis exists in females and arises from the perineal body. Fibres pass forwards on either side of the vagina and urethra to meet their contralateral counterparts in a flat band, anterior to the urethra, below compressor urethrae.

Actions

The direction of the fibres of compressor urethrae and sphincter urethrovaginalis suggests that they produce elongation as well as compression of the membranous urethra and thus aid continence in females.

Superficial and deep perineal fasciae

Superficial perineal fascia

The tissue commonly referred to as the superficial fascia of the perineum (Colles' fascia) forms a clear, surgically recognizable plane beneath the skin of the anterior perineum. It is firmly attached posteriorly to the fascia over the superficial transverse perinei and the posterior limit of the perineal membrane. Laterally, it is attached to the margins of the ischiopubic rami as far back as the ischial tuberosities. From here it runs more superficially to the skin of the urogenital triangle, lining the skin of the external genitalia; in the male it is also continuous with the fascial layer in the skin of the scrotum which contains the dartos muscle. In females, the fascia follows the same limits but is much less extensive in the labia majora. This layer runs anteriorly and superiorly into the skin of the lower abdominal wall where it is continuous with the membranous fascia (Scarpa's fascia). These tissue layers are referred to in English as a 'superficial fascia' but this is really a misnomer since they are correctly referred to as the membranous layer of the subcutaneous tissue (the tela subcutanea).

Deep perineal fascia (investing fascia of the superficial perineal muscles)

The tissue commonly referred to as the deep perineal fascia is a layer of fascia overlying the superficial muscles of the perineum (bulbospongiosus, ischiocavernosus, superficial transverse perinei). It is in effect the investing fascia of the superficial perineal muscles and as such is firmly attached to the borders of the muscles at attachments to the ischiopubic rami, posterior margin of the perineal membrane and perineal body. In front it fuses with the suspensory ligament of the penis or clitoris and the fasciae of external oblique and the rectus sheath.

Superficial and subcutaneous perineal pouches

Subcutaneous perineal pouch

The subcutaneous perineal pouch lies between the deep perineal fascia and the superficial perineal fascia. Under normal circumstances these two layers are only separated by relatively thin subcutaneous connective tissue and the skin of the anterior perineum and genitals is relatively mobile over the deeper structures. This pouch is, however, capable of expanding considerably in the presence of fluid accumulation; blood, urine or fluid collecting in the subcutaneous pouch due to trauma or surgery on the urogenital triangle will spread throughout the tissues of the triangle including the scrotum or labia majora, but cannot pass posteriorly into the anal triangle or laterally into the medial thigh due to the firm tethering of the posterior attachments of the subcutaneous fascia. Since the superficial perineal fascia is in continuity with the fascia of the anterior abdominal wall, fluid, blood or pus may also track freely between the subcutaneous tissues of the anterior abdominal wall and the subcutaneous perineal pouch (e.g. post surgical haematomas of the abdominal wall readily cause discolouration of the perineal and genital skin).

Superficial perineal pouch

The superficial perineal pouch lies below the perineal membrane and is limited superficially by the deep perineal fascia (investing fascia of the superficial perineal muscles) (Fig. 63.13). It contains the corpora cavernosa and corpus spongiosum, ischiocavernosus, bulbospongiosus and the superficial transverse perinei, and branches of the pudendal vessels and nerves. In the female, it is crossed by the urethra and vagina and contains the clitoris. In the male, it contains the urethra as it runs in the root of the penis.

It is a fully confined space; injuries to the contents of the space (such as bleeding into the urethra in the penile root) do not communicate with the deep or subcutaneous pouches unless the fascial coverings are also lacerated or breached.

Perineal body

The perineal body is a poorly defined aggregation of fibromuscular tissue located in the midline at the junction between the anal and urogenital triangles. It is attached to many structures in both the deep and superficial urogenital spaces. Posteriorly, it merges with fibres from the middle part of the external anal sphincter and the conjoint longitudinal coat. Superiorly, it is continuous with the rectoprostatic or rectovaginal septum, including fibres from levator ani (puborectalis or pubovaginalis). Anteriorly, it receives a contribution from the deep transverse perinei, the superficial transverse perinei and bulbospongiosus (Fig. 63.4). The perineal body is continuous with the perineal membrane and the superficial perineal fascia. Since the superficial perineal fascia runs forward into the skin of the perineum, the perineal body is tethered to the central perineal skin, which is often puckered over it. In males, this is continuous with the perineal raphe in the skin of the scrotum. In females, the perineal body lies directly posterior to, and is attached to, the posterior commissure of the labia majora and the introitus of the vagina.

The anus can be surgically detached from the perineal body without any clinical consequences. However, spontaneous lacerations of the body sustained during childbirth are often associated with damage to the anterior fibres of the external anal sphincter. The deliberate division of the perineal body to facilitate delivery (episiotomy) is angled laterally to avoid such injuries. The perineal body is often used for the positioning of radiological markers used to determine the amount the perineum descends during straining in order to assess pelvic floor dysfunction.

Superficial transverse perinei

The superficial transverse perinei are narrow strips of muscle which run more or less transversely across the superficial perineal space anterior to the anus. The muscles are occasionally small and rarely absent. On each side the muscle is attached to the medial and anterior aspects of the ischial tuberosity. Medially, the fibres mostly run into the perineal body although some may also pass into the ipsilateral bulbospongiosus or external anal sphincter.

Bulbospongiosus

Bulbospongiosus differs between the sexes. In the male, it lies in the midline, anterior to the perineal body. It consists of two symmetrical parts united by a median fibrous raphe. The fibres attach to the perineal body, in which they decussate, and to the transverse superficial perinei and the external anal sphincter; they diverge like the sides of a feather from the median raphe. A thin layer of posterior fibres joins the posterior portion of the perineal membrane. The majority of the middle fibres encircle the bulb of the penis and adjacent corpus spongiosum and attach to an aponeurosis on the dorsal surfaces. The anterior fibres spread out over the sides of the corpora cavernosa, ending partly in them, anterior to ischiocavernosus, and partly in a tendinous expansion which covers the dorsal vessels of the penis. In the female, bulbospongiosus also attaches to the perineal body, but the muscle on each side is separate and covers the superficial parts of the vestibular bulbs and greater vestibular glands. Fibres run anteriorly on either side of the vagina to attach to the corpora cavernosa clitoridis, and a few fibres cross over the dorsum of the body of the clitoris.

Actions

Bulbospongiosus helps to empty the urethra of urine after the bladder has emptied. In the male, it may assist in the final stage of erection as the middle fibres compress the erectile tissue of the bulb and the anterior fibres contribute by compressing the deep dorsal vein of the penis. It contracts six or seven times during ejaculation, assisting in the expulsion of semen. In the female, bulbospongiosus acts to constrict the vaginal orifice and express the secretions of the greater vestibular glands. Anterior fibres contribute to erection of the clitoris by compressing its deep dorsal vein.

Ischiocavernosus

In the male, ischiocavernosus covers the crus penis. It is attached by tendinous and muscular fibres to the medial aspect of the ischial tuberosity behind, and to the ischial ramus on both sides of the crus. These fibres end in an aponeurosis which is attached to the sides and under surface of the crus penis. In the female, ischiocavernosus is related to a smaller crus clitoris and has a much smaller attachment to the ischiopubic ramus, but is otherwise similar to the corresponding muscle in the male (Figs 63.14, 63.15).

Fig. 63.15 Muscles and fasciae of the female perineum – coronal T2-weighted MRI.

(By courtesy of Dr J Lee and Ms K Wimpey, Chelsea and Westminster Hospital, London.)

Action

Ischiocavernosus compresses the crus penis in males and may help to maintain penile erection. The muscles form a triangle on each side of the midline with bulbospongiosus medially and the superficial transverse perinei posteriorly, attached to the perineal membrane: when contracted, the two ischiocavernosi act together to stabilize the erect penis. In the female, ischiocavernosus may help to promote clitoral erection.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE PERINEUM

Arteries of the perineum

Internal pudendal artery (in the perineum)

The internal pudendal artery enters the perineum around the posterior aspect of the ischial spine and runs on the lateral wall of the ischio-anal fossa in the pudendal (Alcock’s) canal with the pudendal veins and the pudendal nerve. The canal is formed by the connective tissue binding the vessels and nerve to the perineal surface of the obturator internus fascia and lies about 4 cm above the lower limit of the ischial tuberosity. As the artery approaches the margin of the ischial ramus, it proceeds above or below the perineal membrane, along the medial margin of the inferior pubic ramus and ends behind the inferior pubic ligament.

In the male, the internal pudendal artery distal to the perineal artery gives a branch to the bulb of the penis before it divides into the deep (cavernosal) and dorsal arteries of the penis (Fig. 63.11). Given its distribution, the internal pudendal artery distal to its perineal branch has been named the artery of the penis. The artery to the bulb supplies the corpus spongiosum and the deep artery to the penis supplies the corpus cavernosa on each side. The dorsal artery runs on the dorsal aspect of the penis, and supplies circumflex branches to the corpora cavernosa and corpus spongiosum which end by anastomosing in the coronal sulcus and supplying the glans penis and its overlying skin.

In the female, the artery to the bulb is distributed to the erectile tissue of the vestibular bulb and vagina. The cavernosal artery is much smaller and supplies the corpora cavernosa of the clitoris; the dorsal artery supplies the glans and prepuce of the clitoris (Fig. 63.11).

Branches of the internal pudendal artery are sometimes derived from an accessory pudendal artery, which is usually a branch of the pudendal artery before its exit from the pelvis; effectively the artery is double before it leaves the pelvis.

Inferior rectal artery

The inferior rectal artery arises just after the internal pudendal artery enters the canal on the lateral wall of the ischio-anal fossa and runs anteromedially through the adipose tissue of the ischio-anal fossa to reach the deep portion of the external anal sphincter. It often branches before reaching the sphincter. During dissections of the anal canal, particularly during perineal excisions of the anorectum, the inferior rectal vessels are encountered in the ischio-anal fossa and must be secured before division or they tend to retract laterally to the canal, where they can cause troublesome bleeding.

Perineal artery

The perineal artery is a branch of the internal pudendal artery near the anterior end of the pudendal canal, and runs through the perineal membrane. In the male, it approaches the scrotum in the superficial perineal space, between bulbospongiosus and ischiocavernosus. A small transverse branch passes medially, inferior to the superficial transverse perineal muscle, to anastomose with the contralateral artery and with the posterior scrotal and inferior rectal arteries. It supplies the transverse perinei, the perineal body and the posterior attachment of the bulb of the penis. The posterior scrotal arteries are usually terminal branches of the perineal artery but may also arise from its transverse branch. They are distributed to the scrotal skin and dartos muscle in the male and supply the perineal muscles. In the female, the perineal artery runs an almost identical course to that in the male, and gives off similar branches; the posterior scrotal arteries are replaced by posterior labial arteries.

Veins of the perineum: internal pudendal veins

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel ending in the internal iliac vein. The perineal tributaries receive veins from the penile bulb and the scrotum (males) or clitoris and labia (females) and the inferior rectal veins join towards the posterior end of the pudendal canal.

Lymphatic drainage of the perineum

The lymphatics from the skin of the penis and scrotum (male) or skin of the clitoris and labia (female) drain together with lymphatics from the perineal skin to the superficial inguinal nodes and thence to the deep inguinal nodes. The glans, corpora cavernosa and corpus spongiosum of the penis or clitoris drain directly to the deep inguinal nodes.

INNERVATION OF THE PERINEUM: PUDENDAL NERVE (IN THE PERINEUM)

The pudendal nerve gives rise to the inferior rectal and perineal nerves and the dorsal nerves of the penis or clitoris.

The pudendal nerve occupies a very constant position over the ischial spine and is readily found. It may be ‘blocked’ by infiltration with a local anaesthetic applied via a needle passed through the lateral wall of the vagina to numb the perineal and anal skin. It may also be palpated over the ischial spine through the lateral wall of the rectum and motor terminal latencies measured.

Inferior rectal nerve

The inferior rectal nerve runs through the medial wall of the pudendal canal with the inferior rectal vessels. It crosses the ischio-anal fossa to supply the external anal sphincter, the lining of the lower part of the anal canal, and the circumanal skin. It frequently breaks into terminal branches just before reaching the lateral border of the sphincter. Its cutaneous branches distributed around the anus overlap the cutaneous branches of the perineal branch of the posterior femoral cutaneous nerve and of the scrotal or labial nerves. The inferior rectal nerve occasionally arises directly from the sacral plexus and crosses the sacrospinous ligament or reconnects with the pudendal nerve. In females, the inferior rectal nerve may supply sensory branches to the lower part of the vagina.

Perineal nerve

The perineal nerve is the inferior and larger terminal branch of the pudendal nerve in the pudendal canal. It runs forwards below the internal pudendal artery and accompanies the perineal artery, dividing into posterior scrotal or labial and muscular branches. The posterior scrotal or labial nerves are usually double and have medial and lateral branches which run over the perineal membrane and pass forwards in the lateral part of the urogenital triangle with the scrotal or labial branches of the perineal artery. They supply the skin of the scrotum or labia majora, overlapping the distribution of the perineal branch of the posterior femoral cutaneous and inferior rectal nerves. In females, the posterior labial branches also supply sensory fibres to the skin of the lower vagina.

Muscular branches arise directly from the pudendal nerve to supply the superficial transverse perinei, bulbospongiosus, ischiocavernosus, deep transverse perinei, sphincter urethrae and the anterior parts of the external anal sphincter and levator ani. In males, a nerve to the bulb of the urethra leaves the nerve to the bulbospongiosus, pierces this muscle to supply the corpus spongiosum penis and ends in the urethral mucosa.

Dorsal nerve of the penis or clitoris

The dorsal nerve of the penis or clitoris runs anteriorly above the internal pudendal artery along the ischiopubic ramus deep to the perineal membrane. It supplies the corpus cavernosum and accompanies the dorsal artery of the penis or clitoris between the layers of the suspensory ligament. In males, the dorsal nerve of the penis runs on the dorsum of the penis to end in the glans. In females the dorsal nerve of the clitoris is very small.

CHAPTER 64

Peritoneum and peritoneal cavity

The peritoneum is the largest serous membrane in the body, and its arrangements are complex. In males it forms a closed sac, but in females it is open at the lateral ends of the uterine tubes. It consists of a single layer of flat mesothelial cells lying on a layer of loose connective tissue. The mesothelium usually forms a continuous surface, but in some areas may be fenestrated. Neighbouring cells are joined by junctional complexes, but probably permit the passage of macrophages. The submesothelial connective tissue may also contain macrophages, lymphocytes and adipocytes (in some regions). Mesothelial cells may transform into fibroblasts, which may play an important role in the formation of peritoneal adhesions after surgery or inflammation of the peritoneum.

The peritoneal cavity is a potential space between the parietal peritoneum, which lines the abdominal wall, and infoldings of visceral peritoneum, which suspend the abdominal viscera within the cavity. It contains a small amount of serous fluid, but is otherwise empty. The fluid lubricates the visceral peritoneum and allows the mobile viscera to glide freely on the abdominal wall and each other within the limits dictated by their attachments. It contains water, proteins, electrolytes and solutes derived from interstitial fluid in the adjacent tissues and from the plasma in the local blood vessels. It normally contains a few cells, including desquamated mesothelium, nomadic peritoneal macrophages, mast cells, fibroblasts, lymphocytes and other leukocytes. Some cells, particularly macrophages, migrate freely between the peritoneal cavity and the surrounding connective tissue. Lymphocytes provide both cellular and humoral immunological defence mechanisms within the peritoneal cavity. The intraperitoneal fluid is directed by gravity to dependent sites within the peritoneal cavity, and also flows in a cephalad direction as a consequence of the negative upper intra-abdominal pressures which are generated by respiration.

The peritoneal cavity never contains gas in normal circumstances, although the amount of fluid may be increased in inflammatory conditions of the viscera. In females blood or fluid may occasionally escape from the uterine tubes into the pelvic peritoneal cavity during menstruation.

Extraperitoneal connective tissue separates the parietal peritoneum from the muscular layers of the abdominal walls. The parietal peritoneum covering the anterior abdominal wall and pelvic walls is generally attached only loosely by this tissue, an arrangement which allows for considerable alteration in the size of the bladder and rectum. The extraperitoneal tissue on the inferior surface of the diaphragm and behind the linea alba is denser and more firmly adherent. The extraperitoneal tissue frequently contains large amounts of fat over the posterior abdominal wall, especially in obese males. The visceral peritoneum is firmly adherent to the underlying tissues and cannot be easily detached. Its connective tissue layer is often continuous with the fibrous matrix of the wall of the underlying viscera and rarely contains much loose connective or adipose tissue. The visceral peritoneum is often considered as part of the underlying viscus for clinical and pathological purposes such as the staging of carcinoma.

GENERAL ARRANGEMENT OF THE PERITONEUM

In utero, the alimentary tract develops as a single tube suspended in the coelomic cavity by ventral and dorsal mesenteries (see Ch. 73). Ultimately, the ventral mesentery is largely resorbed, although some parts persist in the upper abdomen and form structures such as the falciform ligament. The mesenteries of the intestines in the adult are the remnants of the dorsal mesentery. The migration and subsequent fixation of parts of the gastrointestinal tract produce the so-called ‘retroperitoneal’ segments of bowel (duodenum, ascending colon, descending colon, and rectum), and four separate intraperitoneal bowel loops suspended by mesenteries of variable lengths. These are all covered by visceral peritoneum which is continuous with the parietal peritoneum covering the posterior abdominal wall. The first intraperitoneal loop is formed by the intraperitoneal oesophagus, the stomach and first part of the duodenum. The second loop is made up of the duodenojejunal junction, jejunum, ileum and occasionally the caecum and proximal ascending colon. The third loop contains the transverse colon and the final loop contains the sigmoid colon and occasionally the distal descending colon.

Where the visceral peritoneum encloses or suspends organs within the peritoneal cavity, the peritoneum and related connective tissues are known as the peritoneal ligaments, omenta or mesenteries. All but the greater omentum are composed of two layers of visceral peritoneum separated by variable amounts of connective tissue. The greater omentum is folded back on itself and is therefore made up of four layers of closely applied visceral peritoneum, which are separated by variable amounts of adipose tissue. The mesenteries attach their respective viscera to the posterior abdominal wall: the attachment is referred to as the mesenteric root, and the peritoneum of the mesentery is continuous with that of the posterior abdominal wall in this area (Fig. 64.1).

Fig. 64.1 The posterior abdominal wall, showing the lines of peritoneal reflection, after removal of the liver, spleen, stomach, jejunum, ileum, caecum, transverse colon and sigmoid colon. The various sessile (retroperitoneal) organs are seen shining through the posterior parietal peritoneum. Note: the ascending and descending colon, duodenum, kidneys, suprarenals, pancreas and inferior vena cava. Line W–W represents the plane of **Fig. 64.2**. Line X–X represents the plane of **Fig. 64.3**. Line Y–Y represents the plane of **Fig. 64.4**. Line A–A represents the plane of **Fig. 64.5A**. Line B–B represents the plane of **Fig. 64.5B**. Line C–C represents the plane of **Fig. 64.5C**.

Although they are described as intraperitoneal, strictly speaking the suspended organs do not lie within the peritoneal cavity because they are covered by visceral peritoneum. They are continuous with the extraperitoneal tissues, including the retroperitoneum, via subperitoneal tissue lying between the folds of visceral peritoneum. The loose areolar connective tissues of the extraperitoneal and subperitoneal tissues are sometimes conceptualized as ‘spaces’ because fluid or blood collects relatively easily within them. The subperitoneal tissues contain the neurovascular bundles and lymphatic channels which supply the suspended organs. In obese individuals, extensive adipose tissue within the mesenteries and omenta may obscure the neurovascular bundles. In contrast, in the very young, the elderly or the malnourished, the mesentery may contain very little adipose tissue and the neurovascular bundles are usually obvious.

PERITONEUM OF THE UPPER ABDOMEN

The abdominal oesophagus, stomach, liver and spleen all lie within a double fold of visceral peritoneum which runs from the posterior to the anterior abdominal wall. This fold has no recognized name, but has been referred to as the mesogastrium by Coakley & Hricak 1999 because it is derived from the fetal mesogastrium. It has a complex attachment to the wall of the abdominal cavity and gives rise to the falciform ligament, coronary ligaments, lesser omentum (gastrohepatic and hepatoduodenal ligaments), greater omentum (including gastrocolic ligament), gastrosplenic ligament, splenorenal ligament, and phrenicocolic ligament (Figs 64.2, 64.3, 64.4).

The falciform ligament

The falciform ligament is a thin anteroposterior peritoneal fold which connects the liver to the posterior aspect of the anterior abdominal wall just to the right of the midline. It extends inferiorly to the level of the umbilicus, and is widest between the liver and umbilicus. The ligament narrows superiorly as the distance between the liver and anterior abdominal wall reduces and narrows to just a centimetre or so in height over the superior surface of the liver. Its two peritoneal layers divide to enclose the liver and are continuous with the visceral peritoneum that is adherent to the surface of the liver. Superiorly, they are reflected onto the inferior surface of the diaphragm and are continuous with the parietal peritoneum over the right dome. At the posterior limit, or apex, of the falciform ligament, the two layers are also reflected vertically left and right, and are continuous with the anterior layers of the left triangular ligament and the superior layer of the coronary ligament of the liver. The inferior aspect of the falciform ligament forms a free border where the two peritoneal layers become continuous with each other as they fold over to enclose the ligamentum teres. Because the peritoneum of the falciform ligament is continuous with that covering the posterior abdominal wall and the periumbilical anterior abdominal wall, blood arising from retroperitoneal haemorrhage (commonly acute haemorrhagic pancreatitis) may track between the folds of peritoneum and appear as haemorrhagic discolouration around the umbilicus (Cullen’s sign). Inflammatory change from the pancreas may spread via the gastrohepatic ligament (lesser omentum) and then via the falciform ligament to the umbilicus.

The peritoneal connections of the liver

The liver is almost completely covered in visceral peritoneum, and only the ‘bare area’ is in direct contact with the right dome of the diaphragm. Peritoneal folds, the ligaments of the liver, run from the liver to the surrounding viscera and to the abdominal wall and diaphragm (Fig. 64.5); they are described in detail in Chapter 68.

Fig. 64.5 Transverse sections through the abdomen. **A**, At the level of the line A–A in **Fig. 64.1**. The line passes through the bare area of the liver at the superior end of the lesser omentum. The parts of the left subphrenic space are clearly seen although they are continuous with each other. **B**, At

the level of line B–B in **Fig. 64.1**, viewed from below. The peritoneal cavity is shown by a blue 'wash'; the peritoneum and its cut edges in pale blue. **C**, Transverse section through the abdomen at the level of the line C–C in **Fig. 64.1**, viewed from below. Colours as in **Fig. 64.1**.

The coronary ligament is formed by the reflection of the peritoneum from the diaphragm onto the posterior surfaces of the right lobe of the liver. Between the two layers of this ligament, a large area of liver, the bare area, is devoid of peritoneal covering. At this point the liver is attached to the diaphragm by areolar tissue and is in continuity inferiorly with the uppermost part of the anterior pararenal space. The layers of the coronary ligament are continuous on the right with the right triangular ligament.

The upper layer of the coronary ligament is continuous superiorly with the peritoneum over the inferior surface of the diaphragm and inferiorly with the peritoneum over the right and superior surfaces of the liver. At the lower margin of the bare area the lower layer of the coronary ligament becomes continuous inferiorly with the peritoneum of the posterior abdominal wall over the right suprarenal gland and upper pole of the right kidney, and superiorly with the peritoneum over the inferior surface of the liver.

The left triangular ligament is a double layer of peritoneum which extends over the superior border of the left lobe of the liver to a variable length. Medially, its anterior leaf is continuous with the left layer of the falciform ligament. The posterior layer is continuous with the left layer of the lesser omentum. The left triangular ligament lies in front of the abdominal part of the oesophagus, the upper end of the lesser omentum and part of the fundus of the stomach. Intraoperative division of the left triangular ligament permits mobilization of the left lobe of the liver in order to expose the abdominal oesophagus and crura of the diaphragm.

The right triangular ligament is a short V-shaped fold formed by the approximation of the two layers of the coronary ligament at its right lateral end, and is continuous with the peritoneum of the right posterolateral abdominal wall. The coronary ligament is reflected inferiorly and is directly continuous with the peritoneum over the upper pole of the right kidney. This fold is sometimes referred to as the hepatorenal ligament. The recess formed between the peritoneum of the inferior surface of the liver, the hepatorenal ligament and the peritoneum over the right kidney is known as the hepatorenal pouch (of Morison). In the supine position this is the most dependent part of the peritoneal cavity in the upper abdomen, and is a common site of pathological fluid accumulation.

The peritoneum is reflected inferolaterally from the posterior layer of the left triangular ligament onto the posterior abdominal wall above the oesophageal opening of the diaphragm. It lines the inferior surface of the left dome of the diaphragm and continues backwards onto the posterior abdominal wall. Inferiorly, it is reflected behind the spleen onto the most lateral part of the mesentery of the transverse colon and the splenic flexure. It continues down lateral to the descending colon into the pelvis, and forms the left paracolic ‘gutter’. Medially, the peritoneum covering the left upper posterior abdominal wall is reflected anteriorly to form the left layer of the upper end of the lesser omentum, the peritoneum over the left aspect of the abdominal oesophagus and the left layer of the splenorenal ligament.

From the inferior layer of the coronary ligament the peritoneum descends over the anterior surface of the right kidney to the front of the first part of the duodenum and hepatic flexure of the colon. Medially it passes in front of a short segment of the inferior vena cava between the duodenum and liver, forming as it does so the posterior wall of the epiploic foramen. This narrow strip broadens out as the peritoneum continues across the midline onto the posterior wall of the lesser sac.

The peritoneum lines the posterior abdominal wall over the diaphragmatic crura, the upper abdominal aorta, the coeliac axis, nodes and plexus and the upper border of the pancreas. Inferiorly, below the liver, it continues down on the posterior abdominal wall to the right of the ascending colon, forming the right paracolic ‘gutter’ between the anterolateral abdominal wall and colon.

The lesser omentum

The lesser omentum is formed of two layers of peritoneum separated by a variable amount of connective tissue and is derived from the ventral mesogastrium. It runs from the inferior visceral surface of the liver to the abdominal oesophagus, stomach, pylorus and first part of the duodenum. Superiorly, its attachment to the inferior surface of the liver forms an L-shape. The vertical component of the L is formed by the fissure for the ligamentum venosum. Inferiorly, the attachment turns and runs horizontally to complete the L in the portal fissure. The vertical and horizontal components of the lesser omentum run between the liver and the stomach and duodenum and are known as the gastrohepatic and hepatoduodenal ligaments, respectively. At the lesser curvature of the stomach, the layers of the lesser omentum split to enclose the stomach and are continuous with the visceral peritoneum covering the anterior and posterior surfaces of the stomach. The anterior layer of the lesser omentum descends from the fissure for the ligamentum venosum onto the anterior surface of the abdominal oesophagus, stomach and duodenum. The posterior layer descends from the posterior part of the fissure for the ligamentum venosum and runs onto the posterior surface of the stomach and pylorus. The lesser omentum forms the anterior surface of the lesser sac. The gastrohepatic ligament contains the right and left gastric vessels, branches of the vagus nerves, and gastrohepatic lymph nodes between its two layers near their attachment to the stomach. The right lateral border of the lesser omentum is thickened and extends from the junction between the first and second parts of the duodenum to the porta hepatis. This border is free and forms the anterior wall of the epiploic foramen. It contains the portal vein, common bile duct, hepatic artery, portocaval lymph nodes and lymphatics and the hepatic plexus of nerves ensheathed in a perivascular fibrous capsule. Occasionally the free margin extends to the right of the epiploic foramen, runs to the gallbladder and is referred to as the cystoduodenal ligament.

The left border of the lesser omentum is short and runs over the inferior surface of the diaphragm between the liver and medial aspect of the abdominal oesophagus. The lesser omentum is thinner on the left and may be fenestrated or incomplete: the variations in thickness are dependent upon the amount of connective tissue, especially fat.

The greater omentum

The greater omentum is the largest peritoneal fold and hangs inferiorly from the greater curvature of the stomach. It is a double sheet: each sheet consists of two layers of peritoneum separated by a scant amount of connective tissue. The two sheets are folded back on themselves and are firmly adherent to each other. The anterior sheet descends from the greater curvature of the stomach and first part of the duodenum. The most anterior layer is continuous with the visceral peritoneum over the anterior surface of the stomach and duodenum and the posterior layer is continuous with the peritoneum over the posterior wall of the stomach and pylorus. The anterior sheet descends a variable distance into the peritoneal cavity and then turns sharply on itself to ascend as the posterior sheet. The posterior sheet passes anterior to the transverse colon and transverse mesocolon. It is attached to the posterior abdominal wall above the origin of the small intestinal mesentery and anterior to the head and body of the pancreas. The anterior layer of the posterior sheet is continuous with the peritoneum of the posterior wall of the lesser sac. The posterior layer is reflected sharply inferiorly and is continuous with the anterior layer of the transverse mesocolon. The posterior sheet is adherent to the transverse mesocolon at its root and is often known as the gastrocolic ligament, which is the supracolic part of the greater omentum. In early fetal life the greater omentum and transverse mesocolon are separate structures, and this arrangement sometimes persists. During surgical mobilization of the transverse colon, the plane between the transverse mesocolon and greater omentum can be entered opposite the taenia omentalis, and the greater omentum can be separated entirely from the transverse colon and mesocolon if required. Access into the lesser sac can be obtained via this approach if the upper part of the posterior sheet of the greater omentum is then divided. This gives a relatively bloodless plane of entry for surgical access to the posterior wall of the stomach and to the anterior surface of the pancreas. The greater omentum is continuous with the gastrosplenic ligament on the left, and on the right it extends to the start of the duodenum. A fold of peritoneum, the hepatocolic ligament, may run from either the inferior surface of the right lobe of the liver or the first part of the duodenum to the right side of the greater omentum or hepatic flexure of the colon.

The right border of the greater omentum is occasionally adherent to the anterior surface of the ascending colon down as far as the caecum: its peritoneal layers are not continuous with the peritoneum over this part of the colon. A thin sheet of peritoneum referred to as Jackson’s membrane may run from the front of the ascending colon and caecum to the posterolateral abdominal wall and may merge with the greater omentum. It often contains several small blood vessels. Occasionally, a band passes from the right side of the ascending colon to the lateral abdominal wall near the level of the iliac crest. It has been called the ‘sustentaculum hepatis’ but plays no role in the support of the liver. Other folds between the ascending colon and posterolateral abdominal wall may divide the right lateral paracolic gutter into several small recesses. Less commonly the greater omentum is adherent to the anterior surface of the left colon; very occasionally it extends to the level of the sigmoid colon.

When the undisturbed abdomen is opened, the greater omentum is frequently wrapped around the upper abdominal organs. Only rarely is it evenly dependent anterior to the coils of the small intestine, although this is the disposition which is frequently illustrated. It is usually thin and cribriform, but it always contains some adipose tissue and is a common site for storage of fat in obese individuals, particularly males.

Between the two layers of the anterior fold of the greater omentum, close to the greater curvature of the stomach, the right and left gastroepiploic vessels form a wide anastomotic arc. Numerous vessels are given off from the arc and extend the full length of the omentum. This supply appears to exceed the metabolic requirements of the omentum, and perhaps reflect the role the greater omentum may play in peritoneal disease processes. The greater omentum is highly mobile and frequently becomes adherent to inflamed viscera within the abdominal cavity. This action may help to limit the spread of infection and the omentum may provide a source of well-vascularized tissue to take part in the early reparative process. It contains numerous fixed macrophages, which are easily mobilized when activated and may accumulate into dense, oval or round visible ‘milky-spots’.

The peritoneal connections of the spleen

The peritoneal connections of the spleen suspend the spleen in the left upper quadrant of the abdomen; they include the gastrosplenic, splenorenal and phrenicocolic ligaments. The gastrosplenic ligament runs between the greater curvature of the stomach and the hilum of the spleen and is in continuity with the left side of the greater omentum. The layers of the gastrosplenic ligament separate to enclose the spleen and then rejoin to form the splenorenal ligament and phrenicocolic ligaments. The splenorenal ligament extends from the spleen to the posterior abdominal wall and the phrenicocolic ligament extends to the anterolateral abdominal wall.

The splenorenal ligament is formed from two layers of peritoneum. The anterior layer is continuous medially with the peritoneum of the posterior wall of the lesser sac over the left kidney and runs up to the splenic hilum where it is continuous with the posterior layer of the gastrosplenic ligament. The posterior layer of the splenorenal ligament is continuous laterally with the peritoneum over the inferior surface of the diaphragm and runs onto the splenic surface over the renal impression. The splenic vessels lie between the layers of the splenorenal ligament: the tail of the pancreas is usually present in its lower portion. The gastrosplenic ligament also has two layers. The posterior layer is continuous with the peritoneum of the splenic hilum and the peritoneum over the posterior surface of the stomach. The anterior layer is formed from the peritoneum reflected off the gastric impression of the spleen and is continuous with the peritoneum over the anterior surface of the stomach. The short gastric and left gastroepiploic branches of the splenic artery, with their corresponding veins, pass between the layers of the gastrosplenic ligament. The phrenicocolic ligament extends from the splenic flexure of the colon to the diaphragm at the level of the eleventh rib. It extends inferiorly and laterally and is continuous with the peritoneum of the lateral end of the transverse mesocolon at the lateral margin of the pancreatic tail, and the splenorenal ligament at the hilum of the spleen.

A fan-shaped presplenic fold frequently extends from the anterior aspect of the gastrosplenic ligament near the greater curvature of the stomach below the inferolateral pole of the spleen and blends with the phrenicocolic ligament.

If the peritoneal attachments of the spleen are not recognized during surgery, the splenic capsule is at risk of injury and there may be subsequent serious bleeding. Downward traction on the phrenicocolic ligament during handling of the descending colon, especially during mobilization of the splenic flexure, may cause rupture of the splenic capsule. This is less likely if traction on the phrenicocolic ligament is made laterally or medially. The superior border and anterior diaphragmatic surface of the splenic capsule are often adherent to the peritoneum of the greater omentum. Medial traction on the omentum during surgery may cause splenic capsular injury: such injury is less likely, if any limited traction required is applied inferiorly.

PERITONEUM OF THE LOWER ABDOMEN

The posterior surface of the lower anterior abdominal wall is lined by parietal peritoneum, which extends from the linea alba centrally to the lateral border of quadratus lumborum. Here it is continuous with the peritoneum of the lateral paracolic gutter and is reflected over the sides and front of the ascending colon on the right and the descending colon on the left. Occasionally the ascending and descending colon are suspended by a short mesentery from the posterior abdominal wall. Between the ascending and descending colon, the peritoneum lines the posterior abdominal wall other than the oblique area, where it is reflected anteriorly to form the right and left layers of the small intestinal mesentery. Over the posterior abdominal wall it covers the left and right psoas major, inferior vena cava, duodenum, vertebral column and right and left ureters. At the upper extent of the posterior abdominal wall the peritoneum is reflected anteriorly and is continuous with the peritoneum of the posterior layer of the transverse mesocolon.

Transverse mesocolon

The mesentery of the transverse colon is a broad fold of visceral peritoneum reflected anteriorly from the posterior abdominal wall and suspends the transverse colon in the peritoneal cavity. The root of the transverse mesocolon lies along an oblique line passing from the anterior aspect of the second part of the duodenum, over the head and neck of the pancreas, above the duodenojejunal junction and over the upper pole of the left kidney to the splenic flexure (Fig. 64.1). It varies considerably in length but is shortest at either end. It contains the middle colic vessels and their branches together with branches of the superior mesenteric plexus, lymphatics and regional lymph nodes. Its two layers pass to the posterior surface of the transverse colon, where they separate to cover the colon. The upper layer of peritoneum is reflected from the posterior abdominal wall immediately anteriorly and inferiorly and becomes continuous with the posterior layer of the greater omentum to which it is adherent. The lower layer of peritoneum of the transverse mesocolon is continuous with the peritoneum of the posterior abdominal wall. Lateral extensions of the transverse mesocolon produce two shelf-like folds on the right and left sides of the abdominal cavity. On the right the duodenocolic ligament extends from the transverse mesocolon at the hepatic flexure to the second part of the duodenum. On the left the phrenicocolic ligament extends from the transverse mesocolon at the splenic flexure to the diaphragm at the level of the eleventh rib. The root of the transverse mesocolon is closely related to the upper limit of the root of the mesentery of the small intestine near the uncinate process of the pancreas.

Mesentery of the small intestine

The mesentery of the small intestine is arranged as a complex fan formed from two layers of peritoneum (anterosuperior and posteroinferior) separated by connective tissue and vessels. The root of the mesentery lies along a line running diagonally from the duodenojejunal flexure on the left side of the second lumbar vertebral body to the right sacroiliac joint (Fig. 64.1). The root crosses over the third part of the duodenum, aorta, inferior vena cava, right ureter and right psoas major. The average length of the root of the mesentery is 15 cm in adults; while along its intestinal attachment is the same length as the small intestine (approximately 5 m), and consequently the mesentery is usually thrown into multiple folds along its intestinal border. The average depth of the mesentery from the root to the intestinal border is 20 cm, but this varies along the length of the small intestine: it is shortest at the jejunum and terminal ileum and longest in the region of the mid ileum. Its two peritoneal layers contain the jejunum, ileum, jejunal and ileal branches of the superior mesenteric vessels, branches of the superior mesenteric plexus, lacteals and regional lymph nodes. Because of the length and mobility of the mesentery, identification of the proximal and distal ends of a loop of small intestine may be difficult through small surgical incisions. Tracing the continuity of the right peritoneal layer of the mesentery onto the posterior abdominal wall above the root towards the ascending colon, and the continuity of the left layer towards the descending and sigmoid colon, may be useful in helping to orientate an individual loop of ileum. The mesentery of the small intestine is sometimes joined to the transverse mesocolon at the duodenojejunal junction by a peritoneal band. Occasionally the fourth part of the duodenum possesses a very short mesentery which is continuous with the upper end of the root of the small bowel mesentery. Pronounced bands of peritoneum may extend to the posterior abdominal wall at the terminal ileum. The root of the mesentery of the small intestine is continuous with the peritoneum surrounding the appendix and caecum in the right iliac fossa.

Mesoappendix

The mesentery of the appendix is a triangular fold of peritoneum around the vermiform appendix, attached to the posterior surface of the lower end of the mesentery of the small intestine close to the ileocaecal junction. It usually reaches the tip of the appendix but sometimes fails to reach the distal third, in which case a vestigial low peritoneal ridge containing fat is present over the distal third. It encloses the blood vessels, nerves and lymph vessels of the vermiform appendix, and usually contains a lymph node.

Sigmoid mesocolon

The sigmoid mesocolon shows individual variation in length and depth. The root of the sigmoid colon forms a shallow inverted V with an apex near the division of the left common iliac artery but may vary from a very short straight line at the pelvic brim to a long curved attachment. The upper, left end of the attachment runs medially over the left psoas major. The lower, right end passes into the pelvis towards the midline at the level of the third sacral vertebra. The root extends for a variable distance over the brim of the pelvis and the lower posterior abdominal wall. The anteromedial peritoneal layer of the mesentery of the sigmoid colon is continuous with the peritoneum of the lower left posterior abdominal wall and its posterolateral layer is continuous with the peritoneum of the pelvis and lateral abdominal wall. The proximal and distal ends of the sigmoid colon are occasionally joined together by a fibrous band which is usually associated with a narrow based sigmoid mesentery and may predispose the sigmoid colon to volvulus. Pronounced bands of peritoneum may also be found running from the proximal sigmoid colon to the posterior abdominal wall. The sigmoid and superior rectal vessels run between its layers and the left ureter descends into the pelvis behind its apex.

PERITONEUM OF THE LOWER ANTERIOR ABDOMINAL WALL

The peritoneum of the lower anterior abdominal wall is raised into five ridges which diverge as they descend from the umbilicus. These are the median and right and left lateral and medial umbilical folds (Fig. 64.6). The median umbilical fold extends from the umbilicus to the apex of the bladder and contains the urachus or its remnant (Ch. 78). The obliterated umbilical artery lies under the medial umbilical fold which ascends from the pelvis to the umbilicus. The supravesical fossa lies between the medial and median umbilical folds on either side of the midline. The lateral umbilical fold covers the inferior epigastric artery and vein below their entry into the rectus sheath, and is separated from the medial umbilical fold by the medial inguinal fossa. The lateral inguinal fossa lies lateral to the lateral umbilical fold, and covers the deep inguinal ring. The femoral fossa lies inferomedial to the lateral inguinal fossa, from which it is separated by the medial end of the inguinal ligament. It overlies the femoral ring (see Ch. 61).

PERITONEUM OF THE PELVIS

The parietal peritoneum of the posterior surface of the anterior abdominal wall and that lining the posterior abdominal wall continue into the pelvis as the pelvic peritoneum. The pelvic peritoneum then follows the surfaces of the true pelvic viscera and pelvic side walls although there are important differences between the sexes.

Peritoneum of the male pelvis

In males, the peritoneum of the left lower abdominal wall is reflected from the junction of the sigmoid colon and anterolateral surface of the rectum to line the brim and upper inner surface of the true pelvis (Fig. 64.7). The peritoneum passes down into the true pelvis, lying over the anterior surface of the rectum, which then becomes an extraperitoneal organ. Laterally, the peritoneum is reflected to the pelvic side walls to form the right and left pararectal fossae: these vary in size according to the degree of distension of the rectum. The peritoneum is reflected anteriorly from the anterior surface of the rectum over the upper poles of the seminal vesicles and onto the posterior surface of the bladder, producing the rectovesical pouch. Anteriorly the rectovesical pouch is limited laterally by peritoneal folds, the sacrogenital folds, which extend from the sides of the bladder posteriorly to the anterior aspect of the sacrum. The peritoneum covers the superior surface of the bladder, and forms a paravesical fossa on each side limited laterally by a ridge of peritoneum which contains the ductus deferens. The size of the paravesical fossae depends on the volume of urine in the bladder. When the bladder is empty, a variable transverse vesical fold divides each fossa into two. The anterior ends of the sacrogenital folds may sometimes be joined by a ridge separating a middle fossa from the main rectovesical pouch. Between the paravesical and pararectal fossae the ureters and internal iliac vessels may cause slight elevations in the peritoneum. From the apex of the bladder the peritoneum extends superiorly along the posterior surface of the lower anterior abdominal wall to the umbilicus. When the bladder distends, the peritoneum is lifted from the lower anterior abdominal wall so that part of the anterior surface of the bladder is in direct contact with the posterior surface of the lower median area of the anterior abdominal wall. This relationship means that a well-distended bladder can be entered by direct puncture through the lower anterior abdominal wall without entering the peritoneal cavity (suprapubic puncture).

Peritoneum of the female pelvis

In females the peritoneum covers the upper rectum as it does in the male, but it descends further over the anterior surface of the rectum. The lateral limit of the pararectal and paravesical fossae is the peritoneum covering the round ligament of the uterus. The rectovesical pouch is occupied by the uterus and vagina. The peritoneum from the rectum is thus reflected anteriorly onto the posterior surface of the posterior fornix of the vagina and the uterus, producing the recto-uterine pouch (of Douglas). The peritoneum covers the fundus of the uterus to its anterior (vesical) surface as far as the junction of the body and cervix, from which it is reflected forwards to the upper surface of the bladder, forming a shallow vesico-uterine pouch. Peritoneum is reflected from the bladder to the posterior surface of the anterior abdominal wall as it is in males. Marginal recto-uterine folds correspond to the sacrogenital folds in males and pass back to the sacrum from the sides of the cervix, lateral to the rectum. Peritoneum is reflected from the anterior and posterior uterine surfaces to the lateral pelvic walls as the broad ligament of the uterus (see Fig. 77.18). This consists of anteroinferior and posterosuperior layers which are continuous at the upper border of the ligament. The broad ligament extends from the sides of the uterus to the lateral pelvic walls, and contains the uterine tubes in its free superior margins and the ovaries attached to its posterior layer. Below, it is continuous with the lateral pelvic parietal peritoneum. Between the ridges formed by the obliterated umbilical arteries and the ureter, the peritoneum forms a shallow depression on the lateral pelvic wall, the ovarian fossa, which lies behind the lateral attachment of the broad ligament. The ovary usually rests in the fossa in nulliparous females.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Parietal and visceral peritoneum develop from the somatopleural and splanchnopleural layers respectively of lateral plate mesoderm (see Ch. 73). Parietal peritoneum is therefore supplied by somatic blood vessels of the abdominal and pelvic walls and its lymphatics join those in the body wall and drain to parietal lymph nodes. Visceral peritoneum is best considered as an integral part of the viscera which it overlies; it derives its blood supply from the viscera, and its lymphatics join the visceral vessels to drain to the regional lymph nodes.

INNERVATION

The parietal peritoneum is innervated by branches from somatic efferent and afferent nerves that also supply the muscles and skin respectively of the overlying body wall. The visceral peritoneum is innervated by branches of visceral afferent nerves which travel with the autonomic supply to the underlying viscera. The different sensations arising from pathologies which affect either the parietal or visceral peritoneum reflect these differences in patterns of innervation. Well-localized pain is elicited by mechanical, thermal or chemical stimulation of the nocioceptors of the parietal peritoneum. The sensation is usually confined to one or two dermatomes for each area of peritoneum stimulated and is both lateralized and well localized. Somatic nerves that innervate the parietal peritoneum also supply the corresponding segmental areas of skin and muscles; when the parietal peritoneum is irritated, muscles tend to contract reflexly, causing localized hypercontractility (guarding) or even rigidity of the abdominal wall. The parietal diaphragmatic peritoneum is supplied with afferent fibres from the phrenic nerves (centrally) and by the lower six intercostal nerves and subcostal nerves (peripherally): peripheral irritation of the diaphragm may therefore result in pain, tenderness and muscular rigidity in the distribution of the lower thoracic spinal nerves, while central irritation may result in pain in the cutaneous distribution of the third to fifth cervical spinal nerves, i.e. the shoulder region.

The visceral peritoneum and viscera are not affected by these stimuli because the visceral afferent innervation provides a much more limited sensation of discomfort. When stimulated, the sensation of pain is of a less severe nature and is referred to the area of abdominal wall according to the region of the intestinal tract affected. Discomfort from structures derived from the foregut is felt in the region of the epigastrium, from midgut structures in the region of the umbilicus, and from hindgut structures in the suprapubic region: none of these sensations shows significant lateralization. However, stretch of the visceral peritoneum is a potent cause of certain sensations and responses. Various neural elements in the visceral walls, mesenteries and overlying peritoneum mediate poorly localized sensations of discomfort when stimulated by stretch, and may also elicit profound reflex autonomic reactions involving vasomotor and cardiac changes. This is of considerable clinical relevance. The effects of division of the parietal peritoneum may be rendered painless by local or regional local anaesthesia. In marked contrast, the direct central connections of the visceral afferents, particularly via the vagus, mean that stretching the visceral peritoneum may have profound effects, and may produce acute haemodynamic instability despite high spinal anaesthesia. Ischaemia of the underlying viscera causes poorly localized abdominal pain, probably due to the spasms of visceral smooth muscle.

GENERAL ARRANGEMENT OF THE PERITONEAL CAVITY

The peritoneal cavity is a single continuous space between the parietal peritoneum lining the abdominal wall and the visceral peritoneum enveloping the abdominal organs. It consists of a main region, termed the greater sac, which is equivalent to the main abdominal cavity surrounding the majority of the abdominal and pelvic viscera. The lesser sac, or omental bursa, is a small diverticulum lined with peritoneum, which is situated behind the stomach and lesser omentum and in front of the pancreas and retroperitoneum. These two areas communicate via the epiploic foramen.

For clinical purposes the peritoneal cavity can be divided into several spaces because pathological processes are often contained within these spaces and their anatomy may influence diagnosis and treatment. It is useful to divide the peritoneal cavity into two main compartments, supramesocolic and inframesocolic, which are partially separated by the transverse colon and its mesentery (the latter connects the transverse colon to the posterior abdominal wall). The pelvic peritoneal spaces are described above.

SUPRAMESOCOLIC COMPARTMENT

The supramesocolic space lies above the transverse mesocolon between the diaphragm and the transverse colon. It can be arbitrarily divided into right and left supramesocolic spaces. These regions can be further subdivided into a number of subspaces, which are normally in communication, but are frequently subdivided by inflammatory adhesions in disease. The right supramesocolic space can be divided into three subspaces; the right subphrenic space, the right subhepatic space, and the lesser sac. The left supramesocolic space can be divided into two subspaces; the left subphrenic space and the left perihepatic space.

Right subphrenic space

The right subphrenic space lies between the diaphragm and the anterior, superior and right lateral surfaces of the right lobe of the liver. It is bounded on the left side by the falciform ligament and behind by the upper layer of the coronary ligament. It is a relatively common site for collections of fluid after right sided abdominal inflammation.

Right subhepatic space (hepatorenal recess)

The right subhepatic space lies between the right lobe of the liver and the right kidney. It is bounded superiorly by the inferior layer of the coronary ligament, laterally by the right lateral abdominal wall, posteriorly by the anterior surface of the upper pole of the right kidney and medially by the second part of the duodenum, hepatic flexure, transverse mesocolon and part of the head of the pancreas. In the supine position the posterior right subhepatic space is more dependent than the right paracolic gutter: postoperative infected fluid collections are common in this location.

Lesser sac (omental bursa)

The lesser sac is a cavity lined with peritoneum and connected to the larger general peritoneal cavity (greater sac) by the epiploic foramen. It is considered part of the right supramesocolic space because embryologically the liver grows into the right peritoneal space and stretches the dorsal mesentery to form the lesser sac behind the stomach. The sac varies in size according to the size of the viscera making up its walls. It has posterior and anterior walls as well as superior, inferior, right and left borders.

The anterior wall is made up of the posterior peritoneal layer of the lesser omentum, the peritoneum over the posterior wall of the stomach and first part of the duodenum, and the uppermost part of the anterior layer of the greater omentum. At its right border, the anterior wall is mostly formed by the lesser omentum but moving towards the left, the lesser omentum becomes progressively shorter and more of the anterior wall is formed by the posterior aspect of the stomach and greater omentum.

The posterior wall is formed mainly by the peritoneum covering the posterior abdominal wall in this area. In the lower part, the posterior wall is made up of the anterior layer of the posterior sheet of the greater omentum as it lies on the transverse mesocolon. The posterior wall covers, from below upwards, a small part of the head and the whole neck and body of the pancreas, the medial part of the anterior aspect of the left kidney, most of the left suprarenal gland, the commencement of the abdominal aorta and coeliac artery and part of the diaphragm. The inferior phrenic, splenic, left gastric and hepatic arteries lie partly behind the bursa. Many of these structures form the ‘bed’ of the stomach and are separated from it only by the linings of the lesser sac.

The superior border of the lesser sac is narrow and lies between the right side of the oesophagus and the upper end of the fissure for the ligamentum venosum. Here peritoneum of the posterior wall of the lesser sac is reflected anteriorly from the diaphragm to join the posterior layer of the lesser omentum.

The inferior border of the lesser sac runs along the line of the fusion of the layers of the greater omentum. This runs from the gastrosplenic ligament to the peritoneal fold behind the first part of the duodenum. In cases where the layers are not completely adherent to each other, the lesser sac may extend as far as the bottom of the two sheets of the greater omentum. In adults, even in these circumstances of separation of the layers, the lowest extent of the inferior border is rarely below the level of the transverse colon.

The right border of the lesser sac is formed by the reflection of the peritoneum from the pancreatic neck and head onto the inferior aspect of the first part of the duodenum. The line of this reflection ascends to the left, along the medial side of the gastroduodenal artery. Near the upper duodenal margin the right border joins the floor of the epiploic foramen round the hepatic artery proper. The epiploic foramen thus forms a break in the right border. Above the epiploic foramen the right border is formed by the reflection of peritoneum from the diaphragm to the right margin of the caudate lobe of the liver and along the left side of the inferior vena cava, enclosing the hepatic recess.

The left border of the lesser sac runs from the left end of the root of the transverse mesocolon and is mostly formed by the inner layer of peritoneum of the splenorenal and gastrosplenic ligaments. The part of the lesser sac lying between the splenorenal and gastrosplenic ligaments is referred to as the splenic recess. Above the level of the spleen, the two ligaments are merged as the short gastrophrenic ligament, which passes forwards from the diaphragm to the posterior aspect of the fundus of the stomach and forms part of the upper left border of the lesser sac. The two layers of the gastrophrenic ligament diverge near the abdominal oesophagus, leaving part of the posterior gastric surface devoid of peritoneum. The left gastric artery runs forwards here into the lesser omentum.

The lesser sac is narrowed by two crescentic peritoneal folds produced by the hepatic and left gastric arteries. The left gastropancreatic fold overlies the left gastric artery as it runs from the posterior abdominal wall to the lesser curvature of the stomach. The right gastropancreatic fold overlies the hepatic artery as it runs from the posterior abdominal wall to the lesser omentum. The folds vary in size. When prominent, they divide the lesser sac into a smaller superior and a larger inferior recess. The superior recess lies posterior to the lesser omentum and liver, and encloses the caudate lobe of the liver, which is covered by peritoneum on both its anterior and posterior surfaces. It extends superiorly into the fissure for the ligamentum venosum and lies adjacent to the right crus of the diaphragm posteriorly. The inferior recess of the lesser sac lies between the stomach and pancreas and is contained in the double sheet of the greater omentum.

Epiploic foramen (of Winslow)

The epiploic foramen (foramen of Winslow, aditus to the lesser sac), is a short, vertical slit, usually 3 cm in height in adults, in the upper part of the right border of the lesser sac. It leads into the greater sac. The hepatoduodenal ligament, which is formed by the thickened right edge of the lesser omentum extending from the flexure between the first and second parts of the duodenum, forms the anterior margin of the foramen. The anterior border contains the common bile duct (on the right), portal vein (posteriorly) and hepatic artery (on the left) between its two layers. Superiorly the peritoneum of the posterior layer of the hepatoduodenal ligament runs over the caudate lobe of the liver which forms the roof of the epiploic foramen. This layer of peritoneum is then reflected onto the inferior vena cava which forms the posterior margin of the epiploic foramen. At the upper border of the first part of the duodenum the peritoneum runs forwards from the inferior vena cava, above the head of the pancreas, and is continuous with the posterior layer of the lesser omentum, forming the floor of the epiploic foramen. A narrow passage, the vestibule of the lesser sac, may be found to the left of the foramen between the caudate process and the first part of the duodenum. To the right, the rim of the foramen is continuous with the peritoneum of the greater sac. The roof is continuous with the peritoneum on the inferior surface of the right hepatic lobe. The anterior and posterior walls of the foramen are normally apposed.

Left subphrenic space

The left subphrenic space lies between the diaphragm, the anterior and superior surfaces of the left lobe of the liver, the anterosuperior surface of the stomach and the diaphragmatic surface of the spleen. It is bounded to the right by the falciform ligament and behind by the anterior layer of the left triangular ligament. It is much enlarged in the absence of the spleen and is a common site for fluid collection particularly after splenectomy. The left subphrenic space is substantially larger than the right and is sometimes described as being divided into anterior and posterior parts, although no obvious demarcation exists in the absence of disease. The left posterior subphrenic space is small and lies between the fundus of the stomach and the diaphragm above the origin of the splenorenal ligament. The left anterior subphrenic space is large and lies between the superior and anterolateral surfaces of the spleen and the left dome of the diaphragm. Inferiorly and medially, this space is bounded by the splenorenal, gastrosplenic, and phrenicocolic ligaments which produces a partial barrier to the left paracolic gutter. This may explain why left subphrenic collections are less frequent than right subphrenic collections following lower abdominal and pelvic surgery, but the left subphrenic space is the commonest site of fluid collection after upper abdominal, particularly splenic, surgery.

Left perihepatic space

The left perihepatic space is sometimes subdivided into anterior and posterior spaces. The posterior perihepatic space is also known as the left subhepatic space or gastrohepatic recess. The left anterior perihepatic space lies between the anterosuperior surface of the left lobe of the liver and diaphragm. The left posterior perihepatic space lies inferior to the left lobe of the liver, and extends into the fissure for the ligamentum venosum on the right, anterior to the main portal vein. Posteriorly, the lesser omentum separates this space from the superior recess of the lesser sac. On the left, the space is bounded by the lesser curvature of the stomach.

INFRAMESOCOLIC COMPARTMENT

The inframesocolic compartment lies below the transverse mesocolon and transverse colon are far as the true pelvis. It is divided in two unequal spaces by the root of the mesentery of the small intestine. It contains the right and left paracolic gutters lateral to the ascending and descending colon. As a consequence of the mobility of the transverse mesocolon and mesentery of the small intestine, disease processes are rarely well contained within these spaces, and fluid within the infracolic space tends to descend into the pelvis or the paracolic gutters.

Right infracolic space

The right infracolic space is a triangular space. It is smaller than its counterpart on the left, and lies posterior and inferior to the transverse colon and mesocolon and to the right of the small intestinal mesentery. The space is narrowest inferiorly because the attachment of the root of the mesentery of the small intestine lies well to the right of the midline. The vermiform appendix often lies in the lower part of the right infracolic space.

Left infracolic space

The left infracolic space is larger than its counterpart on the right and is in free communication with the pelvis to the right of the midline. It lies posterior and inferior to the transverse colon and mesocolon and to the left of the mesentery of the small intestine. The sigmoid colon and its mesentery may partially restrict the flow of fluid or blood into the pelvis to the left of the midline.

Paracolic gutters

The right and left paracolic gutters are peritoneal recesses on the posterior abdominal wall lying alongside the ascending and descending colon. The main paracolic gutter lies lateral to the colon on each side. A less obvious medial paracolic gutter may be formed, especially on the right side, if the colon possesses a short mesentery for part of its length. The right (lateral) paracolic gutter runs from the superolateral aspect of the hepatic flexure of the colon, down the lateral aspect of the ascending colon, and around the caecum. It is continuous with the peritoneum as it descends into the pelvis over the pelvic brim. Superiorly, it is continuous with the peritoneum which lines the hepatorenal pouch and, through the epiploic foramen, the lesser sac. Bile, pus or blood released from viscera anywhere along its length may run along the gutter and collect in sites quite remote from the organ of origin. In supine patients, infected fluid from the right iliac fossa may ascend in the gutter to enter the lesser sac. In patients nursed in a sitting position, fluid from the stomach, duodenum or gallbladder may run down the gutter to collect in the right iliac fossa or pelvis and may mimic acute appendicitis or form a pelvic abscess. The right paracolic gutter is larger than the left, which together with the partial barrier provided by the phrenicocolic ligament, may explain why right subphrenic collections are more common than left subphrenic collections.

Extraperitoneal subphrenic spaces

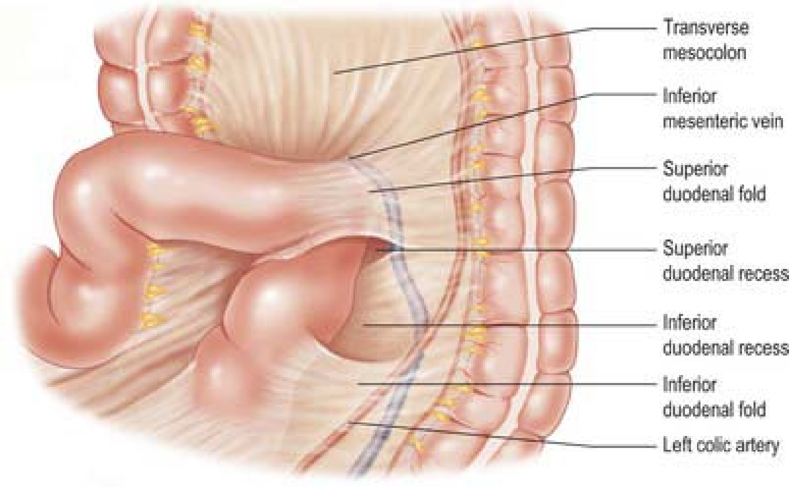
There are two potential ‘spaces’ which actually lie outside the peritoneal coverings of the abdomen, but are of clinical relevance because of the possibility that fluid collections will accumulate in them. The right extraperitoneal space is bounded by the two layers of the coronary ligament, the bare area of the liver and the inferior surface of the right dome of the diaphragm. The left extraperitoneal space lies anterior to the left suprarenal gland and upper pole of the left kidney. It contains extraperitoneal connective tissue.

RECESSES OF THE PERITONEAL CAVITY

Peritoneal folds may create fossae or recesses within the peritoneal cavity. These are of clinical interest because a length of intestine may enter one and be constricted by the fold at the entrance to the recess: it may subsequently become a site of internal herniation. The contents of the peritoneal fold may be important if surgical incision is required to reduce such a hernia. Although internal herniation may occur into the lesser sac via the epiploic foramen, the sac is not usually considered to be a peritoneal recess.

Duodenal recesses

Several folds of peritoneum may exist around the fourth part of the duodenum and the duodenojejunal junction forming a number of named recesses (Fig. 64.8).



Transverse mesocolon
Inferior mesenteric vein
Superior duodenal fold
Superior duodenal recess
Inferior duodenal recess
Inferior duodenal fold
Left colic artery

Fig. 64.8 The superior and inferior duodenal recesses. The transverse colon and jejunum have been displaced.

Superior duodenal recess

The superior duodenal recess is occasionally present, usually in association with an inferior duodenal recess. It lies to the left of the end of the fourth part of the duodenum, opposite the second lumbar vertebra, and behind a crescentic superior duodenal fold (duodenojejunal fold). The fold has a semilunar free lower edge which merges to the left with the peritoneum anterior to the left kidney. The inferior mesenteric vein is directly behind the junction of the left (lateral) end of this fold and the posterior parietal peritoneum. The recess varies in size but is commonly 2 cm deep, admitting a fingertip. It opens downwards, its orifice being in the angle formed by the left renal vein as it passes across the abdominal aorta.

Inferior duodenal recess

The inferior duodenal recess is usually present often associated with a superior recess with which it may share an orifice. It lies to the left of the fourth part of the duodenum, opposite the third lumbar vertebra. It sits behind a non-vascular, triangular inferior duodenal fold (duodenomesocolic fold), which has a sharp upper edge. It is usually 3 cm deep, admits one or two fingers and opens upwards towards the superior duodenal recess. It sometimes extends behind the fourth part of the duodenum and to the left, in front of the ascending branch of the left colic artery and the inferior mesenteric vein.

Paraduodenal recess

The paraduodenal recess may occur in conjunction with superior and inferior duodenal recesses. It is rare in adults but is more commonly seen in newborn children. It lies a little to the left and slightly behind of the fourth part of the duodenum, behind a falciform paraduodenal fold. The free right edge of the fold contains the inferior mesenteric vein and ascending branch of the left colic artery, and represents part of the upper left colic mesentery. Its free edge lies in front of the wide orifice of the recess, which faces right.

Retroduodenal recess

The retroduodenal recess is the largest of the duodenal recesses, but is rarely present. It lies behind the third and fourth parts of the duodenum in front of the abdominal aorta. It ascends nearly to the duodenojejunal junction, is 8–10 cm deep, and bounded on both sides by duodenoparietal folds. It has a wide orifice which faces down and to the left.

Duodenojejunal recess

The duodenojejunal or mesocolic recess typically occurs in 20% of adults. When present, it is almost never associated with any other duodenal recesses. It is approximately 3 cm deep and lies to the left of the abdominal aorta, between the duodenojejunal junction and the root of the transverse mesocolon. It is bounded above by the pancreas, on the left by the kidney, and below by the left renal vein. It has a circular opening between two peritoneal folds, and faces down and to the right.

Mesentericoparietal recess

The mesentericoparietal recess is only rarely present. It lies just below the third part of the duodenum and invaginates into the upper part of the mesentery towards the right. Its orifice is large and faces left behind a fold of mesentery raised by the superior mesenteric artery.

Caecal recesses

Several folds of peritoneum may exist around the caecum and form recesses (Fig. 64.9). Paracaecal recesses are common sites for abscess formation following acute appendicitis.

Inferior ileocaecal recess
Mesoappendix
Caecal fold
Caecum
Retrocaecal recess
Vermiform appendix

Fig. 64.9 The peritoneal folds and recesses in the caecal region.

Superior ileocaecal recess

The superior ileocaecal recess is usually present and best developed in children. It is often reduced and absent in the aged, especially the obese. It is formed by the vascular fold of the caecum, which arches over the anterior caecal artery, supplying the anterior part of the ileocaecal junction, and its accompanying vein. It is a narrow slit bounded in front by the vascular fold, behind by the ileal mesentery, below by the terminal ileum and on the right by the ileocaecal junction. Its orifice opens downwards to the left.

Inferior ileocaecal recess

The inferior ileocaecal recess is well marked in youth but frequently obliterated by fat in adults. It is formed by the ileocaecal fold, which extends from the anteroinferior aspect of the terminal ileum to the front of the mesoappendix (or to the appendix or caecum). It is also known as the ‘bloodless fold of Treves’, although it sometimes contains blood vessels and will often bleed if divided during surgery. If inflamed, especially when the appendix and its mesentery are retrocaecal, it may be mistaken for the mesoappendix. The recess is bounded in front by the ileocaecal fold, above by the posterior ileal surface and its mesentery, to the right by the caecum, and behind by the upper mesoappendix. Its orifice opens downwards to the left.

Retrocaecal recess

The retrocaecal recess lies behind the caecum. It varies in size and extent and ascends behind the ascending colon, often being large enough to admit an entire finger. It is bounded in front by the caecum (and sometimes the lower ascending colon), behind by the parietal peritoneum and on each side by caecal folds (parietocolic folds) passing from the caecum to the posterior abdominal wall. The vermiform appendix frequently occupies this recess when in the retrocaecal position.

Intersigmoid recess

The intersigmoid recess is constant in fetal life and infancy, but may disappear during later development. It lies behind the apex of the V-shaped parietal attachment of the sigmoid mesocolon and is funnel shaped. It is directed upwards and opens downwards. It varies in size from a slight depression to a shallow fossa. Its posterior wall is formed by the parietal peritoneum of the posterior abdominal wall which covers the left ureter as it crosses the bifurcation of the left common iliac artery. Occasionally the recess is within the layers of the sigmoid mesocolon, and is nearer the bowel wall than the mesenteric root. It is probably produced by an imperfect blending of the mesocolon with the posterior parietal peritoneum.

CLINICAL MANAGEMENT OF FLUID COLLECTIONS IN THE PERITONEAL CAVITY

Fluid collections frequently occur within the peritoneal cavity as a result of a wide range of pathological processes. In the absence of any inflammation, peritoneal adhesions or previous surgery, serous fluid is almost always distributed freely between the peritoneal spaces and is not confined to any particular area. Simple ascites, for example, can therefore be drained freely from any convenient dependent part of the peritoneal cavity. This is most commonly performed by blind or ultrasound guided insertion of a catheter into the lower left or right paracolic gutters, which usually readily fill with fluid. The colon and some loops of small bowel may be present, but their relatively mobility ensures that they are very unlikely to be injured during this procedure.

Fluid collections caused by inflammatory processes are often much more viscid because they contain pus, fibrin or blood and are usually associated with peritoneal inflammation which results in, at least transient, peritoneal adhesions. These factors mean that collections may become localized if the flow of fluid is restricted by the partial compartmentalization of the peritoneum. Once collected in a particular ‘space’, this fluid often becomes further confined by ongoing inflammation and may even form a truly walled-off cavity over time. Any of the spaces of the peritoneum may develop a collection, but the subphrenic, subhepatic and pelvic spaces are the commonest since they are most well defined by the fixed peritoneal folds and organs forming their boundaries. These spaces are also the most dependent spaces within the peritoneum in the supine position and consequently any initially free fluid tends to gravitate to them.

Surgical access to the peritoneal spaces is rarely necessary today because of the great advances which have been made in radiologically guided drainage. When necessary, lateral subcostal or intercostal incisions may give adequate access to the subphrenic spaces and the anterior wall of the rectum is also a useful route to access the rectouterine or rectovesical space. Computerized tomography or ultrasound guided drainage offers a much more reliable and versatile method of accessing even difficult spaces such as subhepatic, perihepatic, paracolic or even intermesenteric collections. Posterolateral translumbar or trans-sciatic approaches can be used to access these more difficult areas.

Peritoneal dialysis

The mesothelium resembles vascular endothelium in being a dialysing membrane which fluids and small molecules may traverse. Numerous endocytic vesicles occur near the cell surfaces, and the remaining cytoplasm is poor in organelles, indicating low metabolic activity. Normally the volumes of fluid transmitted by peritoneal surfaces are small, but large volumes may be administered via the intraperitoneal route. Conversely, substances such as urea can be dialysed from blood into fluid circulated through the peritoneal cavity.

Ventriculoperitoneal shunts

The absorptive capabilities of the peritoneum can be used to absorb excess transitional fluids from several sites in the body. The commonest of these is the absorption of cerebrospinal fluid drained from the intracerebral ventricles or the intrathecal space via a fine calibre catheter. The catheter can be placed within the peritoneum with a one way valve preventing reflux of peritoneal fluid into the cerebrospinal fluid. The fluid is then continuously absorbed, maintaining a low pressure within the intrathecal or intraventricular space.

CHAPTER 65

Abdominal oesophagus and stomach

ABDOMINAL OESOPHAGUS

The abdominal oesophagus is 1–2.5 cm in length, and is slightly broader at the cardiac orifice than the diaphragmatic aperture. It lies to the left of the midline and enters the abdomen through the oesophageal aperture (formed by the two diaphragmatic crura) opposite the level of the tenth thoracic vertebra. It runs obliquely to the left and slightly posteriorly, and ends at the gastro-oesophageal junction/cardiac orifice of the stomach. The abdominal oesophagus lies posterior to the left lobe of the liver, which it grooves slightly, anterior to the left crus, the left inferior phrenic vessels and the left greater splanchnic nerve; its surface is covered in a thin layer of connective tissue and visceral peritoneum which contains the anterior and posterior vagi as well as the oesophageal branches of the left gastric vessels. The anterior vagus may be single or composed of multiple trunks, and is closely related to the outer fibres of the longitudinal muscle coat of the oesophagus. The posterior vagus is usually a single trunk and is less closely applied to the oesophageal muscle within the loose connective tissue, which makes its identification during surgery somewhat easier.

The abdominal oesophagus is effectively tethered to the diaphragm by connective tissue (Fig. 65.1); the phreno-oesophageal ligament. This is formed of two thickened bands of elastin-rich connective tissue; the inferior phreno-oesophageal ligament is effectively an extension of the transversalis fascia extending beneath the parietal peritoneum as it is reflected from the diaphragm onto the abdominal oesophagus. The fibres are only loosely attached to the adventitial tissues and a variable amount of fat often lies beneath it, between the oesophageal wall and the crural sling. This oesophageal fat pad tends to act to tether the oesophagus to the fibres of the crura but tends to regress with age. On the thoracic side of the diaphragm the superior phreno-oesophgeal ligament is similarly formed from an extension of the subpleural endothoracic fascia. It is denser than its inferior counterpart with more elastin present and is tethered much more firmly through the muscle fibres of the oesophageal wall into the submucosal tissues. It may well act to restore lower oesophageal position after the movement engendered by the peristalsis of swallowing (Kwok et al 1999). Anteriorly, the subperitoneal connective tissue is particularly dense and blends with both the outer layer of the oesophageal wall and the apex of the crural fibres of the diaphragm. On the posterior aspect the peritoneal reflection is extremely short since the crura lie steeply angled, and the posterior oesophageal wall has a much shorter 'effective length' than the anterior. This short reflection of peritoneum is sometimes referred to as the gastrophrenic ligament and, via the peritoneum over the oesophagus continues directly onto the posterior surface of the stomach. It covers the oesophageal branches of the left gastric vessels and the coeliac branches of the posterior vagus and can thus be said to form an extremely short, wide mesentery to the abdominal oesophagus. In all but the thinnest individuals a pad of adipose tissue is found beneath the peritoneum covering the anterior surface of the lower abdominal oesophagus and the adjacent gastric wall. It is a useful surgical marker for the external location of the gastro-oesophageal junction.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The abdominal oesophagus is supplied by oesophageal branches of the left gastric artery. These ascend as an anterior and posterior branch beneath the visceral peritoneum to supply perforating branches to the intramural and submucosal plexuses. The posterior surface usually receives an additional supply via branches of the upper short gastric arteries, the terminal branches of the oesophageal branches of the thoracic aorta and occasionally an ascending branch of the posterior gastric artery.

Veins

Veins drain via plexuses to the left gastric and upper short gastric veins (see Stomach veins below).

Lymphatic drainage

Lymphatic drainage occurs to the left gastric and left and right paracardial nodes and from the posterior surface directly to the uppermost para-aortic nodes (see Fig. 65.13).

among the highest nodes for these viscera but have been removed for clarity (see **Ch. 66**).

INNERVATION

The abdominal oesophagus is innervated by sympathetic and parasympathetic fibres. The parasympathetic fibres are derived directly from the peri-oesophageal thoracic plexus and to a lesser extent from the anterior and posterior vagi. They are motor to the distal oesophagus and both stimulatory and inhibitory to the functional lower oesophageal sphincter (LOS), maintaining both background tone and co-ordinating distal oesophageal peristalsis with relaxation of the LOS during swallowing. The sympathetic supply originates from the fifth to 12th thoracic spinal segments and is mainly distributed via the greater and lesser splanchnic nerves and the coeliac plexus.

STOMACH

The stomach is the widest part of the alimentary tract and lies between the oesophagus and the duodenum. It is situated in the upper abdomen, extending from the left upper quadrant downwards, forwards and to the right, lying in the left hypochondriac, epigastric and umbilical areas. It occupies a recess beneath the diaphragm and anterior abdominal wall that is bounded by the upper abdominal viscera on either side. The mean capacity of the stomach increases from approximately 30 ml at birth, to 1000 ml at puberty, and approximately 1500 ml in adults. The peritoneal surface of the stomach is interrupted by the attachments of the greater and lesser omenta which define the greater and lesser curvatures that separate two surfaces.

PARTS OF THE STOMACH

For descriptive purposes, the stomach is divided by arbitrary lines drawn on its external surface into a fundus, body, pyloric antrum and pylorus (Fig. 65.2). The internal appearance and microstructure of these regions varies to some degree. The fundus is dome shaped and projects above and to the left of the cardiac orifice to lie in contact with the left dome of the diaphragm. It lies above a line drawn horizontally from the incisura cardiaca to the greater curvature. The body extends from the fundus to the incisura angularis, which is a constant external notch at the lower end of the lesser curvature. A line drawn from the incisura angularis to an indentation on the greater curvature defines the lower boundary of the body. The pyloric antrum extends from this line to the sulcus intermedius, where the stomach narrows to become the pyloric canal (1–2 cm long), which terminates at the pyloric orifice.

GASTRIC RELATIONS

Gastric curvatures

Lesser curvature

The lesser curvature extends between the cardiac and pyloric orifices and forms the medial (posterior and superior) border of the stomach. It descends from the medial side of the oesophagus in front of the decussating fibres of the right crus of the diaphragm, curves downwards and to the right and lies anterior to the superior border of the pancreas (Fig. 65.3). It ends at the pylorus just to the right of the midline. In the most dependent part there is typically a notch, the incisura angularis, whose position and appearance vary with gastric distension. The lesser omentum is attached to the lesser curvature and contains the right and left gastric vessels.

Fig. 65.3 Posterior relations of the stomach.

Greater curvature

The greater curvature is four or five times longer than the lesser. It starts from the incisura cardiaca formed between the lateral border of the abdominal oesophagus and the fundus of the stomach. It arches upwards, posterolaterally and to the left. Its highest convexity, the apex of the fundus, is approximately level with the left fifth intercostal space just below the left nipple in males, but varies with respiration. From this level it sweeps inferiorly and anteriorly, slightly convex to the left, almost as far as the tenth costal cartilage in the supine position, where it turns medially to end at the pylorus. There is frequently a groove, termed the sulcus intermedius, in the curvature close to the pyloric constriction. The start of the greater curvature is covered by peritoneum which continues over the anterior surface of the stomach. Laterally the greater curvature gives attachment to the gastrosplenic ligament and beyond this to the greater omentum, which contains the gastroepiploic vessels. The gastrosplenic ligament and the greater omentum, together with the gastrophrenic and splenorenal ligaments, are continuous parts of the original dorsal mesogastrium: their names merely indicate regions of the same continuous sheet of peritoneum and its associated connective tissue.

Gastric volvulus

Volvulus of the stomach is much less common than volvulus of either the sigmoid colon or caecum. Two types of gastric volvulus may occur. The first, organoaxial volvulus, occurs about a line of rotation running from below the cardiac orifice to the pylorus. The antrum, body and fundus rotate upwards, with the greater curvature coming to lie above the lesser curvature as the volvulus progresses. The second, mesenteroaxial volvulus, occurs about a line drawn ‘across’ the body of the stomach, usually just above the incisura angularis. This type of volvulus is perpendicular to the line of organoaxial volvulus. The distal body and antrum rotate anteriorly, superiorly and laterally while the upper body and fundus rotate posteriorly, medially and inferiorly. Although relatively mobile within the upper abdomen, the stomach is normally tethered to the oesophagus at the gastro-oesophageal junction (see above), to the duodenum at the pylorus, to the spleen by the gastrosplenic omentum, and to the liver by the lesser omentum. The attachment to the transverse colon via the gastrocolic omentum also restrains the stomach but is the most mobile of all. For either type of gastric volvulus to occur, it is necessary for some or all of these points of tethering to be loosened either by previous surgical division or by chronic lengthening and loosening of their connective tissue. Organoaxial volvulus is most common because the lesser omentum, gastrosplenic ligament and gastrocolic omentum are more likely to undergo chronic lengthening by traction than the other attachments of the stomach. Mesenteroaxial volvulus requires the gastro-oesophageal junction and pylorus to be sufficiently mobile as to come into close approximation. These structures are firmly tethered and consequently this form of gastric volvulus is much less common. Despite the profuse gastric arterial supply, either type of volvulus may compromise the vascularity of the stomach.

Gastric surfaces

When the stomach is empty and contracted, the two surfaces tend to lie facing almost superiorly and inferiorly, but with increasing degrees of distension they come to face progressively more anteriorly and posteriorly (Fig. 65.4).

Full

Fig. 65.4 Axes of the empty and full stomach. As the stomach distends, the greater curvature 'rolls' downwards and the anterosuperior surface comes to lie almost completely vertical as the anterior surface.

Anterior (superior) surface

The lateral part of the anterior surface is posterior to the left costal margin and in contact with the diaphragm, which separates it from the left pleura, the base of the left lung, the pericardium and the left sixth to ninth ribs (Fig. 65.5). It lies posterior to the costal attachments of the upper fibres of transversus abdominis, which separate it from the seventh to ninth costal cartilages. The upper and left part of this surface curves posterolaterally and is in contact with the gastric surface of the spleen. The right half of the anterior surface is related to the left and quadrate lobes of the liver and the anterior abdominal wall. When the stomach is empty, the transverse colon may lie adjacent to the anterior surface. The entire anterior (superior) surface is covered by peritoneum.

Fig. 65.5 Anterior relations of the stomach, viewed from behind. The fibres of the diaphragm (oblique), transversus abdominis (transverse) and rectus abdominis (vertical) can be seen through the outlines of the stomach and its visceral relations.

Posterior (inferior) surface

The posterior surface lies anterior to the left crus and lower fibres of the diaphragm, the left inferior phrenic vessels, the left suprarenal gland, the superior pole of the left kidney, the splenic artery, the anterior pancreatic surface, the splenic flexure of the colon and the upper layer of the transverse mesocolon (Fig. 65.3). Together these form the shallow stomach bed: they are separated from the stomach by the lesser sac (over which the stomach slides as it distends). The upper left part of the surface curves anterolaterally and lies in contact with the gastric surface of the spleen. The greater omentum and the transverse mesocolon separate the stomach from the duodenojejunal flexure and ileum. The posterior surface is covered by peritoneum, except near the cardiac orifice, where a small, triangular area contacts the left diaphragmatic crus and sometimes the left suprarenal gland. The left gastric vessels reach the lesser curvature at the right extremity of this bare area in the left gastropancreatic fold. The gastrophrenic ligament passes from the lateral aspect of this bare area to the inferior surface of the diaphragm.

GASTRIC ORIFICES

Cardiac orifice and gastro-oesophageal junction

The opening from the oesophagus into the stomach is the cardiac orifice (Fig. 65.1). It is typically situated to the left of the midline behind the seventh costal cartilage at the level of the eleventh thoracic vertebra. It is typically 10 cm from the anterior abdominal wall and 40 cm from the incisor teeth. The abdominal oesophagus is continuous with the cardiac orifice; the right side is continuous with the lesser curvature, the left side with the greater curvature. There is no specific anatomically discernible cardiac sphincter related to the orifice.

Internally, the transition between oesophagus and stomach is difficult to define because mucosa of gastric fundal pattern extends a variable distance up into the abdominal oesophagus. It usually forms a ‘zig-zag’ squamo-columnar epithelial junction with the oesophageal epithelium above this Z line: for histological and endoscopic purposes, this is often referred to as the gastro-oesophageal junction. A sling of longitudinal and oblique gastric muscle fibres forms a loop on the superior, left, side of the gastro-oesophageal junction between the oesophagus and the lesser curvature, and this is taken as the external boundary of this junction. Bands of thickened circular smooth muscle in the upper wall of the greater curvature and the distal oesophagus are sometimes confusingly referred to as ‘clasp’ or ‘sphincter’ fibres.

Lower oesophageal sphincter and gastro-oesophageal reflux

At rest there is a gastro-oeosophageal pressure gradient due to the presence of negative intra-thoracic pressure (transferred to the thoracic oesophagus) and positive intra-abdominal pressure (transferred to the stomach and augmented by any contraction of the stomach wall itself). Several anatomical and physiological factors normally prevent gastro-oesophageal reflux. Minor factors include the folds of gastric mucosa present in the gastro-oesophageal junction, the mucosal rosette, which contribute to the formation of a fluid-

and gas-tight seal and also help to ensure that even low levels of tone within the lower oesophageal wall muscles may occlude the lumen of the junction against low pressures of gastric gas; the angle of the cardiac orifice, which is formed, in part, by the pull of the long oblique fibres of the inner layer of the gastric smooth muscle and may help to form a type of ‘flap valve’; and the length of the abdominal oesophagus, which is buttressed externally by pads of adipose connective tissue at and below the level of the diaphragmatic hiatus. However, the major anti-reflux mechanisms are the tonic contractions of the specialized smooth muscle of the wall lower oesophageal and the encircling fibres of the right diaphragmatic crus, which, together, exert a radial pressure that can be measured by electromyography or manometric testing (Paterson 2001, Mittal 2006), and form an effective high pressure zone (HPZ). At and just below the level of the entry of the abdominal oesophagus into the stomach, the circular fibres of the intermediate layer of the muscularis externa lying over the upper lesser curvature are particularly pronounced and sometimes referred to as ‘clasp’ fibres and exert fairly constant myogenic tone (Fig. 65.6). Since the oesophagus passes obliquely into the stomach, with increasing gastric distension the tone in the clasp fibres rises and they may act to draw the anterior and posterior surfaces together, increasing the tone at the gastro-oesophageal junction, contributing to the HPZ. These anatomical and physiological features are together referred to as the lower oesophageal sphincter (LOS). If reflux is to be prevented, the pressure within the HPZ must exceed the difference between the pressures on either side of the junction. The oesophageal part of the LOS is controlled by the intramural plexuses of the enteric nervous system via the neural release of nitric oxide which relaxes the smooth muscle of the LOS. Tone is reduced in advance of the oesophageal peristaltic wave during swallowing and raised again after the food bolus has passed. During inspiration, the greater negative intrathoracic pressure which increases the gastro-oesophageal pressure gradient is offset by increased pressure in the HPZ due to contraction of the peri-oesophageal fibres of the right diaphragmatic crus. Activation of the crural diaphragm slightly before the costal fibres ensures that this increase precedes the increase in the gradient.

Reflux of gastric contents into the abdominal and lower thoracic oesophagus as a result of transient relaxation of the LOS occurs as a normal event in most individuals for a small percentage of their daily life. It also occurs as a result of a weak LOS, or of hiatus hernia which disrupts the normal anatomical barriers. Surgical procedures to prevent excessive reflux mainly focus on the restoration of a normal length of intra-abdominal oesophagus, by reduction of any hiatus hernia which carries the gastro-oesophageal junction into the thorax, and an increase in the tonic contraction surrounding the intra-abdominal oesophagus, which is usually achieved by partial wrapping of the fundus of the stomach around the intra-abdominal oesophagus to provide greater tone, 'fundoplication'.

Barrett's oesophagus

The squamous epithelium lining the lower oesophagus may be pathologically replaced by islands, strips, or circumferential patches of columnar, gastric type epithelium. This process is most likely to be the result of chronic reflux of gastric contents, acid or alkali, into the oesophagus, inducing a change in mucosal cell type. The abnormal columnar type epithelium, which may extend for a variable length up the lower part of the oesophagus, is referred to as Barrett's epithelium.

Pyloric orifice

The pyloric orifice is the opening from the stomach into the duodenum, and typically lies 1–2 cm to the right of the midline in the transpyloric plane when the body is supine and the stomach empty. The pyloric sphincter is a muscular ring formed by a marked thickening of the circular gastric muscle interlaced with some longitudinal fibres. The circular pyloric constriction on the surface of the stomach usually indicates the location of the pyloric sphincter, and is often marked by a prepyloric vein which crosses the anterior surface vertically downwards.

GASTRIC FORM AND INTERNAL APPEARANCES

Numerous factors influence both the form and position of the stomach, including the posture and build of the individual, the extent of filling of the stomach, the position of the surrounding viscera, and the tone of the abdominal wall and gastric musculature. The empty stomach is most commonly J-shaped, the fundus usually contains gas, and, in the erect posture, the pylorus descends to the level of the second or the third lumbar vertebra. The lowest part of the antrum often lies below the level of the umbilicus, and the overall axis of the organ is slightly inclined from the vertical (Fig. 65.7). In short, obese individuals, the axis of the stomach lies more towards the horizontal as a ‘steer-horn’ shape.

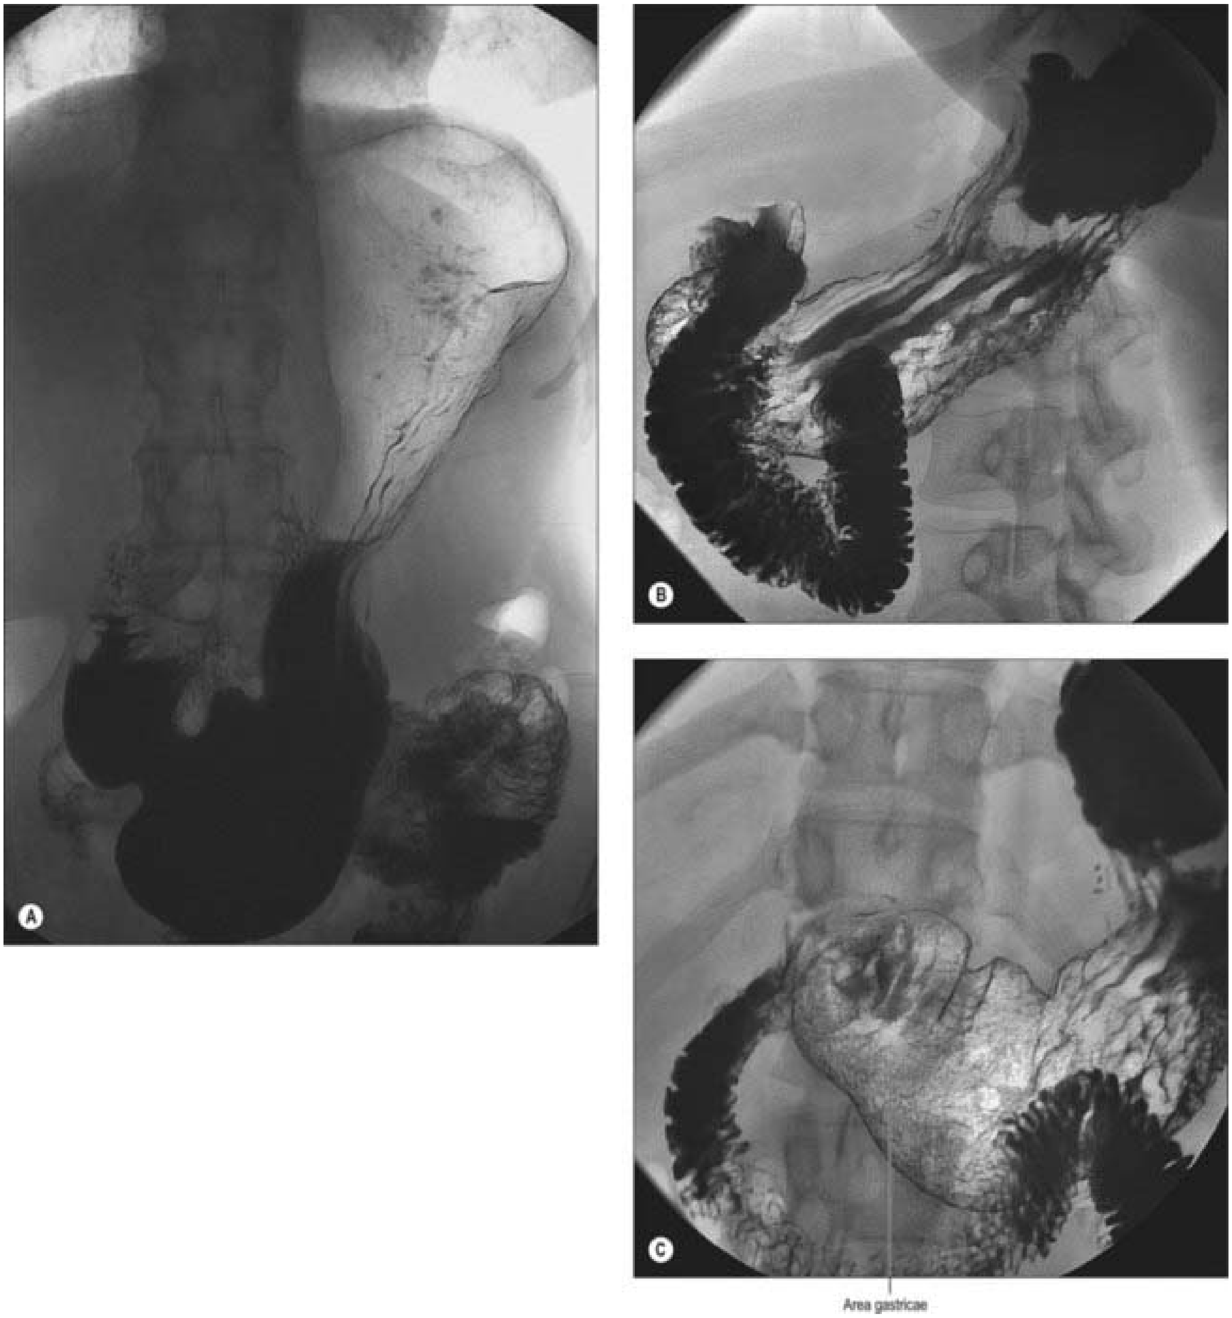

Fig. 65.7 Double contrast barium meal. **A**, In the erect position the stomach has a more ‘J’-shaped configuration. **B**, Initial stomach filling demonstrates a horizontally lying stomach with prominent gastric rugal folds. **C**, The area gastricae within the antrum are clearly identified on distension of the stomach.

The extent of filling mainly affects the shape and position of the body, because the pyloric part usually remains contracted during digestion. As the stomach fills, it expands forwards and downwards but, when the colon or small bowel is distended, the fundus enlarges towards the liver and diaphragm. As stomach capacity increases, the pylorus is displaced to the right and the axis of the whole organ lies in a more oblique direction. In this position the anterior and posterior surfaces tend to face forwards and backwards and the lowest part is the pyloric antrum, which extends below the umbilicus. When intestinal distension interferes with downward expansion of the body, the stomach retains a horizontal position.

Internal appearances

During endoscopic examination (Fig. 65.8), the stomach is typically at least partially distended by air. The cardiac orifice and the lowest portion of the abdominal oesophagus viewed from above are typically closed at rest by tonic contraction of the lower oesophageal musculature. The gastric mucosa lining the orifice is puckered into ridges and is present for a short but variable distance up the abdominal oesophagus; the transition between columnar and squamous epithelium is usually clearly visible. The presence of abnormal columnar epithelium within the oesophagus is referred to as Barrett's oesophagus but the precise definition of this condition is difficult (see above). From within the distended stomach, the cardiac orifice appears in the medial wall of the fundus and is asymmetrical. The medial edge of the cardiac orifice is continuous with the medial wall of the body of the stomach. The mucosa is slightly thickened at this point with a raised profile, forming part of the 'mucosal rosette' that lines the orifice. The 'rosette' aids closure of the cardiac orifice and helps prevent reflux of stomach contents into the oesophagus. The medial edge of the orifice is more clearly visible than the lateral edge because it forms a more acute angle with the mucosal lining of the abdominal oesophagus.

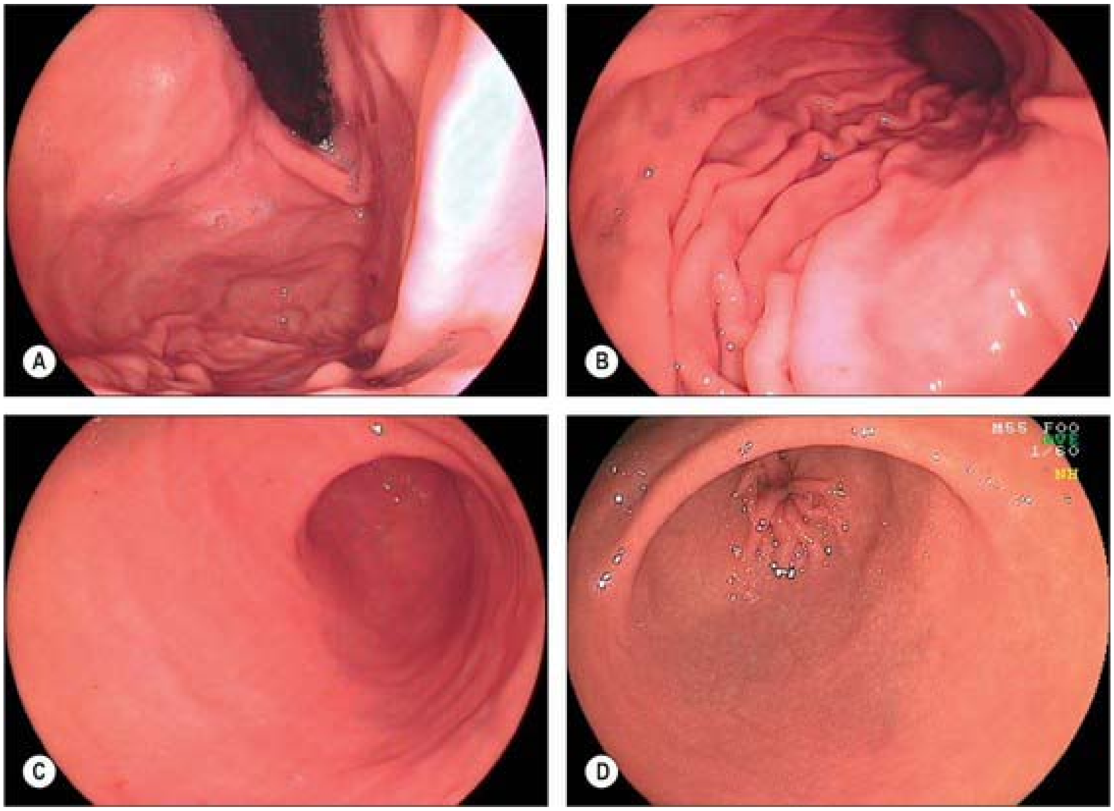

Fig. 65.8 Endoscopic appearances of the stomach. **A**, Cardiac orifice and fundus from below showing the pronounced lateral mucosal fold at the cardiac orifice; **B**, Body and greater curvature showing mucosal folds (‘magenstrasse’); **C**, Antrum showing the internal appearance of the incisura angularis; **D**, Prepyloric antrum and opening of the pyloric canal.

In the partly distended stomach, the mucosa of the fundus is thrown into gentle folds with no particular pattern (rugae). As the stomach fills towards capacity, these folds rapidly become less pronounced, and the wall is nearly smooth when the stomach is over-inflated. The body of the stomach has the most pronounced mucosal folds. Even in moderate distension, they appear as long, broad mucosal ridges running in sinuous strips from fundus to pyloric antrum (Fig. 65.7). They are seen on all mucosal surfaces of the body but are most obvious on the anterolateral, lateral and posterolateral parts (which correspond to the inner surface of the anterior and posterior external surfaces and to the greater curvature). Here they are occasionally called the *magenstrasse*, a reference to their possible role in directing liquid entering the stomach immediately down into the pyloric antrum. These folds are least prominent on the medial surface (corresponding to the inner surface of the lesser curvature), which is much smoother, particularly when the stomach distends.

The areae gastricae within the antrum are small elevations or puckerings of the mucosal surface that are readily seen on double contrast barium meal (Fig. 65.7). The few folds present in the antrum when the stomach is relaxed disappear with distension. The antrum adjacent to the pyloric canal, the prepyloric antrum, has a smooth mucosal surface that culminates in a slight puckering of the mucosa at the pyloric orifice caused by the contraction of the pyloric sphincter.

Gastrostomy

Since the lower body and antrum of the stomach is related to the posterior aspect of the left anterior abdominal wall, it may usefully be accessed to form a gastrostomy. Its mobility enables the anterior surface of the stomach to be readily approximated to the parietal peritoneum on the posterior surface of the abdominal wall, and a communication to be established between the lumen of the stomach and the surface of the skin. Although this may be performed as a direct open surgical procedure under general anaesthetic, it is much more commonly performed using a percutaneous puncture guided by either endoscopic visualization of the stomach or radiological imaging. The procedure is made easier by the fact that the anterior surface of the stomach lies most nearly in the vertical plane when the stomach is distended. One of the main hazards of the procedure results from the occasional interposition of the transverse colon between the stomach and anterior abdominal wall, which may lead to inadvertent transfixion of the colon by the needle puncture system. The variable length of the transverse colonic mesentery means that it may sometimes lie adjacent to the anterior gastric surface when a subject is recumbent. These risks may be reduced by radiological guidance.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply to the stomach comes predominantly from the coeliac axis although intramural anastomoses exist with vessels of other origins at the two ends of the stomach (Figs 65.9, 65.10, 65.11). The left gastric artery arises directly from the coeliac axis. The splenic artery gives origin to the short gastric arteries as well as the left gastroepiploic artery and may occasionally give origin to a posterior gastric artery. The hepatic artery gives origin to the right gastric artery and to the gastroduodenal artery, which in turn gives origin to the right gastroepiploic artery.

Fig. 65.11 Principle variations in the gastric arterial supply. Accessory vessels or possible replaced origins of vessels are shown by pale pink lines.

Left gastric artery

The left gastric artery is the smallest branch of the coeliac axis. It ascends to the left of the midline and crosses either just over the lower end of or below the level of the origin of the left crus of the diaphragm beneath the peritoneum of the upper posterior wall of the lesser sac. Here it lies adjacent to the left inferior phrenic artery and medial or anterior to the left suprarenal gland. It runs forwards into the superior portion of the lesser omentum adjacent to the superior end of the lesser curvature, and turns anteroinferiorly to run along the lesser curvature between the two peritoneal leaves of the lesser omentum. At the highest point of its course, it gives off one or more oesophageal branches. In its course along the lesser curvature, it gives off multiple branches that run onto the anterior and posterior surfaces of the stomach and anastomose with the right gastric artery in the region of the incisura angularis.

The left gastric artery rarely arises from the common hepatic artery or its branches. The most common of these rare variations is an origin from the left hepatic artery, when the left gastric artery passes between the peritoneal layers of the superior lesser omentum to reach the lesser curvature of the stomach. Other variants include a common origin with the common hepatic artery. (A replaced/accessory left hepatic artery origin from the left gastric artery is more common than a replaced/accessory left gastric origin.)

Short gastric arteries

There is no universally accepted definition of what constitutes the short gastric arteries but a practical definition is ‘vessels which supply the fundus of the stomach above the level of the splenic artery and which arise to the left of the greater curvature of the stomach’. The short gastric arteries are variable in number, commonly between five and seven. They arise from the splenic artery or its divisions, or from the proximal left gastroepiploic artery, and pass between layers of the gastrosplenic ligament to supply the cardiac orifice and gastric fundus. They anastomose with branches of the left gastric and left gastroepiploic arteries. An accessory left gastric artery may arise with these vessels from the distal splenic artery.

Left gastroepiploic artery

The left gastroepiploic artery is the largest branch of the splenic artery. It arises near the splenic hilum and runs anteroinferiorly between the layers of the gastrosplenic ligament into the upper gastrocolic omentum. It lies between the layers of peritoneum close to the greater curvature, running inferiorly to anastomose with the right gastroepiploic artery. It gives off gastric branches to the fundus of the stomach through the gastrosplenic ligament, and to the body of the stomach through the gastrocolic omentum. These are necessarily longer than the gastric branches of the right gastroepiploic artery and may be 8–10 cm long. Epiploic (omental) branches arise along the course of the vessel and descend between the layers of the gastrocolic omentum into the greater omentum. A particularly large epiploic branch commonly originates close to the origin of the left gastroepiploic artery, descends in the lateral portion of the greater omentum and provides a large arterial supply to the lateral half of the omentum.

Posterior gastric artery

A distinct posterior gastric artery may occur. When present, it arises from the splenic artery in its middle section posterior to the body of the stomach (Fig. 65.11). It ascends behind the peritoneum of the lesser sac towards the fundus and reaches the posterior surface of the stomach in the gastrophrenic fold.

Right gastric artery

The right gastric artery arises from the hepatic artery as it passes forwards from the posterior wall of the lesser sac into the lower border of the lesser omentum above the first part of the duodenum. It runs between the peritoneal layers of the lesser omentum just above the medial end of the lesser curvature, passes superiorly along the lesser curvature, giving off multiple branches onto the anterior and posterior surfaces of the stomach, and anastomoses with the left gastric artery.

The origin of the right gastric artery often varies: the most common alternative origins are from the common hepatic, left hepatic, gastroduodenal or supraduodenal arteries.

Gastroduodenal artery

The gastroduodenal artery arises from the common hepatic artery posterior and superior to the first part of the duodenum. It gives origin to the right gastroepiploic and superior pancreaticoduodenal arteries at the lower border of the first part of the duodenum. (For details of the gastroduodenal artery and its relevance to clinical situations, see Chapter 66.)

Right gastroepiploic artery

The right gastroepiploic artery originates from the gastroduodenal artery behind the first part of the duodenum, anterior to the head of the pancreas. It passes inferiorly towards the midline between the layers of the gastrocolic omentum, lies inferior to the pylorus, then runs laterally along the greater curvature and ends by anastomosing with the left gastroepiploic artery. It is adjacent to the pylorus but, more distally, lies approximately 2 cm from the greater curvature of the stomach. The right gastroepiploic artery gives off gastric branches that ascend onto the anterior and posterior surfaces of the antrum and lower body of the stomach, epiploic branches that descend into the greater omentum, and branches that contribute to the supply of the inferior aspect of the first part of the duodenum.

Arterial anastomoses of the stomach

There is an anastomosis between the oesophageal arteries originating from the thoracic aorta and the vessels that supply the fundus in the region of the cardiac orifice. At the pyloric orifice the extensive network of vessels supplying the duodenum allows for some anastomosis between vessels of superior mesenteric artery origin and the pyloric vessels. The major named vessels supplying the stomach form extensive arterial anastomoses both on the serosal surface and around the curvatures. The right and left gastroepiploic arteries and the left and right gastric arteries anastomose freely with each other along the greater and lesser curvatures respectively. Anastomoses also form between the short gastric and left gastric arteries in the region of the fundus, and between the right gastric and right gastroepiploic arteries in the region of the antrum. In addition to the extensive serosal anastomoses, networks form within the stomach wall at intramuscular, submucosal and mucosal levels. A true plexus of small arteries and arterioles is present within the submucosa: it supplies the mucosa and shows considerable regional variation both in the gastric wall and in the proximal duodenum. The rich arterial supply to the stomach ensures that the high mucosal blood flow required for physiological functioning is maintained even if one or more vessels become occluded: the stomach exhibits considerable resistance to ischaemia even when multiple arterial supplies are lost.

The pyloric arteries are rami of the right gastric and right gastroepiploic arteries. They pierce the duodenum distal to the sphincter around its entire circumference and pass through the muscular layer to the submucosa where they divide into two or three rami. The latter turn back into the pyloric canal beneath the mucosa and run to the end of the pyloric antrum: they supply the entire mucosa of the pyloric canal (Fig. 65.12). Branches of the pyloric submucosal arteries may anastomose close to their origin with the duodenal submucosal arteries, and their terminal rami also anastomose with gastric arteries from the prepyloric antrum. The pyloric sphincter is supplied by the gastric and pyloric arteries via rami that leave their parent vessels in the subserosal and submucosal levels to penetrate the sphincter.

Dieu la Foy lesions

Abnormalities of the intramural vascularity of the stomach are a rare cause of bleeding from the upper gastrointestinal tract. So-called ‘Dieu la Foy’ lesions commonly occur in the proximal body or fundus. Originally thought to be small arteriovenous malformations of the submucosal plexus, they are now considered to be caused by a larger than normal penetrating arterial vessel running through the muscular coat of the stomach into the submucosa before branching into the submucosal plexus.

Veins

The veins draining the stomach ultimately empty into the portal vein. A rich submucosal and intramural venous network gives rise to veins that usually accompany the corresponding named arteries and drain into either the splenic or superior mesenteric veins, although some pass directly into the portal vein. The course and distribution of the veins is highly variable even up to the level of the major named vessels.

Short gastric veins

Four or five short gastric veins drain the gastric fundus and the upper part of the greater curvature into the splenic vein or one of its large tributaries.

Left gastroepiploic vein

The left gastroepiploic vein drains both anterior and posterior surfaces of the body of the stomach and the adjacent greater omentum via multiple tributaries. It runs superolaterally along the greater curvature, between the layers of the gastrocolic omentum, and drains into the splenic vein within the gastrosplenic ligament.

Right gastroepiploic vein

The right gastroepiploic vein drains the greater omentum, distal body and antrum of the stomach. It passes medially, inferior to the greater curvature, in the upper portion of the gastrocolic omentum. Just proximal to the pyloric constriction it passes posteriorly to drain into the superior mesenteric vein below the neck of the pancreas. The right gastroepiploic vein may receive the superior pancreaticoduodenal vein close to its entry into the superior mesenteric vein.

Left gastric vein

The left gastric vein drains the upper body and fundus of the stomach. It ascends along the lesser curvature to the oesophageal opening where it receives several lower oesophageal veins, then curves posteriorly and medially behind the posterior peritoneal surface of the lesser sac. It drains into the portal vein directly at the level of the upper border of the first part of the duodenum.

Right gastric vein

The right gastric vein is typically small and runs along the medial end of the lesser curvature, passing under the peritoneum as it is reflected from the posterior aspect of the pylorus and first part of the duodenum onto the posterior wall of the lesser sac. It drains directly into the portal vein at the level of the first part of the duodenum. It receives the prepyloric vein as it ascends anterior to the pylorus at the level of the pyloric opening.

Posterior gastric veins

Distinct posterior gastric veins may occur, sometimes as multiple small vessels. When present, they accompany the posterior gastric artery from the middle of the posterior surface of the stomach and drain into the splenic vein.

Oesophageal and gastric varices

Blood from the mucosa normally drains into a superficial venous plexus, then into a deeper intrinsic venous plexus and finally into the peri-oesophageal veins via perforating veins. In the abdominal oesophagus the perforating veins drain into tributaries of the left gastric veins; in the lower thoracic oesophagus they form tributaries of the azygos and hemiayzgos systems. Bidirectional flow is possible in this region, and accommodates pressure changes that occur during breathing and Valsalva manoeuvres.

Varices are progressive dilatations which occur predominantly in the submucosal plexus of the distal abdominal oesophagus and occasionally on the gastric side of the gastric orifice at portal venous pressures above 15 mmHg. Portal venous hypertension, of any cause, predisposes to the opening up of pre-existing embryonic venous channels between venous tributaries of the portal system and the systemic venous circulation (Paquet 2000), such as the venous plexuses which exist in the lower abdominal oesophagus and gastric orifice. In portal hypertension, the valves within the perforating vessels become incompetent, permitting retrograde flow, and this causes variceal dilatation of the deep and superficial veins. Varices in the distal oesophagus are often easily visible at endoscopy, because they are situated superficially in the lamina propria and protrude into the oesophageal lumen; they are a frequent cause of substantial upper gastrointestinal bleeding. Spontaneous cessation of the bleeding is less common than at other sites, in part because the pressure and the flow rate within the veins is high, but also because there is a relative lack of submucosal supporting connective tissue to allow for venous contraction and thrombosis. Gastric varices are often present on the inferior aspect of the gastric orifice. They present less commonly in clinical practice than oesophageal varices, are less easy to diagnose because of their location, and occasionally exist without the presence of oesophageal varices. In these circumstances, it may be that the embryonal ‘point of meeting’ between portal and systemic venous systems is lower than usual and occurs in the upper stomach rather than the lower oesophagus.

Lymphatic drainage

The stomach has a rich network of lymphatics that connect with lymphatics draining the other visceral organs of the upper abdomen. At the gastro-oesophageal junction the lymphatics are continuous with those draining the lower oesophagus, and in the region of the pylorus they are continuous with those draining the duodenum. In general, they follow the course of the arteries supplying the stomach. However, many separate groups of nodes are now recognized (Fig. 65.13), and their relationship to the regions of the stomach and the vascular territories supplied, is of great importance during resection of the stomach, particularly for malignancy. Pancreatic and hepatic lymphatics play a significant role in draining areas of the stomach during disease.

Gastrectomy and gastric lymphadenectomy

Surgery for gastro-oesophageal malignancy involves varying degrees of radical resection of the associated lymph nodes that potentially drain the tumour area. The wide ramification of the gastro-oesophageal lymph node drainage and the multiple possible nodes which may be involved in a tumour inevitably mean that the extent of lymphadenectomy undertaken may be wide. The extent of possible/actual nodal involvement by the tumour is classified as N1 (loco-regional nodes specific to the tumour site), N2 (regional and major named vessel nodes draining the tumour) and N3 (wider draining nodes including para-aortic nodes). Gastrectomies can be classified according to the node groups excised for the tumour: D1 (e.g. removal of the portion of the stomach involved and the local lymph nodes directly related to the arteries ligated), D2 (e.g. total gastrectomy including all gastric lymph node groups often including the spleen) and D3 (e.g. total gastrectomy plus extensive lymphadenectomy that includes the associated upper abdominal lymph nodes, namely pancreatic, superior mesenteric, coeliac, hepatic and transverse colic). (For details of the lymph node stations relevant to surgical gastric resection, see Japanese Gastric Cancer Association 1998 and UICC 1997.)

INNERVATION

The stomach is innervated by sympathetic and parasympathetic fibres.

Sympathetic innervation

The sympathetic supply to the stomach originates from the fifth to 12th thoracic spinal segments, and is mainly distributed to the stomach via the greater and lesser splanchnic nerves via the coeliac plexus. Periarterial plexuses form along the arteries and supply the stomach from the coeliac axis. Additional innervation comes from fibres of the hepatic plexus, which pass to the upper body and fundus via the upper limit of the lesser omentum and via direct branches from the greater splanchnic nerves.

The gastric sympathetic nerves are vasoconstrictor to the gastric vasculature and inhibitory to gastric musculature. The sympathetic supply to the pylorus is motor, and brings about pyloric constriction. The sympathetic supply also conducts afferent impulses that mediate sensations, including pain.

Parasympathetic innervation

The parasympathetic supply to the stomach is from the anterior and posterior vagus nerves (Fig. 65.14). The anterior vagus (formed mainly from fibres from the left vagus originating from the oesophageal plexuses) is often double or even triple and supplies filaments to the cardiac orifice. The nerve lies very closely applied to the outer muscle of the abdominal oesophagus and divides near the oesophageal end of the lesser curvature into gastric and pyloric/hepatic branches. The upper anterior gastric branches radiate on the anterior surface of the upper body and fundus. The main gastric branch is termed the greater anterior gastric nerve and lies in the lesser omentum near the lesser curvature; branches from this nerve pass to the body and antrum with the gastric arterial supply branches. Hepatic/pyloric branches (generally one main and possibly one accessory) originate below the cardiac orifice. The main hepatic/pyloric nerve runs between the peritoneal layers of the lesser omentum almost horizontally towards its free edge to reach the hilum of the liver where hepatic branches ramify and pyloric branches turn down on the left side of the hepatic artery to reach the pylorus. The second nerve usually arises from the greater anterior gastric nerve during its course and runs inferomedially to the pyloric antrum where pyloric (and antral) branches form and hepatic branches (one or two) run superiorly to contribute to the hepatic plexus. Variations in the anterior nerve include accessory pyloric branches, long gastric branches with a high lying nerve trunk and a low origin of the pyloric branch with a low lying nerve trunk.

Fig. 65.14 Distribution of the vagal nerves to the stomach. The two commonest variations in the anterior vagus are shown in pink. **A**, Multiple main trunks. **B**, Low origin of the hepatic/pyloric branch lying close to the lesser curvature.

The posterior nerve tends to lie more medial than the anterior and is often a short distance from the wall of the abdominal oesophagus. It produces two main groups of branches, gastric and coeliac. Gastric branches arise and then run behind the cardiac orifice and upper body of the stomach. They extend over the posterior surface of the body and fundus to the proximal antrum but do not normally reach the pyloric sphincter. The largest is termed the greater posterior gastric nerve and runs posteriorly along the lesser curvature. Large coeliac branches (one or more) arise from the posterior nerve as thick bundles which carry the majority of fibres forming the nerve to the coeliac plexus (and onwards). Hepatic branches (one or two) are often small and originate from the coeliac branches. No true plexus occurs on either the anterior or posterior gastric surfaces, but plexuses are present in the submucosa and between the layers of the muscularis externa.

The parasympathetic gastric supply is secretomotor to the gastric mucosa and motor to the gastric musculature. It is responsible for coordinated relaxation of the pyloric sphincter during gastric emptying.

Referred pain

The majority of the sensation of pain arising from the stomach is poorly localized, and in common with other structures of foregut origin, is referred to the central epigastrium. Pain arising from the region of the gastro-oesophageal junction is commonly referred to the lower retrosternal and subxiphoid areas.

MICROSTRUCTURE

The gastric wall consists of the major layers found elsewhere in the gut, i.e. mucosa, submucosa, muscularis externa and serosa, together with gastric vessels and nerves (Figs 65.15, 65.16). The microstructure reflects the functions of the stomach as an expandable muscular sac lined by secretory epithelium, although there are local structural and functional variations in this pattern.

A muscularis mucosae layer and submucosa follow the contours of the rugae. Part of the external muscularis layers is seen below left.

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Mucosa

The mucosa is a thick layer with a soft, smooth surface that is mostly reddish brown in life but pink in the pyloric region. In the contracted stomach the mucosa is folded into numerous folds or rugae, most of which are longitudinal. They are most marked towards the pyloric end and along the greater curvature. The rugae represent large folds in the submucosal connective tissue (see below) rather than variations in the thickness of the mucosa covering them, and they are obliterated when the stomach is distended. As elsewhere in the gut, the mucosa is composed of a surface epithelium, lamina propria and muscularis mucosae.

Epithelium

When viewed microscopically at low magnification, the internal surface of the stomach wall appears honeycombed by small, irregular gastric pits approximately 0.2 mm in diameter (Figs 65.15, 65.16). The base of each gastric pit receives several long, tubular gastric glands that extend deep into the lamina propria as far as the muscularis mucosae. Simple columnar mucus-secreting epithelium covers the entire luminal surface including the gastric pits, and is composed of a continuous layer of surface mucous cells which release gastric mucus from their apical surfaces to form a thick protective, lubricant layer over the gastric lining. This epithelium commences abruptly at the cardiac orifice, where there is a sudden transition from oesophageal stratified squamous epithelium.

Gastric glands

Although all gastric glands are tubular, they vary in form and cellular composition in different parts of the stomach. They can be divided into three groups – cardiac, principal and pyloric. The most highly specialized are the principal glands.

Principal gastric glands

The principal glands are found in the body and fundus, three to seven opening into each gastric pit. Their junction with the base of the pit is the isthmus, immediately basal to this is the neck, and the remainder is the base. The walls of the gland contain at least five distinct cell types: chief, parietal, mucous neck, stem and neuroendocrine.

Chief (peptic) cells (Fig. 65.15) are the source of the digestive enzymes pepsin and lipase. They are usually basal in position and cuboidal in shape, and their nuclei are rounded and euchromatic. They contain secretory zymogen granules and their abundant cytoplasmic RNA renders them strongly basophilic. Parietal (oxyntic) cells are the source of gastric acid and of intrinsic factor, a glycoprotein necessary for the absorption of vitamin B_{12}. They are large, oval and strongly eosinophilic, and have centrally placed nuclei. Parietal cells occur intermittently along the walls of the more apical half of the gland, but can reach as far as the isthmus; they bulge laterally into the surrounding connective tissue. They have a unique ultrastructure related to their ability to secrete hydrochloric acid. The luminal side of the cell is deeply invaginated to form a series of blind-ended channels (canaliculi) that bear numerous irregular microvilli covered by a plasma membrane rich in H^+/K^+ ATPase antiporter channels. The latter actively secrete hydrogen ions into the lumen; chloride ions follow along the electrochemical gradient. The mitochondria-rich cytoplasm facing these channels contains a tubulo-vesicular system of abundant fine membranous tubules directed towards the canalicular surface. The precise structure of the cell varies with its secretory phase: when stimulated, the number and surface area of the microvilli increases up to five-fold, probably as a result of the rapid fusion of the tubulo-vesicular system with the plasma membrane. This process is reversed at the end of stimulated secretion, when the excess membrane retreats back into the tubulo-alveolar system and microvilli are lost.

Mucous neck cells are numerous at the necks of the glands and are scattered along the walls of the more basal regions. They are typical mucus-secreting cells, displaying apical secretory vesicles containing mucins, and basally displaced nuclei: their products are distinct histochemically from those of the superficial mucous cells.

Stem cells are relatively undifferentiated mitotic cells from which the other types of gland cell are derived. They are relatively few in number, and are situated in the isthmus of the gland and the bases of the gastric pits. Stem cells are columnar and possess a few short apical microvilli. They periodically undergo mitosis; their progeny migrate either apically, to differentiate into new surface mucous cells, or basally, to form mucous neck, parietal, chief or neuroendocrine cells. All of these cells have a limited lifespan, especially the mucus-secreting types, and so they are constantly replaced. The typical replacement period for surface mucous cells is 3 days, and for mucous neck cells is 1 week. Other cell types appear to live much longer.

Neuroendocrine (enteroendocrine) cells occur in all types of gastric gland, but more frequently in the body and fundus of the stomach. They are situated mainly in the deeper parts of the glands, among the chief cells. They are basally situated, pleomorphic cells and display irregular nuclei surrounded by granular cytoplasm that contains clusters of large (0.3 μm) secretory granules. Neuroendocrine cells synthesize a number of biogenic amines and polypeptides that are important in the control of gut motility and glandular secretion. They are part of the system of dispersed neuroendocrine cells: in the stomach they include G cells, which secrete gastrin; D cells, which secrete somatostatin; and ECL (enterochromaffin-like) cells, which secrete histamine.

Cardiac glands

Cardiac glands are confined to a small area near the cardiac orifice: some are simple tubular glands, others are compound branched tubular. Mucus-secreting cells predominate; parietal and chief cells are present, but sparse.

Pyloric glands

Pyloric glands empty via groups of two or three short convoluted tubes into the bases of the deep gastric pits of the pyloric antrum: the pits occupy about two-thirds of the mucosal depth (Fig. 65.17). The glands are populated mainly by mucus-secreting cells, but they also contain neuroendocrine cells, especially G cells, which secrete gastrin when activated by appropriate mechanical stimulation (causing increased gastric motility and secretion of gastric juices). Although parietal and chief cells are scarce, parietal cells are always present in both fetal and postnatal pyloric glands, and may also appear in the duodenal mucosa, proximally near the pylorus, in adult tissue.

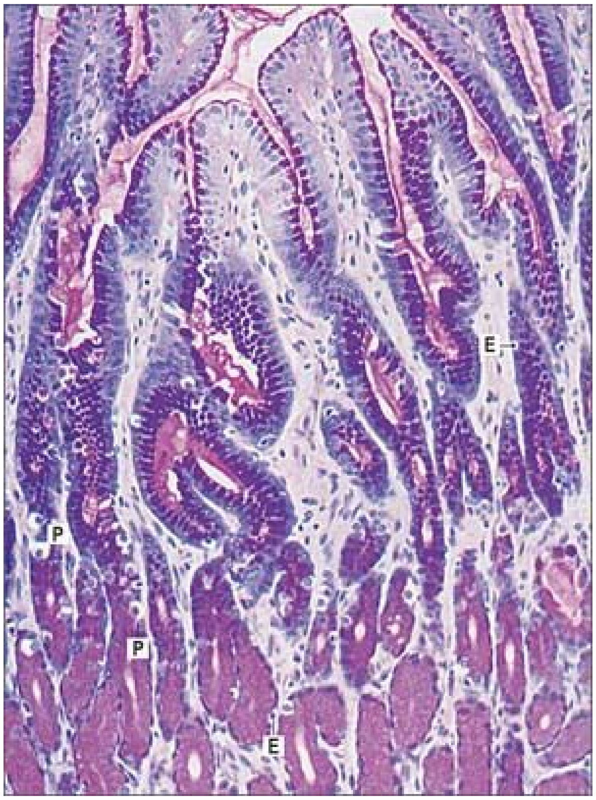

Fig. 65.17 Micrograph showing the pyloric region of the stomach. Pyloric glands are stained with the periodic acid-Schiff (PAS) technique to show mucin (magenta) in the gastric pits and glands. Pale staining cells are the larger parietal cells (P) and smaller enteroendocrine cells (E).

(By permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)

Lamina propria

The lamina propria forms a connective tissue framework between the glands. It contains small masses of lymphoid tissue, gastric lymphatic follicles, which resemble solitary intestinal follicles (especially in early life). It also contains a complex periglandular vascular plexus involved in the maintenance of the mucosal environment, e.g. the removal of bicarbonate produced in the tissues as a counterpart to acid secretion, and neural plexuses rich in both sensory and motor terminals.

Muscularis mucosae

The muscularis mucosae is a thin layer of smooth muscle fibres lying external to the layer of glands, arranged as continuous inner circular and outer longitudinal layers, and a discontinuous external circular layer. The inner layer sends strands of smooth muscle cells between the glands: their contraction probably assists in emptying into the gastric pits.

Submucosa

The submucosa is a variable layer of loose connective tissue. It contains thick bundles of collagen, numerous elastin fibres, blood vessels and nervous plexuses, including the ganglionated submucosal (Meissner's) plexus.

Muscularis externa

The muscularis externa is a thick muscle coat immediately under the serosa, with which it is closely connected by subserous loose connective tissue. From innermost outwards, it contains oblique, circular and longitudinal layers of smooth muscle fibres. The layers are not always easily separated: the circular layer is poorly developed in the oesophageal region, but is thickened at the distal pyloric antrum to form the anular pyloric sphincter; the outer longitudinal layer is most pronounced in the upper two-thirds of the stomach; the inner oblique layer is most obvious in the lower half.

The actions of the muscularis externa of the stomach produce a churning movement that mixes food with the gastric secretions. When the muscles contract, they reduce the volume of the stomach and throw the mucosa into longitudinal folds or rugae (see above). The folds flatten as the stomach distends with food and the musculature relaxes and thins. Muscle activity is controlled by a network of unmyelinated autonomic nerve fibres and their ganglia which lie between the muscle layers in the myenteric (Auerbach's) plexus.

Serosa or visceral peritoneum

The serosa is an extension of the visceral peritoneum. It covers the entire surface of the stomach other than along the attachments of the greater and lesser omenta to the greater and lesser curvatures respectively, where the peritoneal layers are separated by vessels and nerves, and over a small posteroinferior area near the cardiac orifice, where the stomach contacts the diaphragm at the reflections of the gastrophrenic and left gastropancreatic folds.

CHAPTER 66

Small intestine

OVERVIEW

The small intestine consists of the duodenum, jejunum and ileum. It extends from the distal end of the pyloric canal to the ileocaecal valve, an overall length of 5 metres (3–7 metres) in the living adult. The duodenum extends up to the duodenojejunal junction, and the remaining small intestine is often referred to as the 'small bowel', of which the proximal two-fifths is referred to as the jejunum and the distal three-fifths as the ileum. There is no clear distinction between the two parts, but there is a gradual change in morphology from the proximal to distal ends of the small bowel. The distal 30 cm or so of the ileum is often referred to as the terminal ileum, which has some specialized physiological functions.

The duodenum lies mostly in the upper retroperitoneum. The jejunum and ileum occupy the central and lower parts of the abdominal cavity and usually lie within the boundary formed by the abdominal colon; they are attached to the posterior abdominal wall by a mesentery which allows considerable mobility of the loops of small bowel. In the supine position, loops of jejunum may be found anterior to the transverse colon, stomach and even lesser omentum, whereas in the upright position, loops of ileum may descend into the pelvis anterior to the rectum and, in women, may occupy the rectouterine pouch. The upper jejunum and some ileum are often covered anteriorly by the greater omentum. The jejunum and ileum are covered by peritoneum on all but their mesenteric borders, here the adipose connective tissue of the mesentery abuts the muscular wall. The serosal peritoneum is continuous with the peritoneum enclosing the tissues of the mesentery. Mesenteric fat covers 20% of the circumference wall of the ileum and somewhat less of the jejunum.

DUODENUM

The adult duodenum is 20–25 cm long and is the shortest, widest and most predictably placed part of the small intestine. It is only partially covered by peritoneum, although the extent of the peritoneal covering varies along its length: the proximal 2.5 cm is intraperitoneal, and the remainder is retroperitoneal. The duodenum forms an elongated ‘C’ that lies between the level of the first and third lumbar vertebrae in the supine position. The lower ‘limb’ of the C extends further to the left of the midline than the upper limb. The head and uncinate process of the pancreas lie within the concavity of the duodenum which is ‘draped’ over the prominence formed from the lumbar spine, the duodenum therefore bends in an antero-posterior direction as well as following the form of a ‘C’. The duodenum lies entirely above the level of the umbilicus and is described as having four parts (Figs 66.1, 66.2).

Duodenal cap
Duodenojejunal flexure

Fig. 66.2 Contrast radiographic appearance of the duodenum showing a distended duodenal cap and the remainder of the duodenum up to the duodenojejunal flexure.

FIRST (SUPERIOR) PART

The first, and most mobile, part of the duodenum is about 5 cm long. It starts as a continuation of the duodenal end of the pylorus and ends at the superior duodenal flexure. Peritoneum covers the anterior and superior part of its posterior aspect close to the pylorus, where the duodenum forms part of the anterior wall of the epiploic foramen. Here the lesser omentum is attached to its upper border and the greater omentum to its lower border. The first 2 or 3 cm have a bland internal mucosal appearance and readily distend on insufflation during endoscopy. This part is frequently referred to as the duodenal ‘cap’. It has a triangular, homogeneous appearance during contrast radiology, shows the same pattern of internal rugae as the pylorus, and is often visible on plain radiographs of the abdomen as an isolated triangular gas shadow to the right of the first or second lumbar vertebra. The duodenum next passes superiorly, posteriorly and laterally for 5 cm before curving sharply inferiorly into the superior duodenal flexure: it rapidly becomes more retroperitoneal during this part of its course, until peritoneum only covers its anterior aspect. From the end of the duodenal cap, its internal appearance is characterized by extensive, deep mucosal folds that involve up to half of the circumference of the lumen. Even during endoscopic insufflation, these folds are pronounced (Fig. 66.3) and they are readily seen on contrast radiographs. The section from the duodenal cap to the superior duodenal flexure lies posterior and inferior to the quadrate lobe of the liver.

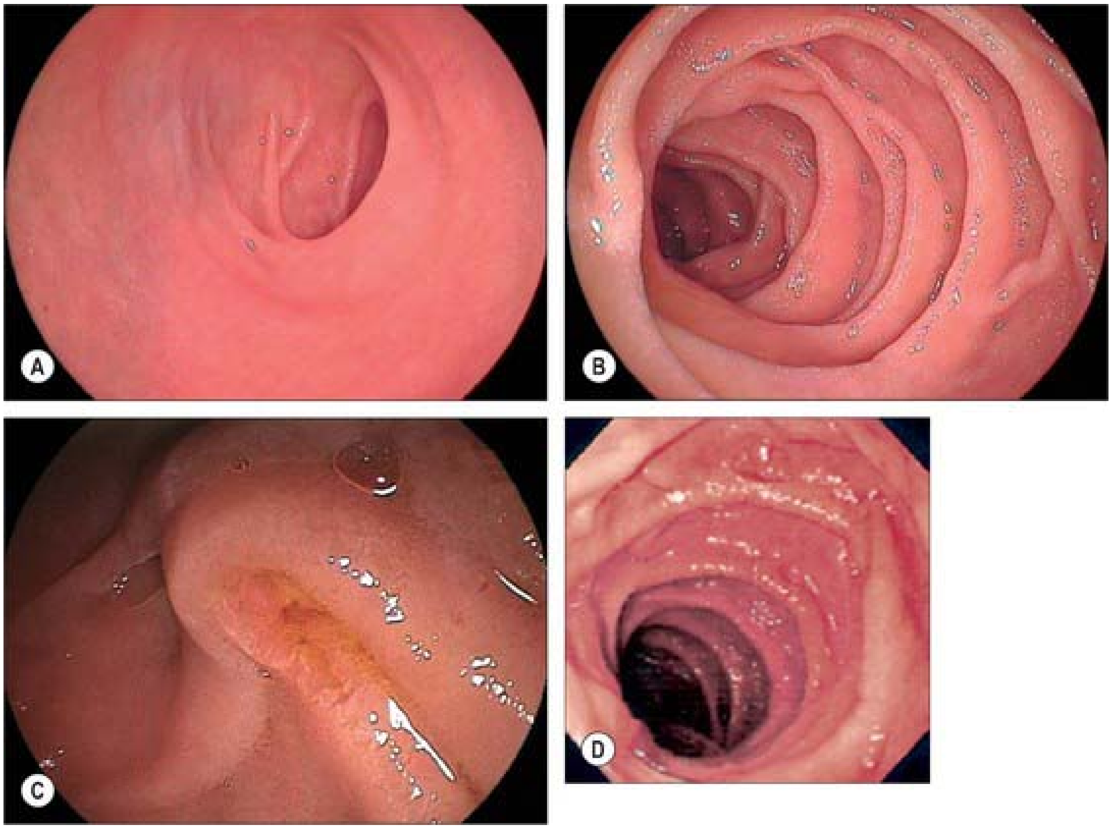

Fig. 66.3 Endoscopic appearance of the duodenum: **A**, Duodenal cap (first part). **B**, Second part showing the pronounced, ‘branched’ mucosal folds. **C**, Major duodenal papilla. **D**, Third part.

The first part of the duodenum lies anterior to the gastroduodenal artery, common bile duct and portal vein and anterosuperior to the head and neck of the pancreas. It is posterior to the neck of the gallbladder. The gastroduodenal artery lies immediately posterior to the posterior wall of the duodenum: penetrating peptic ulceration in the posterior wall and subsequent erosion of the gastroduodenal artery may lead to dramatic haemorrhage. Penetrating peptic ulceration in the anterior wall may lead to free perforation into the peritoneal cavity because the anterior surface of the first part is covered only by peritoneum.

The common hepatic and hepatoduodenal lymph nodes lie close to the first part of the duodenum and can be visualized using endoscopic ultrasound. This may be important in the staging of gastric, pancreatic or bile duct tumours. The proximity of the common bile duct to the first part of the duodenum allows endoscopic ultrasound examination of the distal common bile duct and the formation of a surgical anastomosis between bile duct and duodenum (choledochoduodenostomy) when required.

The junction of the first and second parts of the duodenum lies posterior to the neck of the gallbladder.

SECOND (DESCENDING) PART

The second part of the duodenum is 8–10 cm long. It starts at the superior duodenal flexure and runs inferiorly in a gentle curve, convex to the right side of the vertebral column and extending to the lower border of the third lumbar vertebral body. It then turns sharply medially into the inferior duodenal flexure which marks its junction with the third part of the duodenum. It is covered by peritoneum only on its upper anterior surface, lies posterior to the neck of the gallbladder and the right lobe of the liver at its start, and is crossed anteriorly by the transverse colon. The medial end of the gastrocolic omentum and the origin of the transverse mesocolon are attached to the anterior surface of the duodenum by loose connective tissue. Below the attachment of the transverse mesocolon, the connective tissue and vessels forming the mesentery of the upper ascending colon and hepatic flexure are loosely attached to its anterior surface. This section of duodenum is at risk of injury during surgical mobilization of the ascending colon.

The second part lies anterior to the hilum of the right kidney, the right renal vessels, the edge of the inferior vena cava and the right psoas major. The head of the pancreas and the common bile duct are medial and the hepatic flexure is above and lateral. A small part of the pancreatic head is sometimes embedded in the medial duodenal wall, and pancreatic ‘rests’ in the duodenal wall may produce small filling defects on contrast radiology. The internal appearance is similar to that of the distal portion of the first part of the duodenum, with pronounced mucosal folds (Fig. 66.3). The common bile duct and pancreatic duct enter the medial wall obliquely and usually unite to form the common hepatopancreatic ampulla. The narrow distal end opens on the summit of the major duodenal papilla (ampulla of Vater), which is situated on the posteromedial wall of the second part, 8–10 cm distal to the pylorus. There are variants of the ductal anatomy. The most common is a second, accessory pancreatic duct which may open 2 cm above the major papilla on a minor duodenal papilla. Peptic ulceration of the second part of the duodenum is less common than that of the first part, and tends to occur on the anterior or lateral wall.

Duodenal diverticula

The duodenum is the most common site for a diverticulum in the small intestine. Diverticula are congenital and usually solitary. They almost always arise in the medial wall of the second part of the duodenum, intimately related to the head of the pancreas, such that the major duodenal papilla may frequently be found either on the mucosal fold at the mouth of a diverticulum or arising from the mucosa within the body of a diverticulum, particularly on the superomedial wall. This may complicate interpretation of contrast radiographs of the duodenum or biliary system, and may cause difficulties during attempted endoscopic cannulation of the papilla because the diverticulum may restrict access. If the papilla is located on or close to the anterior wall of a diverticulum, the procedure of opening the ampulla with an electrocautery current during attempted cannulation (sphincterotomy) is made more hazardous because the wall is thin at this point and so there is a risk of free perforation into the peritoneal cavity.

THIRD (HORIZONTAL) PART

The third part of the duodenum starts at the inferior duodenal flexure and is approximately 10 cm long. It runs from the right side of the lower border of the third lumbar vertebra, angled slightly superiorly, across to the left, anterior to the inferior vena cava, becoming continuous with the fourth part in front of the abdominal aorta. It lies posterior to the transverse mesocolon, the origin of the small bowel mesentery and the superior mesenteric vessels. The lower portion of its anterior aspect is covered by peritoneum which is reflected anteriorly to form the posterior layer of the origin of the small bowel mesentery. The anterior surface of the left lateral end, close to the junction with the fourth part, is also covered with peritoneum.

The third part is anterior to the right ureter, right psoas major, right gonadal vessels, inferior vena cava and abdominal aorta (at the origin of the inferior mesenteric artery), and inferior to the head of the pancreas. Anteroinferiorly, loops of jejunum lie in the right and left infracolic compartments. The mid portion of the third part lies in the angle between the superior mesenteric vessels, just below their origin, anteriorly, and the abdominal aorta posteriorly: very rarely, this arrangement is associated with intermittent symptoms of obstruction of the duodenum at this point.

FOURTH (ASCENDING) PART

The fourth part of the duodenum is 2.5 cm long. It starts just to the left of the aorta, runs superiorly and laterally to the level of the upper border of the second lumbar vertebra, then turns sharply anteroinferiorly at the duodenojejunal flexure to become continuous with the jejunum. The main trunk of the inferior mesenteric vein lies either posterior to the duodenojejunal flexure or beneath the adjacent peritoneal fold. (The duodenojejunal flexure is a useful landmark to locate the vein radiologically or surgically.) The aorta, left sympathetic trunk, left psoas major, left renal and left gonadal vessels are all posterior relations, the left kidney and left ureter are posterolateral, and the upper part of the root of the small bowel mesentery, the left lateral transverse mesocolon and transverse colon, which separate it from the stomach, are anterior. The peritoneum of the root of the small bowel mesentery continues over its anterior surface. The lower border of the body of the pancreas is superior.

At its left lateral end, the fourth part becomes progressively covered in peritoneum on its superior and inferior surfaces, such that it is suspended from the retroperitoneum by a double fold of peritoneum, the ligament of Treitz, at the start of the duodenojejunal flexure. The ligament of Treitz may contain a small slip of muscle, the suspensory muscle of the duodenum. When present, the suspensory muscle contains skeletal muscle fibres that run from the left crus of the diaphragm to connective tissue around the coeliac axis, and smooth muscle fibres that run from the coeliac axis: its function is unknown. It is an important landmark in the radiological diagnosis of incomplete rotation and malrotation of the small intestine (see Ch. 73). The ligament of Treitz does not form part of the duodenal mesentery because the vascular supply to the fourth part of the duodenum continues to enter its wall from the posteromedial aspect.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The main vessels supplying the duodenum are the superior and inferior pancreaticoduodenal arteries. The first and second parts also receive contributions from several sources including the right gastric, supraduodenal, right gastroepiploic, hepatic and gastroduodenal arteries. Branches of the superior pancreaticoduodenal artery may contribute to the supply of the pyloric canal, with a minor degree of anastomosis to the gastric arteries in the muscular layer across the pyloroduodenal junction (Fig. 66.4).

Fig. 66.4 The arterial supply of the duodenum. Only representative branches of the small vessels, which may be multiple, are shown.

Gastroduodenal artery

The gastroduodenal artery usually arises from the common hepatic artery behind, or sometimes above, the first part of the duodenum. It descends between the first part of the duodenum and the neck of the pancreas, immediately to the right of the peritoneal reflection from the posterior surface of the duodenum. It usually lies to the left of the common bile duct but occasionally is anterior. At the lower border of the first part of the duodenum it divides into the right gastroepiploic and superior pancreaticoduodenal arteries. Before its division, the lowest part of the artery gives rise to small branches that supply the pyloric end of the stomach and the pancreas, and retroduodenal branches that supply the first part and the proximal portion of the second part of the duodenum directly. Although the gastroduodenal artery usually branches from the common hepatic artery, it may also arise as a trifurcation with the right and left hepatic arteries, or from the superior mesenteric artery or the left hepatic artery (occasionally), or from the coeliac axis or right hepatic artery (rarely).

The supraduodenal artery often arises from the gastroduodenal artery behind the upper border of the first part of the duodenum and supplies the superior aspect of the first part; it may occasionally arise from the common hepatic artery or right gastric artery. Because of its close relationship to the posteromedial wall of the second part of the duodenum, deeply penetrating ulcers or tumours of the duodenum may cause torrential bleeding from the gastroduodenal ‘artery of haemorrhage’, not least because of the profuse arterial network in the region ensures a high flow rate in the vessel.

Superior pancreaticoduodenal arteries

The superior pancreaticoduodenal artery is usually double. The anterior artery is a terminal branch of the gastroduodenal artery and descends in the anterior groove between the second part of the duodenum and the head of the pancreas. It supplies branches to the first and second parts of the duodenum and to the head of the pancreas, and anastomoses with the anterior division of the inferior pancreaticoduodenal artery. The posterior artery is usually a separate branch of the gastroduodenal artery and is given off at the upper border of the first part of the duodenum. It descends to the right, anterior to the portal vein and common bile duct as the latter lies behind the first part of the duodenum. It then runs behind the head of the pancreas, crosses posterior to the common bile duct (which is embedded in the head of the pancreas), enters the duodenal wall and anastomoses with the posterior division of the inferior pancreaticoduodenal artery. The posterior artery supplies branches to the head of the pancreas, the first and second parts of the duodenum, and several branches to the lowest part of the common bile duct.

Inferior pancreaticoduodenal artery

The inferior pancreaticoduodenal artery usually arises from the superior mesenteric artery or its first jejunal branch, near the superior border of the third part of the duodenum. It crosses behind the superior mesenteric vein and divides directly into anterior and posterior branches. The anterior branch passes to the right, anterior to the lower border of the head of the pancreas, and runs superiorly to anastomose with the anterior superior pancreaticoduodenal artery. The posterior branch runs posteriorly and superiorly to the right, lying posterior to the lower border of the head of the pancreas, and anastomoses with the posterior superior pancreaticoduodenal artery. Both branches supply the pancreatic head, its uncinate process and the second and third parts of the duodenum. Occasionally the anterior and posterior branches arise separately from the superior mesenteric or first jejunal artery.

Jejunal artery branches

Branches from the first jejunal branch of the superior mesenteric artery supply the fourth part of the duodenum and frequently form an anastomosis with the terminal branch of the anterior inferior pancreaticoduodenal artery (which arises from the superior mesenteric artery). The fourth part of the duodenum therefore receives a potential collateral supply from the coeliac axis and superior mesenteric artery, which means that it is not commonly affected by ischaemia.

Veins

The duodenal veins drain ultimately into the portal vein. Submucosal and intramural veins give rise to pancreaticoduodenal veins that usually accompany the corresponding named arteries. The superior pancreaticoduodenal vein is formed medial to the mid point of the second part of the duodenum. It runs superomedially on the posterior surface of the head of the pancreas, passes posterior to the distal common bile duct and drains into the portal vein behind the neck of the pancreas. The inferior pancreaticoduodenal vein runs from the anteromedial aspect of the second part of the duodenum inferiorly in the groove between the second and third parts of the duodenum and the head of the pancreas. It usually drains into the superior mesenteric vein but may drain into the right gastroepiploic vein. Small veins from the first and upper second part of the duodenum may drain into the prepyloric vein and veins from the third and fourth parts may drain directly into the superior mesenteric vein.

Lymphatics

Duodenal lymphatics run to anterior and posterior pancreatic nodes that lie in the anterior and posterior grooves between the head of the pancreas and the duodenum: these nodes drain widely into the supra-pyloric, infrapyloric, hepatoduodenal, common hepatic and superior mesenteric nodes.

INNERVATION

The duodenum is innervated by both parasympathetic and sympathetic neurones.

Preganglionic sympathetic axons originate from neurones in the intermediolateral columns of the grey matter in the fifth to the 12th thoracic spinal segments. They travel via the greater and lesser splanchnic nerves to the coeliac plexus where they synapse on neurones in the coeliac ganglion: postganglionic axons are distributed to the duodenal wall via periarterial plexuses on the branches of the coeliac axis and superior mesenteric artery. The sympathetic nerves are vasoconstrictor to the duodenal vasculature and inhibitory to duodenal musculature.

The preganglionic parasympathetic supply is carried by vagal axons that are distributed via the coeliac plexus and which synapse on neurones in the duodenal wall. The parasympathetic supply is secretomotor to the duodenal mucosa and motor to the duodenal musculature. The sympathetic nerves are vasoconstrictor to the duodenal vasculature and inhibitory to duodenal musculature.

Referred pain

In common with other structures derived from the foregut, the visceral sensation of pain arising from the duodenum is poorly localized and referred to the central epigastrium.

JEJUNUM

The jejunum has a median external diameter of 4 cm and an internal diameter of 2.5 cm. It has a thicker wall than the ileum, and an extensive arterial blood supply that makes it appear redder than the ileum in the living. The plicae circulares are most pronounced in the proximal jejunum, where they are more numerous and deeper than elsewhere in the small bowel (Fig. 66.5A). They frequently ‘branch’ around the lumen and may appear to be ranged one on top of another, giving the jejunum a characteristic appearance during single contrast radiography (Fig. 66.6). Lymphoid aggregates are almost absent from the proximal jejunum, but are present distally, although they are fewer in number and smaller than in the ileum. Where present, they are usually discoid in shape and impalpable.

Fig. 66.5 Typical cross sections through the proximal jejunum (**A**) and terminal ileum (**B**). The mesenteric attachment is wider in the jejunum, and two leaves of vessels enter the bowel wall. The latter is also thicker in the jejunum.

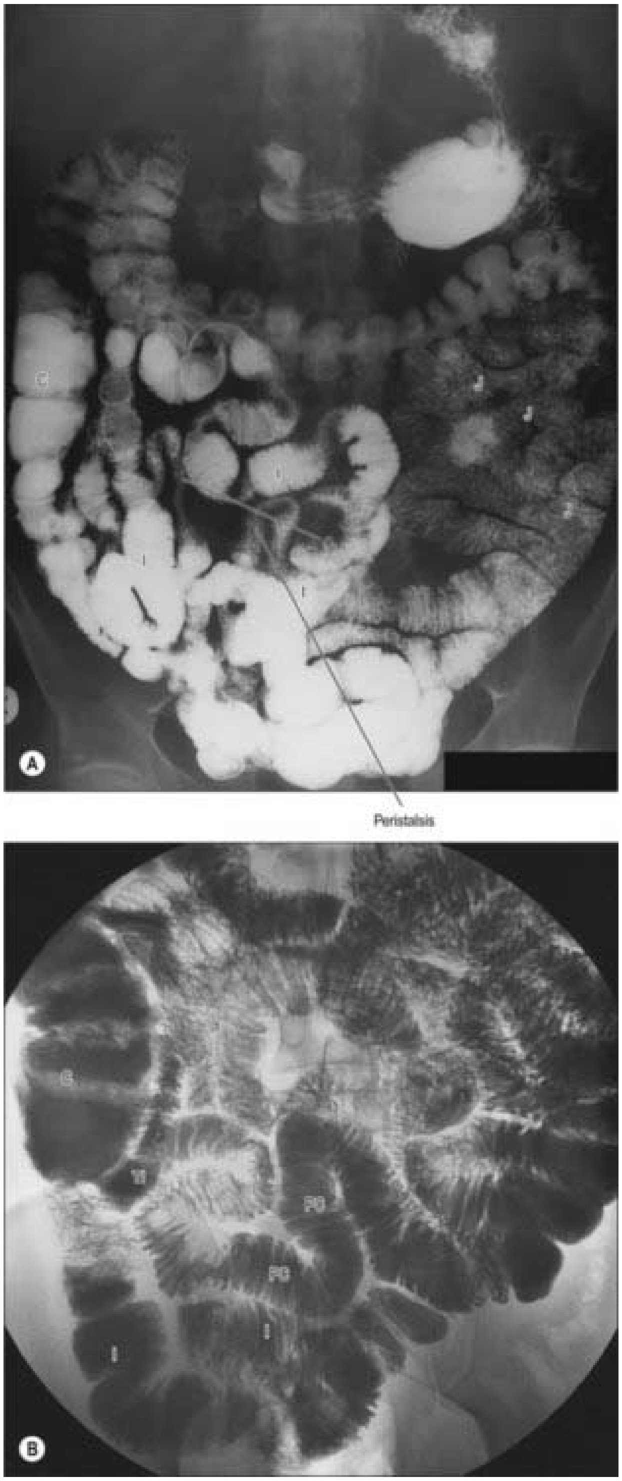

Fig. 66.6 Barium studies of the jejunum and ileum. **A**, Barium follow-through. The feathery appearance of the small intestine is due to the plicae circulares and is most prominent in the jejunum. The constrictions are the result of peristalsis. **B**, Small bowel enema (enteroclysis). The plicae

circulares are clearly demonstrated by this technique. C, caecum; I, ileum; J, jejunum; PC, plicae circulares; TI, terminal part of ileum.

In the supine position the jejunum usually occupies the upper left infracolic compartment, extending down to the umbilical region. The first one or two loops often occupy a recess between the left part of the transverse mesocolon and the left kidney. On supine radiological examination, the jejunal loops are characteristically situated in the upper abdomen, to the left of the midline, whereas the ileal loops tend to lie in the lower right part of the abdomen and pelvis. This distribution can be reversed during paralytic ileus or small bowel obstruction due to rotation around the mesenteric attachment following bowel distension.

Jejunal feeding

In situations where the stomach and duodenum are either unsuitable or unavailable for receiving oral nutrition, delivery of prepared feed to the jejunum is possible using either a surgically created jejunostomy or by insertion of a feeding tube. Because the jejunum is highly mobile, it is possible to bring the first or second loop of jejunum into contact with the abdominal wall to create a surgical jejunostomy. Insertion of a fine-bore feeding tube via the nose as far as the jejunum is also possible: the end of the feeding tube must lie beyond the duodenojejunal flexure to prevent reflux of the feed into the duodenum and stomach, and this is usually confirmed by radiological monitoring of the progress of the tube through the duodenum.

ILEUM

The ileum has a median external diameter of 3.5 cm and an internal diameter of 2 cm, and tends to have a thinner wall than the jejunum (Fig. 66.5B). The plicae circulares become progressively less obvious in the distal mucosa in the ileum; they tend to be single and flatter with less pronounced crests (Figs 66.6, 66.7), and the mucosa of the terminal ileum immediately proximal to the ileocaecal valve may appear almost flat. Lymphoid aggregates are larger and more numerous than in the jejunum and may be easily palpable in the terminal ileum. They are most prominent in early childhood and, when enlarged in viral infections, may form the apex of an ileo-ileal intussusception. They become less prominent prior to puberty, and attain adult morphology by late teenage years. In the supine position, the ileum lies mainly in the hypogastric region and right iliac fossa. The terminal ileum frequently lies in the pelvis, whence it ascends over the right psoas major and right iliac vessels, to end by opening into the ileocaecal valve in the right iliac fossa.

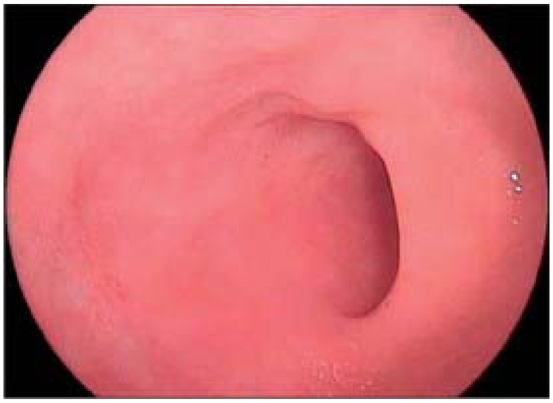

Fig. 66.7 Endoscopic appearance of the terminal ileum.

Meckel's diverticulum

An ileal diverticulum (of Meckel) exists in 3% of adults and represents the remnant of the proximal part of the intestino-vitelline duct. It projects from the antimesenteric border of the terminal ileum and is commonly located between 50 and 100 cm from the ileocaecal valve. It is variable in length (median 5 cm), often possessing a short ‘mesentery’ of adipose tissue that extends from the ileal mesentery up to its base. The lumen of the diverticulum usually has a calibre similar to that of the ileum. The tip is normally free but occasionally it may be connected to the anterior abdominal wall near the umbilicus by a fibrous band. The mucosa is typically ileal, but small heterotopic areas of gastric body type epithelium, pancreatic, colonic or other tissues may also occur in the wall of a diverticulum. Unopposed acid secretion by heterotopic gastric body type epithelium may occasionally give rise to bleeding in the adjacent normal ileal mucosa. Diverticular inflammation may mimic acute appendicitis; since Meckel’s diverticulum and the appendix are both derived from midgut structures, pain from either structure is referred to the periumbilical region.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Branches from the superior mesenteric artery supply the jejunum and ileum. The arteries divide as they approach the mesenteric border, giving off numerous branches which extend between the serosal and muscular layers, supplying the muscle and forming an intricate sub-mucosal plexus that supplies the glands and villi. Although there is a profuse anastomotic network of arteries within the mesentery, anastomoses between the terminal branches close to the intestinal wall are few (Fig. 66.8). The intramural and submucosal arterial networks are not of large calibre, which means that flow along lengths of small bowel is limited to a few centimetres, and division or occlusion of several consecutive vasa recta may produce segmental, focal ischaemia. Division of more proximal vessels allows flow to continue in the arcades for moderately long lengths of intestine.

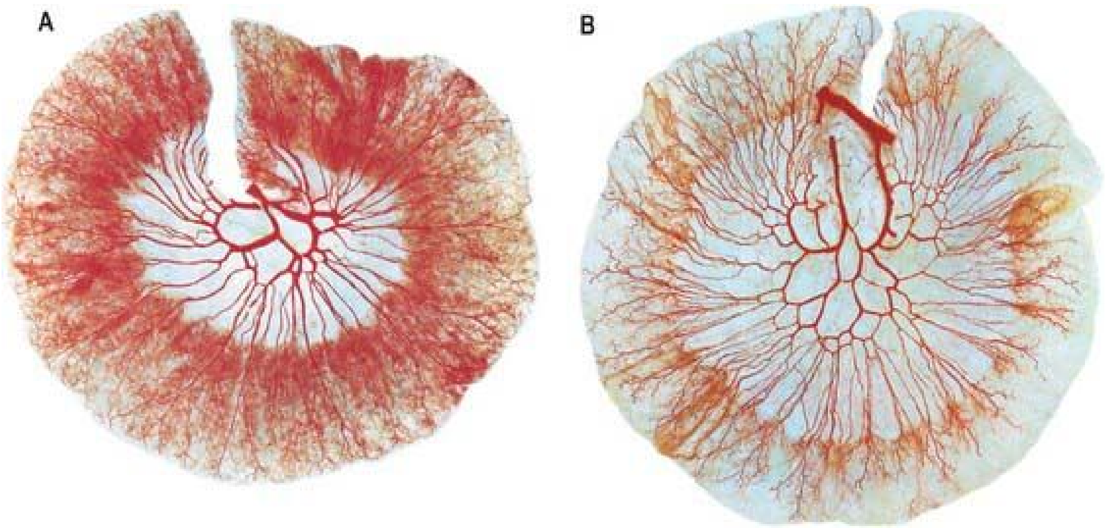

Fig. 66.8 Specimens of the jejunum (**A**) and ileum (**B**) from a cadaver where the superior mesenteric artery was injected with a red coloured mass of gelatin before fixation. Subsequently the specimens were dehydrated and then cleared in benzene followed by methyl salicylate. The largest vessels present are the jejunal and ileal branches of the superior mesenteric artery

and these are succeeded by anastomotic arterial arcades, which are relatively few in number (1–3) in the jejunum, becoming more numerous (5–6) in the ileum. From the arcades, straight arteries pass towards the gut wall; frequently, successive straight arteries are distributed to opposite sides of the gut. Note the denser vascularity of the jejunal wall.

(Specimens prepared by MCE Hutchinson; photographs by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)

Superior mesenteric artery

The superior mesenteric artery originates from the aorta 1 cm below the coeliac trunk, at the level of the intervertebral disk between the first and second lumbar vertebrae (Figs 66.9, 66.10). The angle of its origin from the aorta is acute, which makes cannulation via the transfemoral route somewhat difficult. The artery runs inferiorly and anteriorly, anterior to the uncinate process of the pancreas and the third part of the duodenum, and posterior to the splenic vein and the body of the pancreas. The left renal vein lies behind it and separates it from the aorta (Fig. 66.11). The artery crosses anterior to the inferior vena cava, right ureter and right psoas major as it descends in the root of the small bowel mesentery. Its calibre progressively decreases as successive branches are given off to loops of jejunum and ileum, and its terminal branch anastomoses with the ileocolic artery.

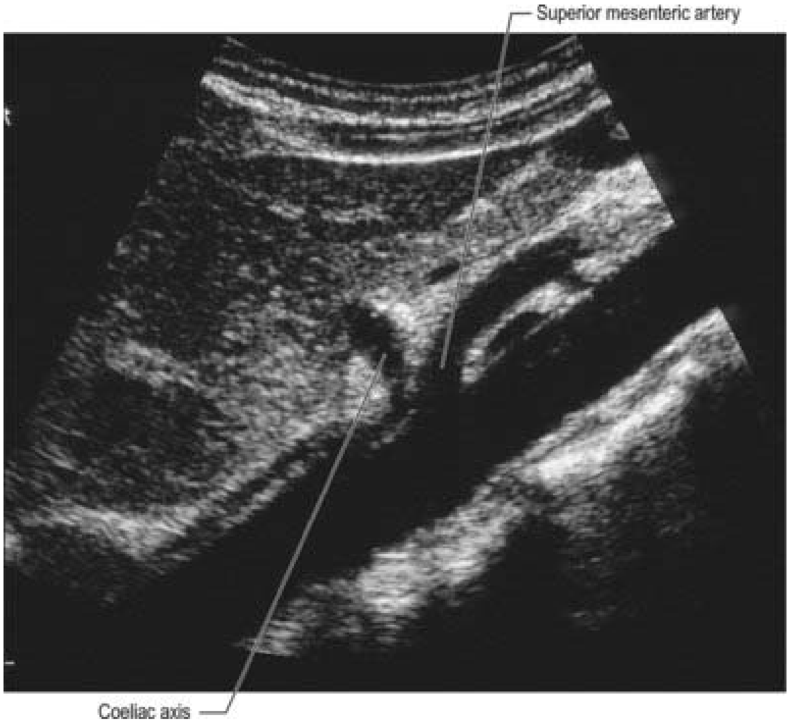

Fig. 66.11 Ultrasound image through the origin of the superior mesenteric artery, sagittal plane.

The superior mesenteric artery gives off middle colic, right colic (sometimes), ileocolic, jejunal and ileal branches. It may be the source of the common hepatic, gastroduodenal, accessory right hepatic, accessory pancreatic or splenic arteries, and may arise from a common coeliacomesenteric trunk. Its jejunal and ileal branches form arcades within the mesentery to a varying extent. The last of these arcades is said to form a 'marginal artery' of the small intestine, although the latter is irregular and not a single definable vessel. Straight arteries, the vasa recta, which supply the small intestine directly without further branches, are given off from this lowest arcade.

The remnant of the vitellointestinal artery (the embryonic artery which originally connected the intestinal circulation to the yolk sac) is usually obliterated; when present, it forms the artery supplying a Meckel's diverticulum. It is occasionally represented in the mesentery by a fibrous strand from the region of the last ileal branch.

Jejunal branches

There are usually five to ten jejunal branches which arise from the left side of the upper portion of the superior mesenteric artery (Figs 66.9, 66.10). They are distributed to the jejunum as a series of short arcades which form a single (occasionally double) tier of anastomotic arcs before giving rise to multiple vasa recta (Fig. 66.8). These vessels run almost parallel in the mesentery and are distributed alternately to opposite aspects of its wall where the two series of vessels form distinct ‘leaves’ within the mesentery. Small twigs supply regional lymph nodes and other structures in the mesentery.

Ileal branches

Ileal branches are more numerous than the jejunal branches but smaller in calibre. They arise from the left and anterior aspects of the superior mesenteric artery. The length of the mesentery is greater in the ileum and the branches form three, four or sometimes five tiers of arcs within the mesentery before giving rise to multiple vasa recta that run directly towards the ileal wall. The ileal branches run parallel in the mesentery and are distributed to alternate aspects of the ileum. They are longer and smaller than similar jejunal vessels, particularly in the distal ileum, and do not form such definite parallel ‘leaves’ of vessels. The vascular supply in the last loop of the terminal ileum is limited. There are usually only two separate arcades, peri-serosal and in the mid-zone of the mesentery. They each receive a contribution from the ileal branch of the ileocolic artery and the last ileal branch of the superior mesenteric artery and are often larger in calibre than the mid-ileal vessels. Other than this connection, few if any vessels connect the ileocolic and superior mesenteric arteries, which makes surgical exposure of the ileocolic artery up to its origin relatively simple.

Veins

Superior mesenteric vein

The superior mesenteric vein drains the small intestine, caecum, ascending and transverse parts of the colon (Fig. 66.12; see Fig. 60.8). It is formed in the right lower mesentery of the small bowel by the union of tributaries from the terminal ileum, caecum and vermiform appendix. It ascends in the mesentery to the right of the superior mesenteric artery, passes anterior to the right ureter, inferior vena cava, third part of the duodenum and uncinate process of the pancreas, and finally joins the splenic vein behind the neck of the pancreas to form the portal vein.

Tributaries

The superior mesenteric vein receives jejunal, ileal, ileocolic, right colic (when present), middle colic, right gastroepiploic and pancreaticoduodenal veins in a similar distribution to the corresponding arteries.

Lymphatics

Lymph vessels, lacteals, are found in the mucosa and muscular coat of the small bowel. Lacteals from the villi arise from an intricate plexus in the mucosa and submucosa and are joined by vessels from lymph spaces at the bases of solitary lymphoid follicles. They drain to larger vessels at the mesenteric border of the gut. The lacteals of the muscular tunic form a close plexus that runs mostly between the two muscle layers; they communicate freely with mucosal vessels and open into vessels at the mesenteric border. Mesenteric lacteals pass between the layers of the mesentery and drain into a series of mesenteric lymph nodes which are arranged in tiers within the mesentery and which follow the same distribution as the regional arterial supply; they may form ‘chains’ along the major arteries. Elsewhere in the ileal and jejunal mesenteries the lacteals form an extensive network that affords a relatively wide field of lymph node drainage. This arrangement makes radical surgical resection of lymph nodes difficult if the vessels to the remaining unaffected small bowel are to be preserved. The mesenteric nodes drain into superior mesenteric nodes around the root of the superior mesenteric artery.

INNERVATION

The ileum and jejunum are innervated by parasympathetic and sympathetic fibres via the superior mesenteric plexus (see Figs 60.2–60.4). Preganglionic sympathetic axons originate from neurones in the intermediolateral grey matter of the mid-thoracic spinal segments and travel in the greater and lesser splanchnic nerves to the superior mesenteric ganglion where they synapse. Postganglionic axons accompany the superior mesenteric artery into the mesentery and are distributed along branches of the artery. The sympathetic nerves are vasoconstrictor to the vasculature and inhibitory to the musculature of the jejunum and ileum.

Preganglionic parasympathetic axons travel in the anterior and right vagus nerve and are secretomotor to the mucosa and motor to the musculature of the jejunum and ileum.

Referred pain

In common with other structures derived from the midgut, the visceral sensation of pain arising from the jejunum or ileum is poorly localized, and is usually referred to the periumbilical region or central epigastrium.

MICROSTRUCTURE

The intestinal wall is composed of mucosa, submucosa, muscularis externa and serosa or adventitia. The mucosa is thick and very vascular in the proximal small intestine, but thinner and less vascular distally. In places it is ridged by the underlying submucosa to form circular folds, plicae circulares, which protrude into the lumen; mucosal finger- or leaf-like intestinal villi cover the whole surface (Fig. 66.13). There are numerous simple tubular intestinal glands or crypts between the bases of the villi, and additional submucosal glands in the duodenum. The submucosa contains aggregates of lymphoid tissue, most numerous in the ileum.

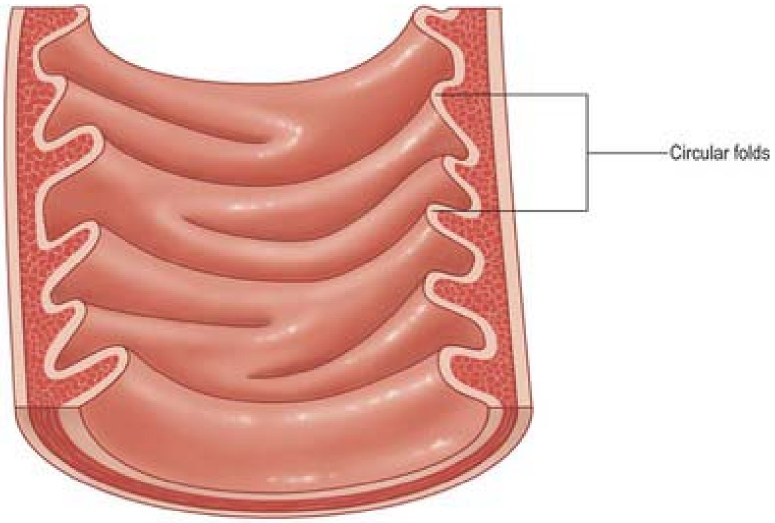

Fig. 66.13 Internal aspect of a representative sample of the proximal jejunum, showing circular folds.

Circular folds

Other than in the first part of the duodenum, large crescentic folds of mucosa project into the lumen of the small intestine, lying either transversely or slightly obliquely to its long axis (Fig. 66.14). Unlike gastric folds they are not lost during physiological distension of the intestine. Most extend round half or two-thirds of the luminal circumference, some are complete circles, some bifurcate and join adjacent folds, yet others are spiral but extend only once (occasionally two or three times) round the lumen. Larger folds are up to 8 mm deep at their broadest, but most are smaller than this, and larger folds often alternate with smaller ones. Folds begin to appear 2.5–5 cm beyond the pylorus. Distal to the major duodenal papilla they are large and close together, as they also are in the proximal half of the jejunum. From here to midway along the ileum they diminish, and they disappear almost completely in the distal ileum, which accounts for the thinness of this part of the intestinal wall. The circular folds slow the passage of the intestinal contents and increase the absorptive surface. They are visible in contrast and occasionally plain radiographs.

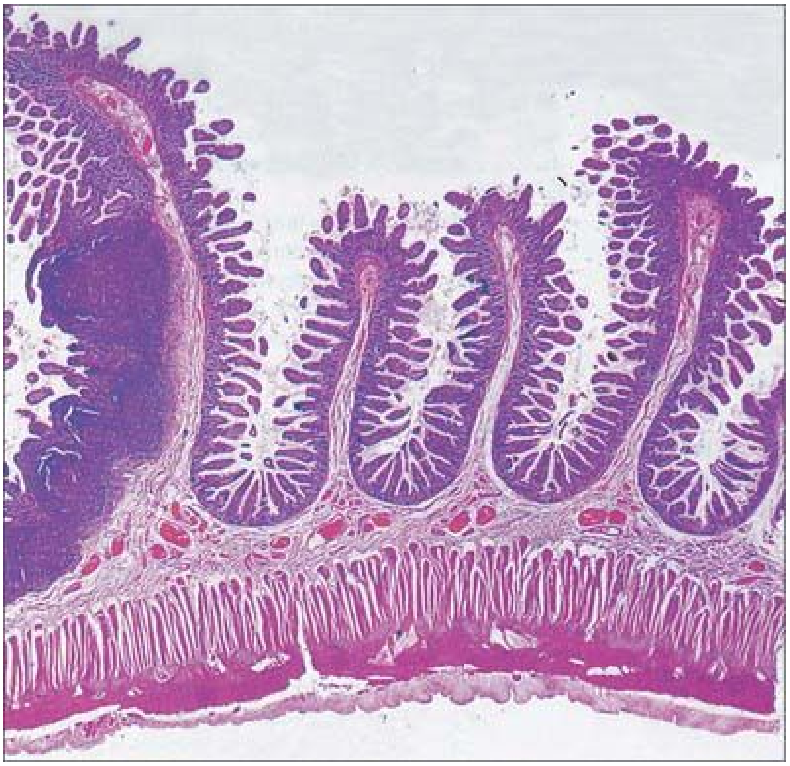

Fig. 66.14 Low-power micrograph showing several circular folds in the wall of the ileum. The folds are covered with villi projecting into the lumen and the submucosa extends into the core of each fold. Circular (innermost) and longitudinal smooth muscle layers form the underlying muscularis externa. Large masses of lymphoid tissue (Peyer’s patches) occupy the mucosa at the left of the field.

Intestinal villi

Intestinal villi are highly vascular projections of the mucosal surface, just visible to the naked eye (Figs 66.15-66.17). They cover the entire intestinal mucosa, increase the surface area of the lumen about eight-fold, and give it a velvety texture. Villi are large and numerous in the duodenum and jejunum, and smaller and fewer in the ileum. In the first part of the duodenum they appear as broad ridges, become tall and foliate in the distal duodenum and proximal jejunum, and then gradually shorten to a finger-like form in the distal jejunum and ileum. Villi vary in density from 10 to 40 per square millimetre and from 0.5–1.0 mm in height (Fig. 66.15). Infoldings of the mucosa dip down from the base of the villi for a short distance into the lamina propria. These crypts (of Lieberkühn), are most prominent in the proximal small intestine (Fig. 66.16).

Mucosa

The mucosa consists of epithelium, lamina propria and muscularis mucosae.

Epithelium

A single-layered epithelium covers the intestinal villi (Figs 66.15, 66.16) and also lines the intestinal glands (crypts) that open between the bases of villi. Two types of cell, enterocytes and goblet cells, cover the surfaces of the villi, whereas microfold cells (M cells) are restricted to the dome epithelium that covers localized accumulations of lymphoid tissues. These cell types are all in contact basally with a basal lamina to which they adhere, and all are derived from a common stem cell in the intestinal crypts.

Enterocytes

Enterocytes are columnar absorptive cells, approximately 20 µm tall. They are the most numerous type of cell in the small intestinal lining, and are responsible for nutrient absorption. Their surfaces bear up to 3000 microvilli, which greatly increase the surface area for absorption. Collectively, microvilli are visible by light microscopy as a brush (striated) border 1 µm thick: individual microvilli can be resolved only by electron microscopy. Enterocyte nuclei are elongated vertically, mainly euchromatic and located just below the centre of the cell.

The apical cell surface is resistant to protease attack because microvilli possess a specialized glycoprotein-rich surface coat (glycocalyx) which, with an overlying layer of mucus, protects the epithelium against pancreatic enzymes in the intestinal lumen. The cell coat also contains a number of digestive enzymes as integral membrane proteins. These include enzymes that degrade disaccharides and oligopeptides prior to absorption. Further details of the structure of microvilli are given on page 18).

The luminal surface is an important barrier to diffusion. Nutrients generally have to pass through enterocytes (transcellular absorption) before they reach the underlying lamina propria and its blood vessels and lymphatics (lacteals). Classical epithelial junctional complexes encircle the apical plasma membranes of adjacent enterocytes: their tight junctions form an effective barrier to non-selective diffusion between the gut lumen and the body as a whole. The lateral plasma membranes of enterocytes are highly folded, interdigitating with each other to form complex intercellular boundaries, anchored periodically by desmosomes, and making contact at gap junctions. The lateral intercellular space expands during active absorption and is an additional conduit (supplementing transport across the basal cell surface) for the passage of fluids, nutrients and other solutes to the vessels of the lamina propria.

Enterocytes have a lifespan after differentiation of about 5 days. Their position on the villus wall reflects their stage in the life cycle: at the tips of intestinal villi they undergo programmed, apoptotic, cell death and are shed from the epithelium. They are replaced at the base of the villus by stem cell mitosis.

Goblet cells

Goblet cells are most numerous in the distal small intestine, increasing in number from the duodenum to their highest density in the terminal ileum. They have elongated basal nuclei, an apical region containing many membrane-bound mucinogen granules, and apical surfaces that bear a few short microvilli. Goblet cell mucins contribute to protection against microorganisms and toxins in the gut lumen, and also provide lubrication and mechanical protection from the intestinal contents.

Microfold (M) cells

Microfold cells are present where the epithelium covers lymphoid aggregates in the intestinal wall (p. 74). They are cuboidal or flattened in shape and have long, widely spaced microfolds rather than microvilli on their apical surfaces. They sample luminal antigens by endocytosis, and transport antigen to lymphocytes lying within intercellular pockets formed by deep invaginations of the M-cell basolateral plasma membranes. See page 78 for details of antigen processing and presentation.

Lymphocytes

Intraepithelial lymphocytes are found in close association with M cells and also between the basolateral regions of enterocytes and goblet cells. They are migratory cells derived from the underlying lymphoid tissue and constitute an important means of immune defence.

Intestinal glands or crypts

Intestinal glands or crypts (of Lieberkühn) are tubular pits that open into the lumen throughout the intestinal mucosa via small circular apertures between the bases of the villi (Figs 66.14-66.16). Their thin walls are composed of columnar enterocytes supplemented by mucous cells, Paneth cells, stem cells and neuroendocrine cells. They are separated by a basement membrane from a rich capillary plexus within the lamina propria.

Enterocytes

Enterocytes in the crypts secrete ions and alkaline fluid to dilute chyme and aid absorption by structurally similar cells that cover the villi.

Mucous cells

The mucous cells in the crypts are similar to the goblet cells of the villi.

Paneth cells

Paneth cells are numerous in the deeper parts of the intestinal crypts, particularly in the duodenum. They are rich in zinc and contain large acidophilic granules that stain strongly with eosin or phosphotungstic haematoxylin. Paneth cells secrete lysozyme, a highly specific antibacterial enzyme, and other defensive proteins (defensins) such as tumour necrosis factor alpha (TNF-α), which protect the intestinal luminal surface.

Stem cells

Stem cells occur in a zone just above the basal region of the crypts and are the source of most of the cell types of the intestinal epithelium. Their progeny, transit (transient) amplifying cells, have one of the most rapid proliferation rates in the body. They migrate out of the intestinal crypts along the sides of the villi, where they differentiate mainly into the short-lived columnar enterocytes or goblet cells (which are thus continually replaced). When not dividing, their apical surfaces have fewer and more irregular microvilli than the differentiated enterocytes.

Neuroendocrine cells

Several types of neuroendocrine cell are scattered among the walls of the intestinal crypts, and less commonly over the villi. They secrete bioactive peptides, such as gastrin, cholecystokinin and secretin, basally into the surrounding lamina propria. Crypt neuroendocrine cells are derived from stem cells, which also give rise to enterocytes and other epithelial elements. For further details of the dispersed neuroendocrine system, see page Chapter 60.

Lamina propria

The lamina propria is composed of connective tissue and provides mechanical support for the epithelium. It has a rich vascular plexus, receives nutrients absorbed by the enterocytes, and forms the cores of the villi. It contains lymphoid tissue, fibroblasts and connective tissue extracellular matrix fibres, smooth muscle cells, eosinophils, macrophages, mast cells, capillaries, lymphatic vessels and unmyelinated nerve fibres. Plasma cells are numerous. Lymphocytes may be clustered in solitary or aggregated follicles, some of which extend through the muscularis mucosae into the submucosa.

Core of the villus

Each villus has a core of delicate connective tissue that contains a large blind-ending lymphatic vessel or lacteal (so called because of its content of suspended chylomicrons, the droplets of apoprotein–lipid complex elaborated by enterocytes from absorbed dietary fats). The core also contains blood vessels, nerves and smooth muscle cells derived from fine extensions of the muscularis mucosae. Each lacteal, usually single but occasionally double, starts in a closed dilated extremity near the tip of a villus, and extends through the core to the base of the villus, where it joins a narrower lymphatic plexus in the deeper lamina propria. Its wall is a single layer of endothelial cells. Smooth muscle cells surround the lacteal throughout the villus and their contraction propels its contents into the underlying lymphatic plexus. Capillaries within the core are lined by fenestrated endothelium to facilitate the rapid intake of nutrients diffusing from the covering absorptive epithelium.

Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT) consists of lymphoid follicles covered by follicle-associated intestinal epithelium which includes scattered M cells. It is found mainly in the lamina propria, but sometimes expands into the submucosa, and is the source of B and T lymphocytes and other related cells involved in the immune defence of the gut wall.

Solitary lymphoid follicles are scattered along the length of the intestinal mucosa, and are most numerous in the distal ileum. Aggregated lymphoid follicles, Peyer’s patches, are circular or oval masses containing 10–260 follicles. They vary in length from 2 to 10 cm, are visible macroscopically as dome-like elevations, and usually situated in the intestinal wall opposite the mesenteric attachment. They are largest and most numerous in the ileum; small, circular and few in the distal jejunum; and rare in the duodenum. Villi are small or absent over the larger follicular groups.

Like other masses of MALT (except lymph nodes), solitary and aggregated lymphoid follicles are most prominent around the age of puberty, after which they diminish in number and size, although many persist into old age. For further details of intestinal MALT and its function, including Peyer's patches, see Didierlaurent, Simonet & Sira (2006).

Muscularis mucosae

The muscularis mucosae forms the base of the mucosa, and has external longitudinal and internal circular layers of smooth muscle cells. It follows the surface profiles of the circular folds and sends fine fascicles of smooth muscle cells into the cores of the villi.

Submucosa

The submucosa is composed of loose connective tissue and contains blood vessels, lymphatics and nerves. Its ridged elevations form the cores of the circular folds. The geometry of its collagen and elastin fibres permits the considerable changes in transverse and longitudinal dimensions that accompany peristalsis, whilst still providing adequate support, elasticity and strength.

Submucosal (Brunner's) glands

Submucosal glands are limited to the submucosa of the duodenum and often referred to as 'Brunner's glands' (see Fig. 66.15). Their ducts traverse the muscularis mucosae to enter the bases of the mucosal crypts. They are largest and most numerous near the pylorus and form an almost complete layer in the proximal half of the descending duodenum, thereafter they gradually diminish in number and disappear at the duodenojejunal junction. They are small, branched tubuloacinar glands: each has several secretory acini lined by low columnar epithelial cells that produce an alkaline (pH 9) mucoid secretion which effectively neutralizes acidic chyme from the stomach. Many neuroendocrine cells are present among the acinar cells.

Muscularis externa

The muscularis externa consists of a thin external longitudinal layer and a thick internal circular layer of smooth muscle cells. It is thicker in the proximal small intestine and is mainly responsible for the differential appearance of proximal jejunum and distal ileum of CT scanning.

Serosa

Serosa is visceral peritoneum and consists of a subserous stratum of loose connective tissue covered by mesothelium. It covers the majority of the muscularis externa, the only exceptions are the part adjacent to mesenteric adipose tissue and the retroperitoneal portions of the duodenum, both of which are covered mainly by a connective tissue adventitia rather than by serosa.

CHAPTER 67

Large intestine

OVERVIEW

The large intestine extends from the ileocaecal valve to the anus. Broadly speaking, it lies in a curve which tends to form a border around the loops of small intestine that are located centrally within the abdomen (Figs 67.1, 67.2). The large intestine begins in the right iliac fossa as the caecum, from which the vermiform appendix arises. The caecum becomes the ascending colon which passes upwards in the right lumbar region and hypochondrium to the inferior aspect of the liver where it bends to the left forming the hepatic flexure (right colic flexure) and becomes the transverse colon. This loops across the abdomen with an anteroinferior convexity until it reaches the left hypochondrium, where it curves inferiorly to form the splenic flexure (left colic flexure) and becomes the descending colon, which proceeds through the left lumbar and iliac regions to become the sigmoid colon in the left iliac fossa. The sigmoid colon descends deep into the pelvis and becomes the rectum which ends in the anal canal at the level of the pelvic floor. The large intestine is approximately 1.5 m long in adults, although there is considerable variation in its length. Its calibre is greatest near the caecum and gradually diminishes to the level of the sigmoid colon. The rectum is largest in calibre in its lower third and forms the rectal ampulla above the anal canal.

The large intestine differs from the small intestine in several ways: it has a greater calibre; for most of its course it is more fixed in position; its longitudinal muscle, though a complete layer, is concentrated into three longitudinal bands, taeniae coli, in all but the distal sigmoid colon and rectum; small adipose projections, appendices epiploicae, are scattered over the free surface of the whole colon (they tend to be absent from the caecum, vermiform appendix and rectum); the colonic wall is puckered into sacculations (haustrations), which may partly be due to the presence of the taeniae coli, and which may be demonstrated on plain radiographs as incomplete septations arising from the bowel wall.

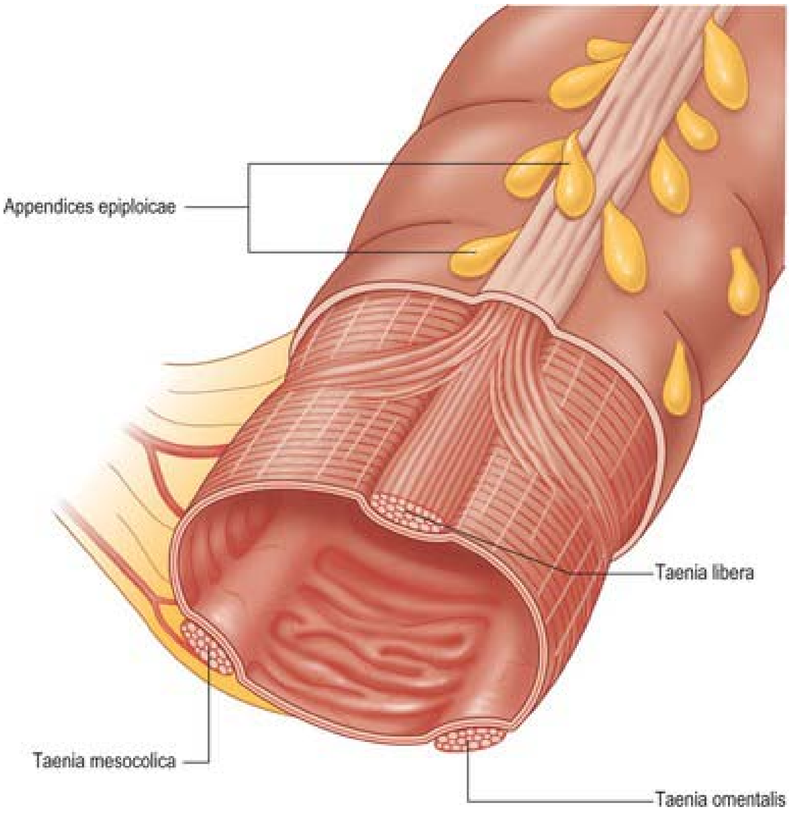
The large intestine develops as a fully mesenteric organ. However, after the rotation of the gut tube *in utero*, large portions of it come to lie adherent to the retroperitoneum, which means that some parts of the colon are fixed within the retroperitoneum, and other parts are suspended by a mesentery within the peritoneal cavity. Those portions of the colon within the retroperitoneum are separated from other retroperitoneal structures by a thin layer of connective tissue which forms an avascular field during surgical dissection, but which offers little or no barrier to the spread of disease within the retroperitoneum.

The caecum may be within the retroperitoneum, but more frequently is suspended by a short mesentery. The ascending colon is usually a retroperitoneal structure although the hepatic flexure may be suspended by a mesentery. The transverse colon emerges from the retroperitoneum on a rapidly elongating mesentery and lies, often freely mobile, in the upper abdomen. The transverse mesocolon shortens to the left of the upper abdomen and may become retroperitoneal at the splenic flexure. Occasionally the splenic flexure is suspended by a short mesentery. The descending colon is retroperitoneal usually to the level of the left iliac crest. As the colon enters the pelvis it becomes increasingly more mesenteric again at the origin of the sigmoid colon, although the overall length of the sigmoid mesentery is highly variable. The distal sigmoid colon lies on a rapidly shortening mesentery as it approaches the pelvis; by the level of the rectosigmoid junction the mesentery has all but disappeared, so that the rectum enters the pelvis as a retroperitoneal structure. The caecum and proximal ascending colon are often more mobile on a longer mesentery in the neonate and infant than they are in the adult.

The mesenteries of the colon consist of visceral peritoneum enclosing connective and adipose tissues which envelop the vessels, nerves and lymphatics as they course from the retroperitoneum. Where the colonic mesenteries lie in contact with the retroperitoneum, the (potential) space between the retroperitoneum and mesentery is referred to as the subperitoneal space, which allows free tracking of pathological processes in either direction.

EXTERNAL APPEARANCE

The haustrations of the colon are often absent in the caecum proximal to the origin of the ascending colon and are often relatively sparse in the ascending and proximal transverse colon. In these regions the taeniae coli are usually thin and occupy only a small percentage of the circumference of the colon. There are few if any appendices epiploicae on the serosal surface of the caecum, and only a limited number on the surface of the ascending colon. The haustrations become more pronounced from the middle of the transverse colon to the distal portion of the descending colon: the sigmoid colon is often characterized by marked sacculation. The width of the taeniae coli remains fairly constant throughout the length of colon but the number of appendices epiploicae usually increases, becoming in the sigmoid colon where they can be large in the obese individual. The taeniae are located in fairly constant positions beneath the serosal surface of the colon except in the transverse colon. They are oriented anteriorly on the anti-mesenteric aspect of the colon opposite the midline of the mesenteric attachment (taenia libera), posterolaterally (taenia omentalis) and posteromedially (taenia mesocolica) midway between the taenia libera and the mesentery (Fig. 67.3). In the caecum and descending colon, which are partly retroperitoneal structures, the posterolateral taenia is often obscured from view by the peritoneal reflection onto the colonic wall. In the transverse colon, the taeniae are rotated through 90° as a consequence of the mobility and dependent position of this part of the colon, thus anterior becomes inferior, posteromedial becomes posterior and posterolateral becomes superior. The taeniae coli broaden to occupy more of the circumference of the sigmoid colon in its distal portion and by the level of the rectosigmoid junction they form distinct anterior and posterior bands. These bands subsequently unite to form a complete longitudinal muscle covering for the rectum which therefore has no external sacculation. The rectum also lacks serosal appendices epiploicae.



Appendices epiploicae
Taenia libera
Taenia mesocolica
Taenia omentalis

Fig. 67.3 Layers of the colonic wall.

INTERNAL APPEARANCE

Throughout its length, the internal aspect of the colon is characterized by the presence of haustrations. These infoldings of the wall consist of mucosa and submucosa, and may partially span the lumen, but they never form a complete, circumferential ring. The pattern of the haustrations and appearance of the colonic mucosa help the clinician appreciate the level reached during flexible endoscopic examinations of the colon. In the portion of the caecum where haustrations occur, the three longitudinal taeniae coli converge to form a characteristic ‘trefoil’ pattern on the caecal wall (Fig. 67.4). Elsewhere, the wall of the lower pole of the caecum is usually devoid of haustrations, although a spiral mucosal pattern is often seen in the region of the appendix orifice (see Fig. 67.19). The upper caecum and ascending colon possess shallow but long haustrations which may extend across one-third of the lumen (Fig. 67.5). This pattern is most pronounced in the transverse colon where the long haustrations often confer a triangular appearance to the cross section of the lumen when viewed along the axis (such as at colonoscopy) (Fig. 67.6). The wall of the colon is thinnest in the region of the caecum and ascending colon and is most at risk of perforation during therapeutic endoscopic procedures. The haustrations of the descending and sigmoid colon tend to be thicker and shorter than those of the transverse colon, and this gives a more circular cross-section to the lumen. The overall luminal diameter is often smallest in the descending colon (Fig. 67.7). During endoscopy, the pattern of the submucosal vessels becomes more conspicuous in the sigmoid colon (Fig. 67.8). The mobility of the sigmoid colon on its mesentery means that shorter lengths of colon tend to be visible during endoscopy than anywhere else in the colon. The haustrations of the rectum tend to form consistent and recognizable folds: the pattern of the submucosal vessels is the most pronounced in the colon being of largest calibre with multiple visible veins (Fig. 67.9). Distinct veins are usually visible during endoscopy, and they are most marked above the anorectal junction.

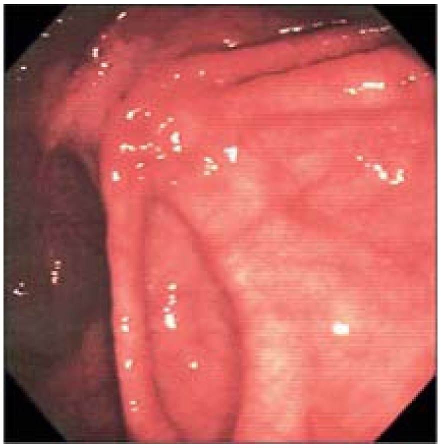


Fig. 67.4 Endoscopic appearance of the caecum. The characteristic trefoil appearance of the confluence of the three taeniae is usually obvious.

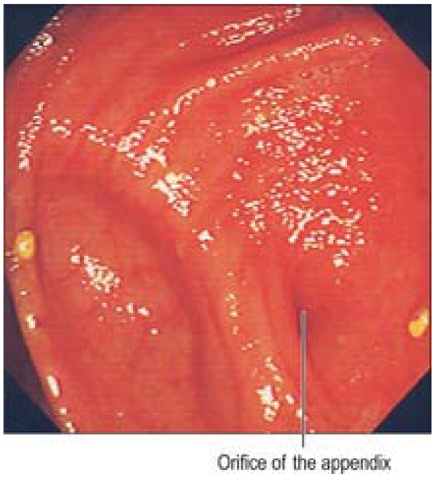

Fig. 67.19 Endoscopic appearance of the orifice of the appendix. The orifice varies from a small depression to an obvious lumenal structure.

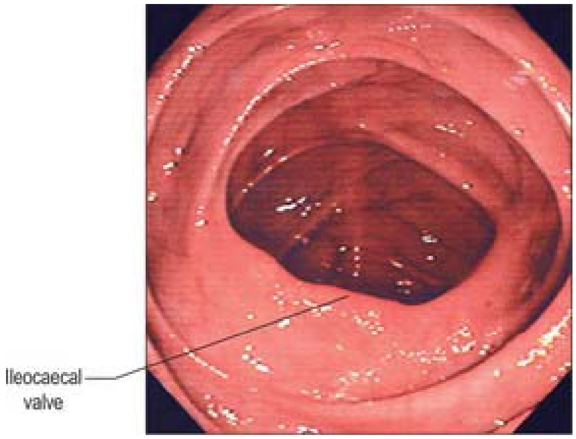

Fig. 67.5 Endoscopic appearance of the ascending colon.

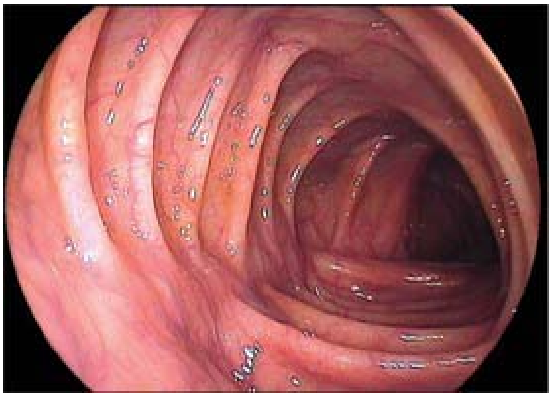

Fig. 67.6 Endoscopic appearance of the transverse colon. Note the characteristic triangular appearance of the haustrations when viewed collectively (see also Fig. 67.10C).

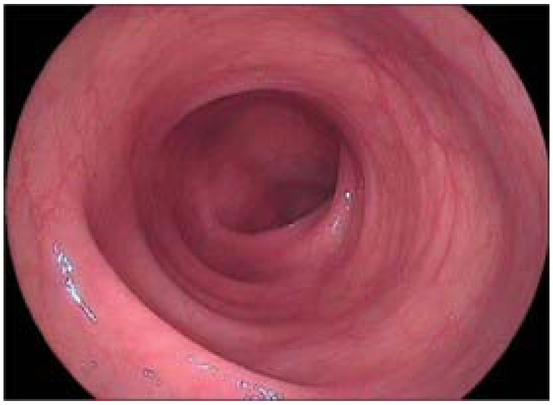

Fig. 67.7 Endoscopic appearance of the descending colon. The lumen tends to look rather more featureless than the more proximal colon.

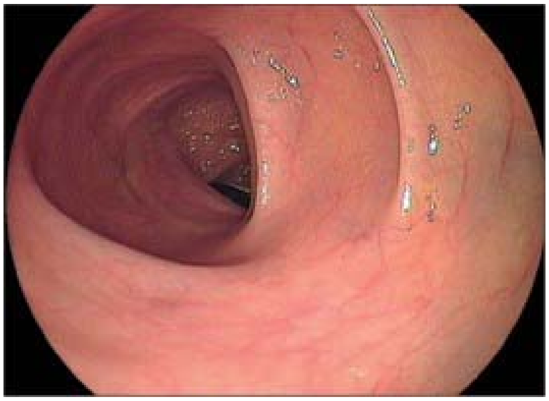

Fig. 67.8 Endoscopic appearance of the sigmoid colon. Multiple large mucosal folds are characteristic.

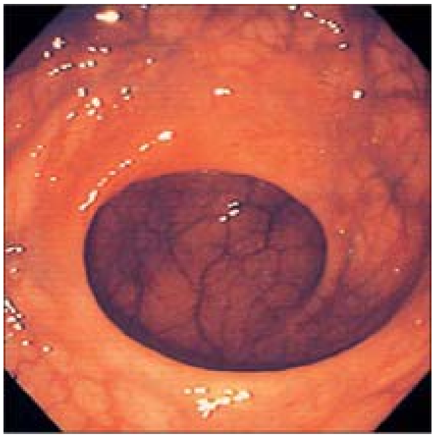

Fig. 67.9 Endoscopic appearance of the rectum. Note the large transverse folds, with little else in the way of mucosal folds, characterizes the rectum. Prominent veins are often seen, particularly in the lower third.

RADIOGRAPHIC APPEARANCES

Cross-sectional imaging of the colon can be performed with computerized tomography (CT) and magnetic resonance imaging (MRI). On axial imaging the colon may be filled with particulate faeces and air (Fig. 67.10). The wall in normal individuals is thin. The caecum and ascending colon often contain faecal residue and are easily identified in the right retroperitoneum. The transverse colon may contain faeces or gas, but lies in a variable position suspended by its mesentery. The descending colon in the left retroperitoneum is frequently collapsed and contains little faecal residue.

The volume data sets produced by modern multislice CT can now produce virtual colonoscopic mucosal images in the distended and cleaned colon, and surface-rendered images of the internal surface of the bowel.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply of the large intestine is derived from both the superior and inferior mesenteric arteries (Fig. 67.11). The caecum, appendix, ascending colon and right two-thirds of the transverse colon (derived from the midgut) are supplied from ileocolic, right colic and middle colic branches of the superior mesenteric artery. The left part of the transverse, descending and sigmoid colon, rectum and upper anal canal (hindgut derivatives) are supplied predominantly from the inferior mesenteric artery via the left colic, sigmoid and superior rectal arteries, with small contributions from branches of the internal iliac artery (the middle and inferior rectal arteries). The larger unnamed branches of these vessels ramify between the muscular layers of the colon which they supply. They subdivide into smaller submucosal rami and enter the mucosa. The terminal branches divide into vasa brevia and vasa longa which either enter the colonic wall directly or run through the subserosa for a short distance before crossing the circular smooth muscle to give off branches to the appendices epiploicae (Fig. 67.12).

Arterial anastomoses and the marginal artery of the colon

The arterial supply to the large intestine has less profuse anastomoses and ‘cross-over’ of arterial territories than the small intestine but there are several areas and anastomoses which provide for some degree of anatomical collateral supply to areas of the large intestine.

The marginal artery (of Drummond) of the colon is the name given to the vessel which lies closest to and parallels the wall of the large intestine. It is formed by the main trunks, and the arcades arising from, the ileocolic and right colic, middle colic and left colic arteries. It is most apparent in the ascending, transverse and descending colons (Fig. 67.13). The sigmoid colon has little if any marginal artery. Anastomoses form between the main terminal branches which run parallel to the colon within the mesentery and give rise to vasa recta and vasa brevia to supply the colon. The marginal artery in the region of the splenic flexure may be absent or of such small calibre as to be of little clinical relevance. It may hypertrophy significantly when one of the main visceral arteries is compromised, e.g. following stenosis or occlusion of the inferior mesenteric artery, and it then provides a vessel of collateral supply.

(By courtesy of Dr J Jackson, Hammersmith Hospital, London.)

The arc of Riolan is the name given to the arterial anastomosis which is sometimes present in the mesentery between the right side of the transverse colon and the upper descending colon. When present it is formed from a large branch of the middle colic artery which runs parallel and posterior to the middle colic artery in the transverse mesocolon and anastomoses with an ascending branch of the left colic artery close to its origin in the root of the mesentery. This provides a direct communication between the superior and inferior mesenteric arteries.

Colonic vascular occlusion

The marginal artery of the colon may become massively dilated when there is chronic, progressive occlusion of the superior mesenteric artery, because under these conditions it is required to supply the majority of the midgut (except the proximal portion which is supplied by collateral vessels from the coeliac artery). Occlusion of the aorta or common iliac arteries may also result in dilatation of the marginal and inferior mesenteric arteries, which become an important collateral supply to the legs via dilated middle rectal vessels arising from the internal iliac artery.

Occlusion of the inferior mesenteric artery does not always result in irreversible ischaemia of the descending and sigmoid colon, because the marginal artery of the colon usually receives an adequate supply from the left branch of the middle colic artery. Moreover, the sigmoid arteries may be supplied by the superior rectal artery, which anastomoses with the middle and inferior rectal arteries. When ischaemia does occur, it is usually maximal in the proximal descending colon because this region is furthest from the collateral arterial supplies.

Veins

The venous drainage of the large intestine is primarily into the hepatic portal vein via the superior mesenteric and inferior mesenteric veins, although a small amount of drainage from the rectum occurs via middle rectal veins into the internal iliac veins and via inferior rectal veins into the pudendal vein. Those parts of the colon derived from the midgut (caecum, appendix, ascending colon and right two-thirds of the transverse colon) drain into colic branches of the superior mesenteric vein, while hindgut derivatives (left part of the transverse, descending and sigmoid colon, rectum and upper anal canal) drain into the inferior mesenteric vein (Fig. 67.14).

Lymphatics

Lymphatic vessels of the caecum, ascending and proximal transverse colon drain ultimately into lymph nodes related to the superior mesenteric artery, while those of the distal transverse colon, descending colon, sigmoid colon and rectum drain into nodes following the course of the inferior mesenteric artery (Fig. 67.15). In cases where the distal transverse colon or splenic flexure is predominantly supplied by vessels from the middle colic artery, the lymphatic drainage of this area may be predominantly to superior mesenteric nodes.

Fig. 67.15 The lymph vessels and nodes during the large intestine.

Colic nodes

Lymph nodes related to the colon form four groups, namely epicolic, paracolic, intermediate colic and preterminal colic nodes. Epicolic nodes are minute nodules on the serosal surface of the colon, sometimes in the appendices epiploicae. Paracolic nodes lie along the medial borders of the ascending and descending colon and along the mesenteric borders of the transverse and sigmoid colon. Intermediate colic nodes lie along the named colic vessels (the ileocolic, right colic, middle colic, left colic, sigmoid and superior rectal arteries). Preterminal colic nodes lie along the main trunks of the superior and inferior mesenteric arteries and drain into para-aortic nodes at the origin of these vessels. These are commonly referred to as the highest nodes of the territory which they drain.

Lymph node clearance in colorectal cancer resections

Radical lymphadenectomy during resection for colorectal cancer requires removal of the highest possible lymph node draining the area of colon in which the tumour is located. In cases of cancer involving the rectum and sigmoid colon, this usually involves resection of the preterminal colic nodes of the inferior mesenteric artery and thus ligation of the inferior mesenteric artery at its root or just below the origin of the left colic artery. A detailed description of the classification of the lymph nodes with regard to the site of the primary tumour within the colon has been suggested by the Japanese Society for the Cancer of the Colon and Rectum.

INNERVATION

The colon and rectum are innervated by the sympathetic and parasympathetic systems (see Ch. 60; see Figs 60.2–60.4).

The sympathetic supply to the caecum, appendix, ascending colon and right two-thirds of the transverse colon originates in the fifth to the 12th thoracic spinal segments and are conveyed to the coeliac and superior mesenteric plexuses via the greater and lesser splanchnic nerves where they and synapse on ganglionic neurones. Postganglionic axons travel along branches of the superior mesenteric artery, and are distributed to the colon from periarterial plexuses. The parasympathetic supply is derived from the vagus nerve via the coeliac and superior mesenteric plexuses.

The sympathetic supply of the left third of the transverse colon, the descending and sigmoid colon, rectum and upper anal canal originates in the first and second lumbar spinal segments. The fibres are distributed via the lumbar splanchnic nerves through the abdominal aortic and the inferior mesenteric plexuses and via the sacral splanchnic nerves through the superior and inferior hypogastric plexuses. Postganglionic axons reach the gut wall via periarterial plexuses on branches of the inferior mesenteric artery. The parasympathetic supply travels via the pelvic splanchnic nerves (nervi erigentes) from cell bodies in the second to the fourth sacral spinal segments. Those distributed to the rectum and upper anal canal run through the inferior and superior hypogastric plexuses to branches of the inferior mesenteric artery. Some of those distributed to the descending and sigmoid colon run via these plexuses; however, a large number of fibres pass directly through the retroperitoneal tissues to the splenic flexure, descending and sigmoid colon independently of the inferior mesenteric artery.

The ultimate distribution within the wall of the large intestine is similar to the small intestine. The colic sympathetic nerves are motor to the ileocaecal valve musculature and inhibitory to mural muscle in the colon and rectum. Some fibres are vasoconstrictor to the colic vasculature. Parasympathetic nerves are secretomotor to colorectal glands, motor to the colic and rectal musculature and inhibitory to the internal anal sphincter.

Afferent impulses mediating sensations of distension are carried by visceral afferent fibres which travel with the parasympathetic nerves; pain impulses pass in visceral afferents travelling with the sympathetic and parasympathetic nerves supplying the rectum and the upper part of the anal canal.

CAECUM, VERMIFORM APPENDIX AND ASCENDING COLON

CAECUM

The caecum is a large blind pouch lying in the right iliac fossa below the ileocaecal valve, continuous proximally with the distal ileum and distally with the ascending colon. The blind-ending vermiform appendix usually arises on its medial side at the level of the ileal opening. Its average axial length is 6 cm and its breadth 7.5 cm. It rests posteriorly on the right iliacus and psoas major, with the lateral cutaneous nerve of the thigh interposed. Posteriorly lies the retrocaecal recess which frequently contains the vermiform appendix. The anterior abdominal wall is immediately anterior to the caecum except when it is empty, in which case the greater omentum and some loops of the small intestine may be interposed. Usually the caecum is entirely covered by peritoneum, but occasionally this is incomplete posterosuperiorly where it lies over the iliac fascia only separated from it by loose connective tissue.

In early fetal life the caecum is usually short, conical and broad based, with an apex turned superomedially towards the ileocaecal junction. As the fetus grows, the caecum increases initially in length more than in breadth, still with the apex turned superomedially; in the later stages of intrauterine growth, the proximal part of the caecum widens so that the caecum is still a conical shape, but the apex (from which the appendix arises) comes to point inferomedially. This infantile form persists throughout life in only a very small percentage of individuals. Occasionally the originally conical caecum becomes quadrate as a result of the outgrowth of a saccule on each side of the anterior taenia: the saccules are of equal size and the appendix arises from the depression between them instead of from the apex of a cone. In the normal adult form, the right saccule grows more rapidly than the left, forming a new ‘apex’. The original apex, with the appendix attached, is pushed towards the ileocaecal junction (Fig. 67.16).

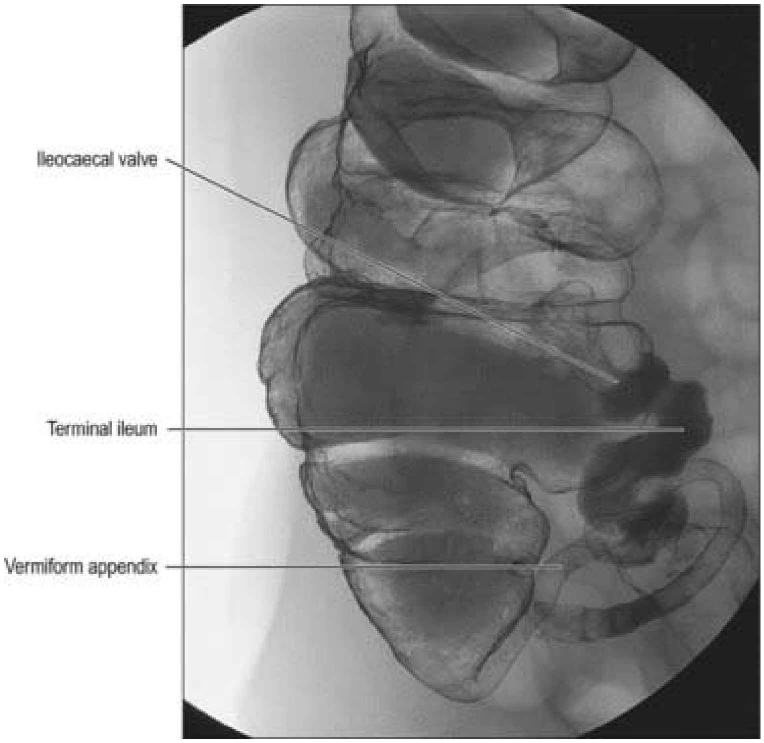

Fig. 67.16 The caecum and ileocaecal valve, double contrast barium enema appearance.

The process of fluid and electrolyte reabsorption starts in the caecum but takes place largely in the ascending and transverse colon. The distensible nature and ‘sac-like’ morphology of the caecum permit storage of large volumes of semi-liquid chyme that enters from the small bowel via the ileocaecal valve. The large resting diameter of the caecum makes it most liable to distension during periods of increased intracolonic pressure and thus it is the most vulnerable portion of the large intestine to perforation secondary to dilatation (obstructed or otherwise).

Ileocaecal valve

The ileum opens into the posteromedial aspect of the large intestine at the junction of the caecum and colon via the ileocaecal ‘valve’. The orifice has two flaps which project into the lumen of the large intestine (Fig. 67.17). The precise shape and form of the valve varies; in the cadaveric caecum the flaps are often semilunar, but in life they can often be seen to form a rosette or trefoil pattern of mucosa. The upper flap, approximately horizontal, is attached to the junction of the ileum and colon; the lower flap is longer and more concave, and is attached to the junction of the ileum and caecum. At their ends the flaps fuse, continuing as narrow membranous ridges, the frenula of the valve. The orifice may appear in many different shapes depending on the state of contraction or distension of the caecum; it is commonly either a slit or an oval.

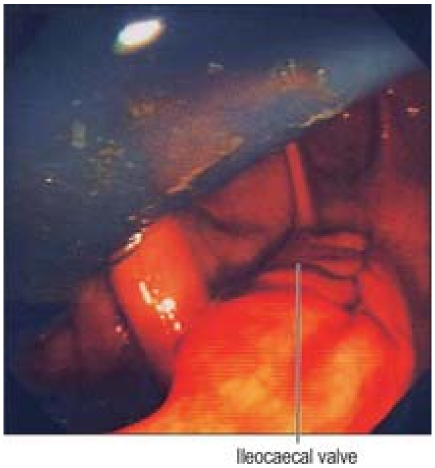

Fig. 67.17 Endoscopic appearance of the ileocaecal valve.

The margin of the ileocaecal valve is formed by a reduplication of the intestinal mucosa and circular muscle. Longitudinal muscle fibres are partly reduplicated as they enter the valve, but the more superficial fibres and the peritoneum continue from the small to the large intestine without interruption. The valve may prevent reflux of chyme from the caecum to the ileum, and may slow the passage of ileal contents into the caecum when the circular muscle of the valve is contracted by sympathetic stimulation. Although circular and longitudinal muscle layers of the terminal ileum continue into the valve, there is little evidence that it constitutes a true functional sphincter.

The ileal valvular surfaces are covered with villi and have the structure of the small intestinal mucosa, whereas their caecal surfaces have no villi but display numerous orifices of tubular glands peculiar to the colonic mucosa.

Caecal volvulus

Because the caecum and ascending colon may possess a mesentery to a variable degree, it is possible for the caecum (and lower portion of the ascending colon) to rotate about their mesenteric attachment (mesentero-axial volvulus) such that the lower pole of the caecum comes to lie in the left or right upper quadrant of the abdomen. The fixed apex of this rotation is formed by the attachment of the caecal mesentery to the retroperitoneum. Volvulus occurs most commonly in those individuals where a large portion of the ascending colon lies on a mesentery and the common origin of the caecal and ascending colic mesentery is narrow. It is extremely unlikely in individuals where the caecum and ascending colon possess a short broadly attached mesentery. True isolated volvulus of the caecum is extremely rare.

VERMIFORM APPENDIX

The vermiform appendix is a narrow, vermiform (worm-like) tube which arises from the posteromedial caecal wall, approximately 2 cm below the end of the ileum. It may occupy one of several positions (Fig. 67.18). The commonest positions seen in clinical practice are retrocaecal or retrocolic (behind the caecum or lower ascending colon respectively), pelvic, or descending (when the appendix hangs dependently over the pelvic brim, in close relation to the right uterine tube and ovary in females). Other positions, including subcaecal (below the caecum), and pre- or post-ilial (anterior or posterior to the terminal ileum respectively), are occasionally seen, especially when there is a long appendicular mesentery which allows greater mobility.

Fig. 67.18 The major positions of the appendix encountered at surgery or postmortem.

The three taeniae coli on the ascending colon and caecum converge on the base of the appendix, and merge into its longitudinal muscle. The anterior caecal taenia is usually distinct and can be traced to the appendix, which affords a guide to its location intra-operatively. The appendix varies from 2–20 cm in length: it is often relatively longer in children and may atrophy and shorten after mid-adult life. It is connected by a short mesoappendix to the lower part of the ileal mesentery. This fold is usually triangular, extending almost to the appendicular tip along the whole viscus.

The lumen of the appendix is small and opens into the caecum by an orifice lying below and slightly posterior to the ileocaecal opening. The orifice is sometimes guarded by a straight mucosal fold forming an asymmetrical 'valve' which gives the appendix orifice the appearance of a 'strung bow' (Fig. 67.19). This fold tends to lie parallel to the medial wall of the caecum and ileocaecal valve and an imaginary 'arrow' placed in the bow usually points in the direction of the ileocaecal valve; this is a useful sign during colonoscopic examinations. The lumen may be widely patent in early childhood but is often partially or wholly obliterated in the later decades of life.

Microstructure

The layers of the wall of the appendix are essentially those of the rest of the large intestine (see below) but some features are notably different and are described here. The serosa forms a complete covering, except along the mesenteric attachment. The longitudinal muscular fibres form a complete layer of uniform thickness, except over a few small areas where both muscular layers are deficient, so that the serosa and submucosa are in contact. At the base of the appendix, the longitudinal muscle thickens to form rudimentary taeniae that are continuous with those of the caecum and colon.

The submucosa typically contains many large lymphoid aggregates that extend from the mucosa and obscure the muscularis mucosae layer, which consequently is discontinuous. These aggregates also cause the mucosa to bulge into the lumen of the appendix, so that it narrows irregularly (Fig. 67.20). The mucosa is covered by a columnar epithelium as it is elsewhere in the large intestine, and the epithelium that overlies the mucosal lymphoid tissue contains M cells. Glands (crypts) are similar to those of the colon but are fewer in number and so are less densely packed. They penetrate deep into the lymphoid tissue of the mucosal lamina propria. The submucosal lymphoid tissue frequently exhibits germinal centres within its follicles, indicative of B-cell activation, as occurs in secondary lymphoid tissue elsewhere. Lymphoid follicles are absent at birth but accumulate over the first 10 years of life to become a prominent feature of the appendix. In adults, the normal layered structure of the appendix is lost and the lymphoid follicles atrophy and are replaced by collagenous tissue, and in the elderly, the appendix may be filled with fibrous scar tissue.

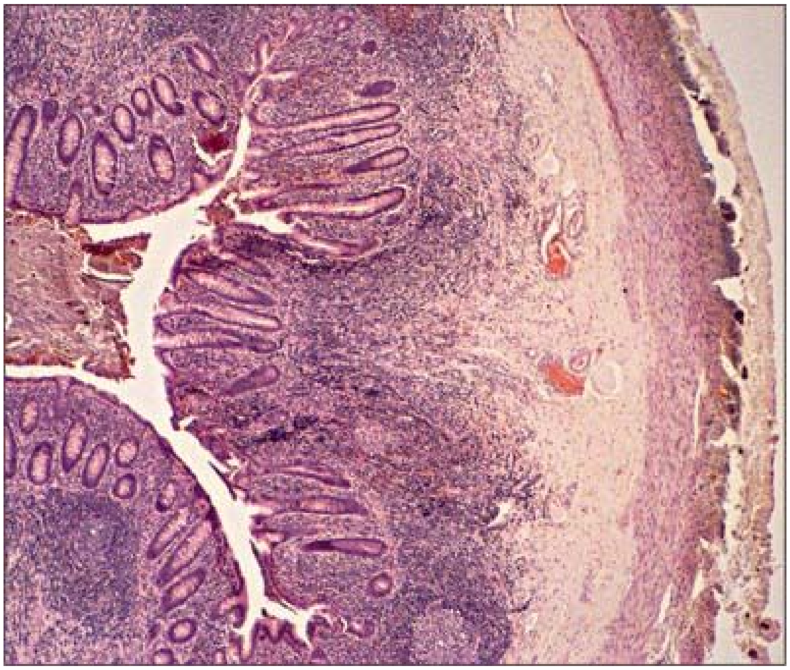

Fig. 67.20 Low-power micrograph of the appendix in transverse section, showing part of its circumference and a faecal pellet lodged in its lumen. Lymphoid tissue (basophilic staining) occupies much of the mucosa between crypts, and part of the submucosa. The muscularis externa and outermost serosal layer are seen at the right of the field.

Acute appendicitis

The genesis of acute appendicitis varies between individuals. It may follow obstruction of the lumen, when it is a consequence of increased intraluminal pressure and retention of (infected) contents which allows acute suppuration to occur. The size of the orifice of the appendix in some individuals may contribute to the risk that this will happen. Appendicoliths may be visible on plain radiographs in 7–15% of the normal population: in those patients with acute abdominal pain, their presence indicates a high risk of appendicitis being present. The increased size of the orifice and lumen at the extremes of life may be a reason why acute appendicitis is relatively uncommon in these age groups. Acute appendicitis may also present as a primary suppuration of the tissues of the appendix itself: the reduction in appendicular lymphoid tissue that occurs in later life may be another reason why the disease is infrequent in the elderly. Although the appendix is well supplied by arterial anastomoses at its base, the appendicular artery is an end artery from the midpoint upwards and its close proximity to the wall makes it susceptible to thrombosis during episodes of acute inflammation. This may render the distal appendix ischaemic and explains the frequency of gangrenous perforation seen in the disease.

The appendix and overlying visceral peritoneum are innervated by sympathetic and parasympathetic nerves from the superior mesenteric plexus. Visceral afferent fibres carrying sensations of distension and pressure mediate the symptoms of ‘pain’ felt during the initial stages of appendicular inflammation. In keeping with other structures derived from the midgut, these sensations are poorly localized initially, and referred to the central (periumbilical) region of the abdomen. It is not until parietal tissues adjacent to the appendix become involved in any inflammatory process that somatic nociceptors are stimulated, and there is an associated change in the nature and localization of pain. The caecum and proximal ascending colon share a common innervation with the appendix (sympathetic and parasympathetic nerves via the superior mesenteric plexus), which means that early inflammation in the caecum (typhlitis) results in similar visceral pain symptoms to those experienced in appendicitis.

ASCENDING COLON

The ascending colon is approximately 15 cm long and narrower than the caecum. It ascends to the inferior surface of the right lobe of the liver, on which it makes a shallow depression, and then turns abruptly forwards and to the left, at the hepatic flexure. It is a retroperitoneal structure covered anteriorly and on both sides by peritoneum. Its posterior surface is separated by loose connective tissue from the iliac fascia, the iliolumbar ligament, quadratus lumborum, the aponeurosis of transversus abdominis, and the anterior peri-renal fascia inferolateral to the right kidney. The lateral femoral cutaneous nerve, usually the fourth lumbar artery, and sometimes the ilioinguinal and iliohypogastric nerves, lie posteriorly as they cross quadratus lumborum. Laterally the peritoneum forms the lateral paracolic gutter and medially the medial paracolic gutter (Fig. 67.21). The ascending colon possesses a narrow mesocolon for part of its course in up to one-third of cases. Anteriorly it is in contact with loops of ileum, the greater omentum and the anterior abdominal wall.

Fig. 67.21 Posterior relations of the ascending colon.

Hepatic flexure

The hepatic flexure forms the junction of the ascending and transverse colon as the latter turns down, forwards and to the left. It is variable in position and usually has a less acute angle than the splenic flexure. The anterior surface of the lower pole of the right kidney is posterior, the right lobe of the liver is superior and anterolateral (Fig. 67.22), the descending (second) part of the duodenum is medial and the fundus of the gallbladder is anteromedial. The posterior aspect of the hepatic flexure is not covered by peritoneum and the gut wall is in direct contact with pararenal fascia. The hepatic flexure is often covered in the greater omentum which may be attached to the anterior surface both of the upper ascending colon and the proximal (right) end of the transverse colon.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Superior mesenteric artery

The arteries to the caecum, appendix and ascending colon are somewhat variable, but all are derived from the superior mesenteric artery via the ileocolic and right colic (when present) arteries (see Figs 67.11, 67.13).

Ileocolic artery

The ileocolic artery arises from the right side of the superior mesenteric artery in its upper half in the root of the mesentery. It descends to the right beneath the parietal peritoneum towards the caecum and crosses anterior to the right ureter, gonadal vessels and psoas major to enter the right iliac fossa. Although the terminal distribution varies, the artery usually divides into a superior division which runs superolaterally towards the ascending colon where it anastomoses with the right colic artery (or right branch of the middle colic artery), and an inferior division which anastomoses with the final ileal branch of the distal superior mesenteric artery. The inferior division approaches the superior border of the ileocolic junction. It usually gives rise to the following branches: ascending colic (which passes up on the ascending colon to anastomose with the superior division), anterior caecal, posterior caecal (which usually gives rise to the appendicular artery) and ileal (which ascends to the left on the lower ileum, supplies it and anastomoses with the last ileal branch of the superior mesenteric artery (Fig. 67.23). The caecum is supplied almost entirely from the ileocolic artery.

Ileal branch
Appendicular artery

Fig. 67.23 The arteries of the caecum, vermiform appendix and ascending colon.

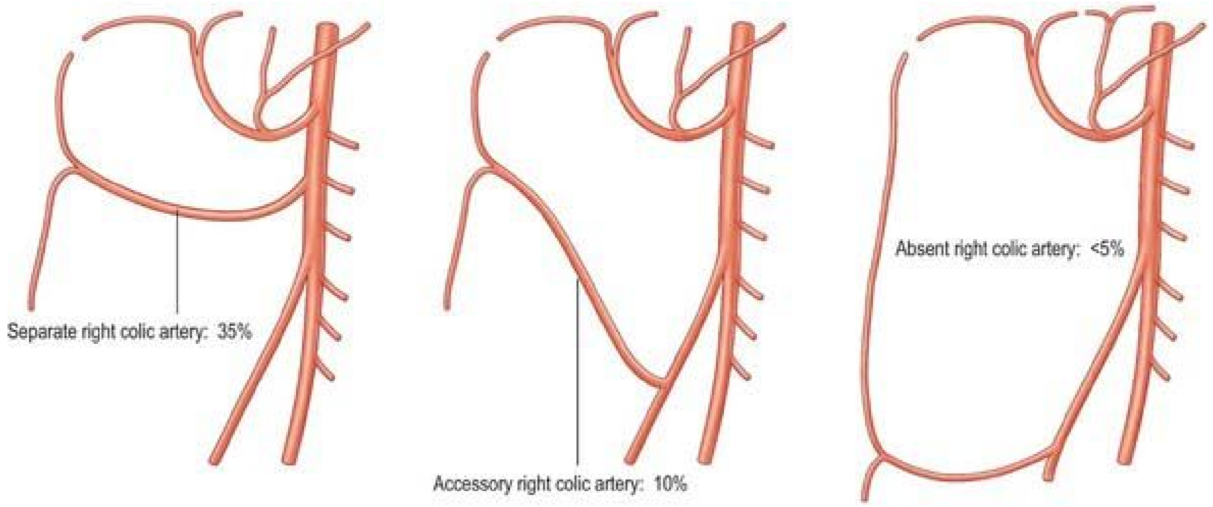
The ileocolic artery is the most prominent vessel in the lower right colic mesentery and traction on the caecum in the direction of the anterior superior iliac crest will readily cause the vessel to ‘tent’ the mesentery due to its direct course towards the caecum. This allows easy identification of the vessel during laparoscopic surgery.

The appendicular artery descends behind the terminal ileum to enter the mesoappendix a short distance from the appendicular base (Fig. 67.23). Here it gives off a recurrent branch, which anastomoses at the base of the appendix with a branch of the posterior caecal artery: the anastomosis is sometimes extensive. The main appendicular artery approaches the tip of the organ, at first near to, and then in the edge of, the mesoappendix. The terminal part of the artery lies on the wall of the appendix and may be thrombosed in appendicitis, which results in distal gangrene or necrosis. Accessory arteries are common, and many individuals possess two or more arteries of supply to the appendix.

The arcades of the terminal ileal artery provide a collateral supply to the caecum via anastomoses with the ileal branch of the ileocolic artery.

Right colic artery

The right colic artery is a small vessel that is highly variable in its anatomy (Fig. 67.24). Most commonly it arises as a common trunk with the middle colic artery. Alternatively it may arise as a separate branch from the right side of the superior mesenteric artery, or from the ileocolic artery (when it is referred to as an accessory right colic artery), and occasionally it may be absent. From its origin in common with the middle colic artery it passes towards the ascending colon, deep to the parietal peritoneum and anterior to the right gonadal vessels, right ureter and psoas major. Sometimes it arises more superiorly and crosses the second part of the duodenum and inferior pole of the right kidney. Near the colon it divides into a descending branch, which anastomoses with the ileocolic artery, and an ascending branch which anastomoses with the right branch of the middle colic artery. These form the marginal artery in the area of the hepatic flexure from which vessels are distributed to the upper third of the ascending colon, and the right side of the transverse colon.



Separate right colic artery: 35%
Accessory right colic artery: 10%
Absent right colic artery: <5%

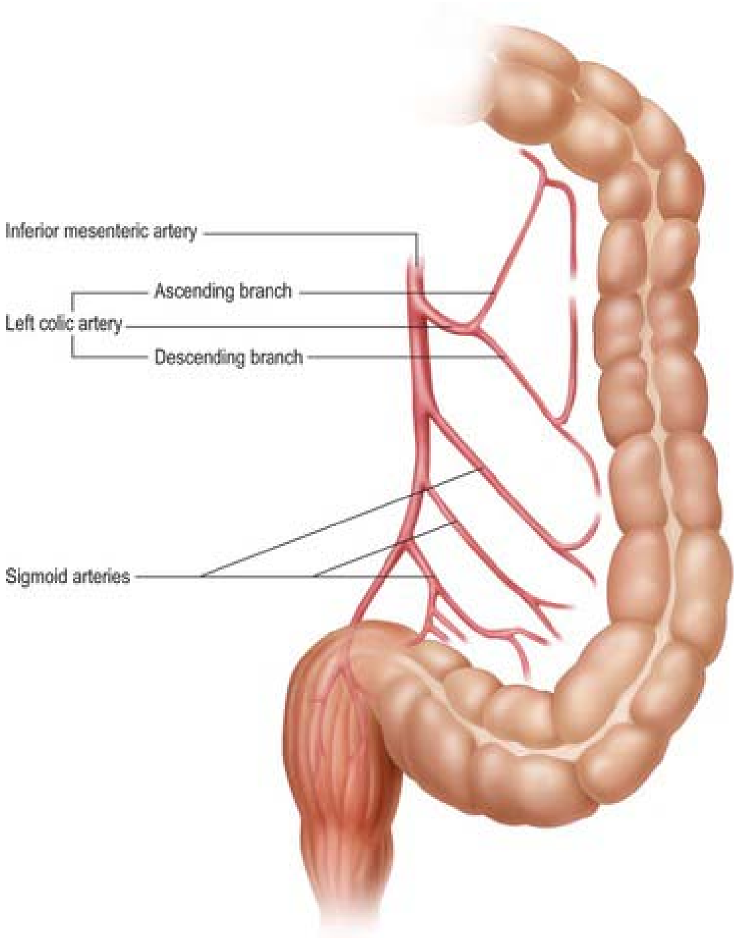
Fig. 67.24 Anatomical variants of the right colic artery.

Veins

Venous blood from the wall of the caecum, appendix and ascending colon drains into mesenteric arcades and subsequently into segmental veins, which accompany their respective arteries and tend to follow variations in arterial drainage. The segmental veins drain into the superior mesenteric vein, which lies to the right of the mesenteric artery.

Superior mesenteric vein

The superior mesenteric vein receives one or more middle colic veins, the right colic vein and the ileocolic vein and drains into the portal vein (see Figs 67.31, 66.12).



Inferior mesenteric artery
Ascending branch
Left colic artery
Descending branch
Sigmoid arteries

Fig. 67.31 The inferior mesenteric artery.

Ileocolic vein

The tributaries of the ileocolic vein follow a broadly similar pattern to the branches of the ileocolic artery, and are formed from superior and inferior tributaries. The vein ascends alongside the ileocolic artery beneath the peritoneum of the ileocaecal mesentery and drains into the superior mesenteric vein. The inferior tributary receives appendicular veins (via the posterior caecal or ileocolic veins) and anterior and posterior caecal and ileal veins, and the superior tributary drains the ascending colic veins.

Ascending tributaries of the ileocolic and right colic veins accompany their respective arteries into the root of the mesentery and drain via the ileocolic vein into the superior mesenteric vein.

Right colic vein

The right colic vein is highly variable and may drain into the superior mesenteric vein directly, or the right gastroepiploic or inferior pancreaticoduodenal vein to form a ‘gastrocolic trunk’ which drains into the superior mesenteric vein, or it may be absent entirely.

Lymphatics

Lymphatic vessels originate from both anterior and posterior aspects of the colon and drain into nodes located along the branches of the ileocolic and the right colic arteries. Lymphatic drainage from the distal ascending colon and hepatic flexure may be predominantly to the nodes of the right colic artery. The lymphatic anastomoses are rich and the preterminal nodes for both routes of drainage are the ileocolic nodes, located close to the superior mesenteric artery (Fig. 67.15).

Lymphatic vessels in the appendix are numerous and there is abundant lymphoid tissue in its walls. From the body and apex of the appendix, 8–15 vessels ascend in the mesoappendix, occasionally interrupted by one or more nodes. They unite to form three or four larger vessels which run into the lymphatic vessels that drain the ascending colon, and end in the inferior and superior nodes of the ileocolic chain.

INNERVATION

The sympathetic supply to the caecum, appendix and ascending colon originates in the intermediolateral grey matter of the fifth to the 12th thoracic spinal segments. Preganglionic axons travel via the greater and lesser splanchnic nerves to the coeliac and superior mesenteric plexuses where they synapse on neurones in the coeliac and superior mesenteric ganglia; postganglionic axons form periarterial plexuses along the branches of the superior mesenteric artery, whence they are distributed to the walls of the colon.

The parasympathetic supply to the caecum, appendix and ascending colon is derived from the vagus nerve via the coeliac and superior mesenteric plexuses.

Referred pain

The appendix and overlying visceral peritoneum are innervated by sympathetic and parasympathetic nerves from the superior mesenteric plexus. Visceral afferent fibres carrying sensations of distension and pressure mediate the symptoms of ‘pain’ felt during the initial stages of appendicular inflammation. In keeping with other structures derived from the midgut, these sensations are poorly localized initially, and referred to the central (periumbilical) region of the abdomen. It is not until parietal tissues adjacent to the appendix become involved in any inflammatory process that somatic nociceptors are stimulated, and there is an associated change in the nature and localization of pain. The caecum and proximal ascending colon share a common innervation to the appendix (sympathetic and parasympathetic nerves via the superior mesenteric plexus); early inflammation in the caecum (typhlitis) results in similar visceral pain symptoms to appendicitis.

TRANSVERSE COLON

The transverse colon is approximately 50 cm long, and extends from the hepatic flexure in the right lumbar region across into the left hypochondriac region, where it curves posteroinferiorly below the spleen as the splenic flexure. It is highly variable in length and position, as may be confirmed by radiological assessment, but it often describes an inverted arch, with its concavity directed posteriorly and superiorly. Near the splenic flexure an abrupt U-shaped curve may descend lower than the main arch. The posterior surface at the hepatic flexure is devoid of peritoneum and is attached by loose connective tissue to the front of the descending part of the duodenum and the head of the pancreas. The transverse colon from here to the splenic flexure is almost completely invested by peritoneum. It is suspended from the anterior border of the body of the pancreas by the transverse mesocolon which is attached from the inferior part of the right kidney, across the second part of the duodenum and pancreas, to the inferior pole of the left kidney. The transverse colon hangs down between the flexures to a variable extent, and sometimes reaches the pelvis. Above it are the liver and gallbladder, the greater curvature of the stomach and the body of the spleen. The transverse colon is usually attached to the greater curvature of the stomach by the gastrocolic ligament, which is in continuity with the greater omentum, lying anteriorly and extending inferiorly. Behind and below the transverse colon lie the descending part of the duodenum, the head of the pancreas, the upper end of the small bowel mesentery, the duodenojejunal flexure and loops of the jejunum and ileum.

The transverse mesocolon permits considerable mobility of the transverse colon: occasionally the colon may be interposed between the liver and the diaphragm (Chilaiditi syndrome), and may be mistaken for free intraperitoneal gas.

SPLENIC FLEXURE

The splenic flexure forms the junction of the transverse and descending colon and lies in the left hypochondrium, inferomedial to the lower pole of the spleen (Fig. 67.25). It is anterior to the pancreatic tail, and also to the left kidney, from which it is separated by the anterior perirenal fascia. The splenic flexure often adopts a very acute angle such that the end of the transverse colon overlaps the beginning of the descending colon; there may be peritoneal and omental adhesions between the two structures. It lies more superiorly and posteriorly than the right hepatic flexure; the visceral peritoneum covering its lateral aspect is often attached to the diaphragm at the level of the 10th and 11th ribs by the phrenicocolic ligament, which lies below the anterolateral pole of the spleen. Its position with respect to the spleen in variable: it usually lies directly inferomedial to the lower pole, forming the colic impression, but it may lie anterior to the splenic hilum, and even a little above. In these cases, the visceral peritoneum is often adherent to the splenic capsule or hilar connective tissue; inadvertent, downwards traction on the splenic flexure during surgery may tear the capsule or hilar vessels. It may lie ‘low’ in the splenorenal recess with no direct attachment to the splenic capsule.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The proximal two-thirds of the transverse colon is supplied by the superior mesenteric artery via the middle colic artery (Fig. 67.11). The distal third is usually supplied by the ascending branch of the left colic artery via the marginal artery of the colon, although this is somewhat variable.

Middle colic artery

The middle colic artery usually arises from the anterolateral aspect of the superior mesenteric artery, either separately or as a common trunk with the right colic artery, just inferior to the uncinate process of the pancreas and anterior to the third part of the duodenum. Initially it passes inferiorly, then turns to run anteriorly and superiorly within the root of the transverse mesocolon, just to the right of the midline, and usually divides into a right and left branch. The right branch anastomoses with the right colic artery, and the left branch anastomoses with the left colic artery. The arterial arches thus formed lie 3 or 4 cm from the transverse colon, which they supply. Sometimes the middle colic artery divides into three or more branches within the transverse mesocolon, in which case the most lateral branches form the arterial anastomoses. An accessory or rarely a replaced middle colic artery may arise from the dorsal pancreatic, hepatic, inferior mesenteric or left colic arteries (Fig. 67.26). In the latter two instances the left half or more of the transverse colon will derive its arterial supply from the inferior mesenteric artery.

Fig. 67.26 Variants in the origin of the middle colic artery: only replaced arteries have been illustrated for simplicity. Accessory arteries are more common in each case than complete replacement of the origin. **A**, Left colic artery or inferior mesenteric artery (<5%). **B**, The dorsal pancreatic artery (<5%). **C**, Hepatic artery (<5%).

Veins

Superior mesenteric vein

The superior mesenteric vein receives one or more middle colic veins and the ileocolic vein (see Figs. 67.31, 66.12). The right colic vein is often absent or drains as a tributary to the right branch of the middle colic vein.

Middle colic veins

Several tributaries drain into one or more middle colic veins which are highly variable in extent and position. The middle colic veins drain either into the superior mesenteric vein, just before its junction with the splenic vein, or directly into the hepatic portal vein.

Lymphatics

Lymph vessels drain into nodes along the middle colic arteries and then into the superior mesenteric nodes. The predominant lymphatic drainage of the splenic flexure is usually via nodes along the left colic artery which drain into the inferior mesenteric nodes: this arrangement is dependent on the arterial supply to the distal third of the transverse colon.

INNERVATION

The proximal two-thirds of the transverse colon is innervated by sympathetic and parasympathetic nerves via the superior mesenteric plexus. The distal third usually receives a sympathetic supply from the inferior mesenteric plexus and a parasympathetic supply that is derived partly from the inferior mesenteric plexus and partly from retroperitoneal fibres which travel in the pelvic splanchnic nerves that arise from neurones in the second, third and fourth sacral spinal segments. The sympathetic nerves are inhibitory to mural muscle in the transverse colon; some fibres are vasoconstrictor to the colic vasculature. Parasympathetic nerves are secretomotor to colic glands and motor to the colic musculature.

DESCENDING COLON

The descending colon is approximately 25 cm long. It descends through the left hypochondrium and lumbar region, initially following the lateral border of the lower pole of the left kidney, and then descending in the angle between psoas major and quadratus lumborum to the iliac crest. It then curves inferomedially, lying anterior to iliacus and psoas major, to become the sigmoid colon below the level of the iliac crest (inlet of the lesser pelvis). It lies on the retroperitoneum covered anteriorly and on both sides by peritoneum. Its posterior surface is separated by loose connective tissue from the anterior peri-renal fascia inferolateral to the left kidney, the aponeurosis of transversus abdominis, quadratus lumborum, iliacus and the most superolateral part of psoas major. The subcostal vessels and nerves, iliohypogastric, ilio-inguinal, lateral femoral cutaneous, femoral and genitofemoral nerves, and the fourth lumbar artery (usually), all lie posterior to the descending colon (Fig. 67.27). Loops of jejunum lie anteriorly. If the anterior abdominal walls are relaxed, the most inferior part of the descending colon may be directly palpated transabdominally. The descending colon is smaller in calibre, more deeply placed, and more frequently covered posteriorly by peritoneum, than the ascending colon.

Fig. 67.27 Posterior relations of the descending colon.

SIGMOID COLON

The sigmoid colon begins below the pelvic inlet and ends at the rectum. Characteristically it forms a mobile loop which normally lies in the lesser pelvis, but its length and form are the most variable of all colonic segments. It is usually completely invested in peritoneum and is attached to the lower posterior abdominal wall and the posterior wall of the false pelvis by the fan-shaped sigmoid mesocolon. The root of the sigmoid mesocolon has an inverted ‘V’ attachment to the posterior abdominal wall.

The sigmoid colon initially descends over the iliac crest into the false pelvis but thereafter its position is extremely variable. It may remain folded and principally in contact with, or adherent to, the peritoneum overlying iliacus, or it may cross the pelvic cavity between the rectum and bladder in males, or the rectum and uterus in females, and it may even reach the right pelvic wall. If long, the sigmoid loop may rise out of the pelvis into the abdominal cavity and lie in contact with loops of ileum. The sigmoid loop ends in a relatively constant position lying just to the left of the midline at the level of the third sacral body, where it bends inferiorly and is continuous with the rectum. The sigmoid loop is fixed at its junctions with the descending colon and rectum but quite mobile between them. Its relations are therefore variable (Fig. 67.28). Laterally are the left external iliac vessels, the obturator nerve, ovary or vas deferens and the lateral pelvic wall; posteriorly lie the left external and internal iliac and gonadal vessels, ureter, piriformis and sacral plexus; anteroinferiorly lie the bladder in males, or uterus and bladder in females; superiorly and to the right the sigmoid colon is in contact with loops of the ileum. The gonadal vessels and ureter lie in a distinct fascial plane which is the inferior extension of the anterior and posterior peri-renal fascia in the lower retroperitoneum and which is separate from the thin fascial coverings of the mesosigmoid. The plane between the two layers can be recognized during surgical dissection of the mesentery of the sigmoid colon because it does not contain the numerous small vessels which are often present in the loose connective tissue surrounding the ureter and gonadal vessels.

Fig. 67.28 Posterior relations of the sigmoid colon.

The position and shape of the sigmoid colon vary according to the length of the colon; the length and mobility of its mesocolon; the degree of distension (when distended the sigmoid colon rises into the abdominal cavity, and it sinks again into the lesser pelvis when empty); the condition of the rectum, bladder and uterus (the sigmoid colon tends to rise when these are distended, and to fall when they are empty). The length and diameter of the sigmoid colon vary in different races.

SIGMOID VOLVULUS

Rotation or volvulus may occur around the mesenteric attachment of the sigmoid colon, similar to the rotation of the caecum around its mesentery. Only the sigmoid colon is affected, because the descending colon rarely possesses sufficient mesentery to become involved in the rotation. Rotation usually involves at least 270°. Volvulus is more common when the length of the sigmoid colon increases, since this is associated with a ‘fan-like’ mesentery with a short retroperitoneal attachment. Volvulus does not occur in individuals where the sigmoid colon is short or where the mesentery is short and its attachment runs over the brim of the pelvis. The combination of anatomical features predisposing to sigmoid volvulus is most commonly found in sub-Saharan Africans and chronically institutionalized patients.

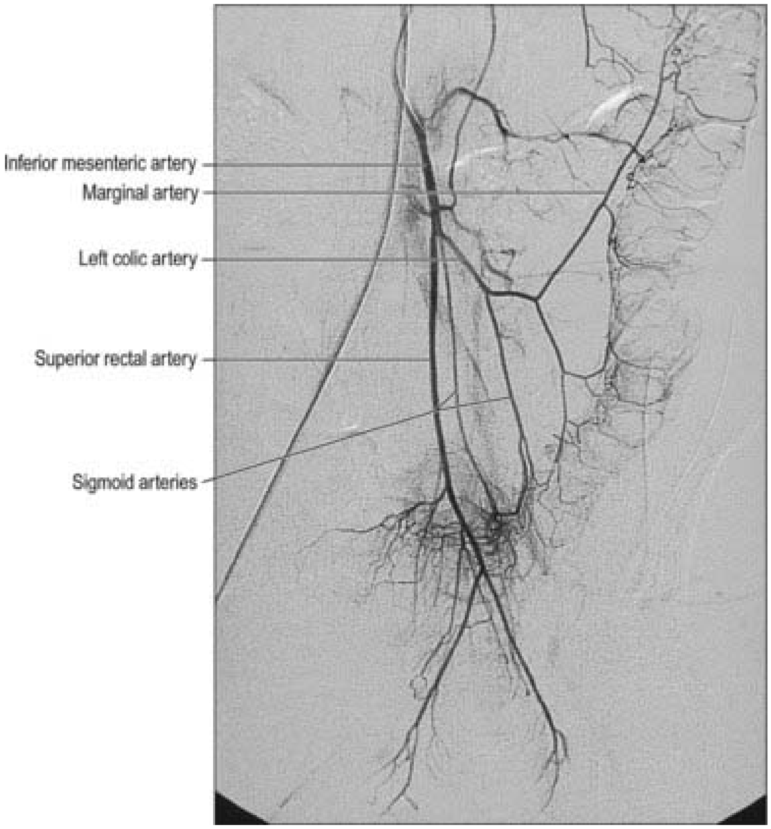
DIVERTICULAR DISEASE

The development of acquired diverticula occurs commonly in the sigmoid colon, particularly in white Caucasian populations. Their location appears to be related to the underlying anatomy of the wall of the colon. Thus, diverticula commonly occur midway between the anti-mesenteric and lateral taeniae, i.e. where the colonic wall is potentially weak, not only because the circular muscle lacks the support of the longitudinal muscle, but also because it is traversed here by arteries as they access the submucosal vascular plexus. The predilection of the diverticula for the sigmoid colon probably relates to causative factors rather than intrinsic differences in the structure of its walls. In marked contrast, congenital diverticula may occur anywhere throughout the colon, and are often found adjacent to the mesenteric attachment of the colon.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply of the descending colon is from the inferior mesenteric artery via its left colic branch, which also anastomoses with the marginal artery of the colon (in the region of the splenic flexure), and the sigmoid arteries (in the region of the junction with the sigmoid colon) (Figs 67.29-67.31).



Inferior mesenteric artery

The inferior mesenteric artery is usually smaller in calibre than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the aorta at about the level of the third lumbar vertebra, 3 or 4 cm above the aortic bifurcation and below the third part of the duodenum. It descends in the root of the left colic mesentery initially anterior and then to the left of the aorta, crosses the origin of the left common iliac artery medial to the left ureter, and then enters, and continues in, the root of the sigmoid mesocolon as the superior rectal artery. The inferior mesenteric vein lies on its lateral side in its distal course. The principal branches of the inferior mesenteric artery are the left colic, sigmoid and superior rectal arteries (see Figs 67.11, 67.29).

Left colic artery

The left colic artery arises from the inferior mesenteric artery shortly after its origin, ascends within the left colic mesentery anterior to the left psoas major, and bifurcates into ascending and descending branches (this division may occur soon after its origin). The artery or its branches cross the left ureter and gonadal vessels. The ascending branch passes anterior to the left kidney and anastomoses with the left branch of the middle colic artery in the subperitoneal space within the transverse mesocolon. The descending branch passes laterally in the retroperitoneum and approaches the descending colon, where it forms part of the marginal artery and anastomoses with the highest sigmoid artery. The arterial arches thus formed supply the distal third of the transverse and the descending colon. Occasionally an accessory, or rarely a replaced, left colic artery may originate from the trunk of the superior mesenteric artery or the first jejunal branches. When present, it runs laterally in the upper left colic mesentery just below the level of the duodenojejunal junction to supply the upper descending colon and form part or all of the marginal artery and the arterial anastomosis in the region of the distal transverse colon (Fig. 67.32). The left colic artery may itself give rise to an accessory left middle colic artery. Occasionally the left colic artery gives rise to a branch shortly after its origin which ascends in the mesentery and anastomoses directly with a similar descending branch of the left branch of the middle colic artery (the arc of Riolan).

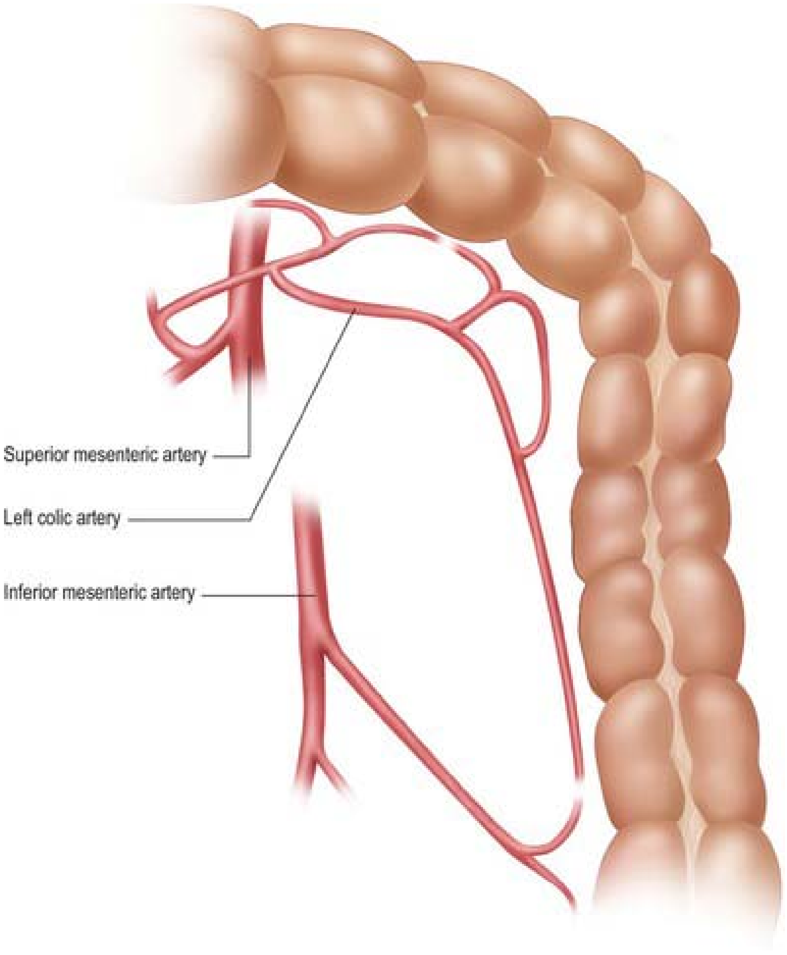

Fig. 67.32 Replaced left colic artery arising from the superior mesenteric artery.

Sigmoid (inferior left colic) arteries

There are between two and five sigmoid arteries, which are branches of the inferior mesenteric artery. They descend obliquely within the subperitoneal space in the sigmoid mesentery, anterior to the left psoas major, ureter and gonadal vessels. They supply the distal descending colon and sigmoid colon, and anastomose superiorly with the left colic artery and inferiorly with the superior rectal artery. Unlike the small intestine, arterial arcades do not form until the arteries are close to the wall of the colon, when small branches arise which supply the sigmoid colon directly. The formation of a true marginal artery is less pronounced in the region of the sigmoid colon than in the region of the descending colon. A significant space often exists in the mesentery between the highest sigmoid artery and the descending branch of the left colic artery: this is a useful guide to the arterial territories during surgical dissection.

In the region of the splenic flexure the marginal artery receives contributions from the left branch of the middle colic artery which anastomoses with an ascending branch of the left colic artery to supply the upper descending colon. The descending branch of the left colic artery anastomoses with upper branches of the highest sigmoid artery to supply the descending colon. The origin of the primary arterial supply for the splenic flexure and distal third of the transverse colon is usually via the left colic artery but may be from the left branch of the middle colic artery. The marginal artery in the region of the splenic flexure may be absent or of such small calibre as to be of little clinical relevance. It may, however, hypertrophy significantly when one of the main visceral arteries is compromised, e.g. following stenosis or occlusion of the inferior mesenteric artery, and it then provides a vessel of collateral supply.

Vascular ligation in left colonic resections

During resection of the distal descending and sigmoid colon, ligation of the inferior mesenteric artery close to its origin preserves the bifurcation of the left colic artery. The arterial supply to the proximal descending colon is maintained via the anastomosis between the ascending branch of the left colic artery and the left branch of the middle colic artery. Less radical resection, involving ligation of the left colic artery close to its bifurcation, may interfere with or obliterate this supply and render the descending colon more likely to become ischaemic. The same is true for ligation of the left colic vein. If the inferior mesenteric vein is ligated, then the bifurcation of the vein forms the route of venous drainage for the descending colon to the middle colic vein territory. Ligation of the branches separately will impair the venous drainage.

Veins

Inferior mesenteric vein

The inferior mesenteric vein drains the rectum, sigmoid, descending and distal transverse colon (Fig. 67.33; see also Fig. 67.14). It begins as the superior rectal vein, from the rectal plexus, through which it connects with middle and inferior rectal veins. The inferior mesenteric vein lies to left of the inferior mesenteric artery, ascends deep to the peritoneum and anterior to the left psoas major and may cross the testicular or ovarian vessels or ascend medial to them. It usually lies lateral to or occasionally posterior to the duodenojejunal flexure and the peritoneal fold directly lateral to the flexure is a useful guide to locating the vein surgically. It usually drains into the splenic vein, but occasionally drains into the confluence of the splenic and superior mesenteric veins or directly into the superior mesenteric vein. If a duodenal or paraduodenal fossa exists, the vein is usually in its anterior wall. The inferior mesenteric vein receives tributaries from several sigmoid veins, the middle and the left colic veins.

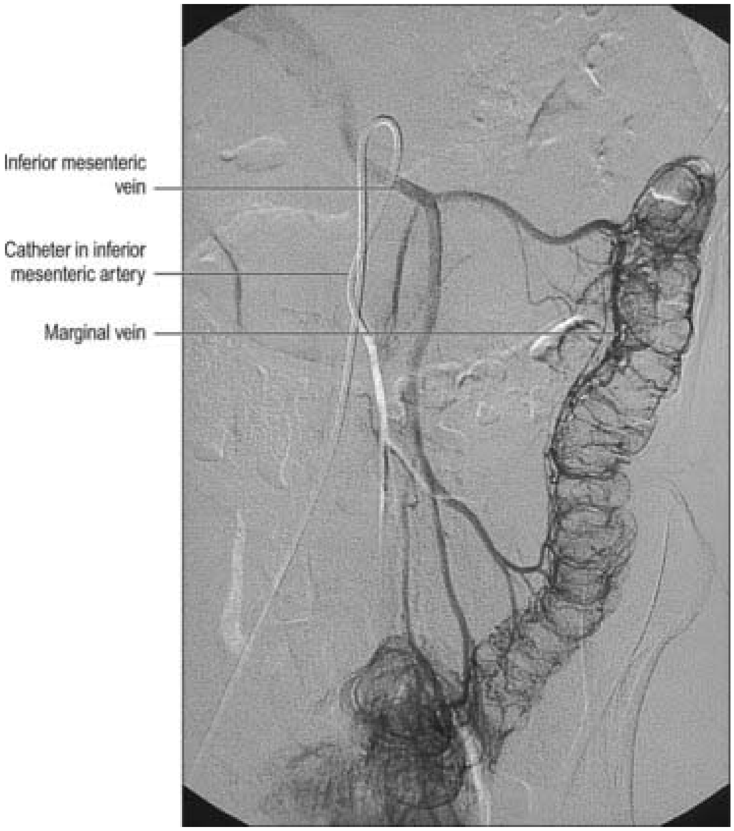

Fig. 67.33 The inferior mesenteric vein and its tributaries, digital subtraction arteriogram.

(By kind permission from Dr Adam Mitchell, Charing Cross Hospital, London.)

Left colic vein

The left colic vein is formed from several tributaries including ascending and descending branches which correspond to the equivalent arteries. These tributaries may not form a discrete vein until they drain into the inferior mesenteric vein, and occasionally there may be two distinct veins which both run into the inferior mesenteric vein. The left colic vein usually lies more superiorly in the left colon mesentery than its equivalent artery, and has a shorter course because the inferior mesenteric vein lies more laterally than the inferior mesenteric artery.

Several sigmoid veins drain the sigmoid colon and run superiorly alongside their respective arteries to drain into the inferior mesenteric vein.

Lymphatics

Lymph vessels drain from the descending colon into nodes along the left colic artery, and from the sigmoid colon into sigmoid nodes in the sigmoid mesocolon which then join superior rectal and left colic vessels. All of these nodes drain into the inferior mesenteric nodes.

INNERVATION

The sympathetic supply to the left third of the transverse colon and the descending and sigmoid colon originates in the first and second lumbar spinal segments, and runs in the upper lumbar splanchnic nerves: preganglionic axons synapse on neurones in the abdominal aortic and the inferior mesenteric plexuses, whence postganglionic axons reach the gut wall via periarterial plexuses on branches of the inferior mesenteric artery. These axons are inhibitory to the mural muscle of the colon and some fibres are vasoconstrictor to the colic vasculature.

The parasympathetic supply is via the pelvic splanchnic nerves. Some fibres run through the inferior and superior hypogastric plexuses and along branches of the inferior mesenteric artery, but many more pass directly through the retroperitoneal tissues, independent of the inferior mesenteric artery, to reach the splenic flexure and descending and sigmoid colon. Parasympathetic nerves are secretomotor to colic glands and motor to the colic musculature. Afferent impulses mediating sensations of distension are carried by visceral afferent fibres which travel with the parasympathetic nerves.

RECTUM

The rectum is continuous with the sigmoid colon at the level of the third sacral vertebra and terminates at the upper end of the anal canal. It descends along the sacrococcygeal concavity as the sacral flexure of the rectum, initially inferoposteriorly and then inferoanteriorly, to join the anal canal by passing through the pelvic diaphragm. The anorectal junction is 2–3 cm in front of and slightly below the tip of the coccyx, which is opposite the apex of the prostate in males. From this level the anal canal passes inferiorly and posteriorly from the lower end of the rectum. The posterior bend is termed the perineal flexure of the rectum and the angle it forms with the upper anal canal is the anorectal angle. The rectum also deviates in three lateral curves: upper, convex to the right; middle (the most prominent), convex to the left; lower, convex to the right. Both ends of the rectum are in the median plane (Fig. 67.34).

Although variable in absolute length, a common landmark used in clinical practice to define the rectum is a length of 15 cm above the external anal margin. The initial diameter is similar to that of the sigmoid colon, but more inferiorly it becomes dilated as the rectal ampulla. The rectum differs from the sigmoid colon in having no sacculations or appendices epiploicae. The taeniae blend approximately 5 cm above the rectosigmoid junction, forming two wide muscular bands which descend anteriorly and posteriorly in the rectal wall. These then fuse to form an encircling layer of longitudinal muscle, which invests the entire length of the rectum. At the rectal ampulla a few strands of the anterior longitudinal fibres pass forwards to the perineal body as the musculus recto-urethralis. In addition, two fasciculi of smooth muscle may pass anteroinferiorly from the anterior surfaces of the bodies of the second and third coccygeal vertebrae to blend with the longitudinal muscle fibres on the posterior wall of the anal canal, forming the rectococcygeal muscles.

The upper third of the rectum is covered by peritoneum on its anterior and lateral aspects. It is related anteriorly to the sigmoid colon or loops of ileum if these lie in the pelvis, otherwise it is related to the urinary bladder in males, or the cervix and body of the uterus in females. The middle third of the rectum is covered by peritoneum only on its anterior aspect. The peritoneum is reflected superiorly onto the urinary bladder in males to form the rectovesical pouch, or onto the posterior vaginal wall in females to form the recto-uterine pouch (pouch of Douglas). The level of this reflection is higher in males; the rectovesical pouch is approximately 7.5 cm (about the length of the index finger) from the anorectal junction. In females the recto-uterine pouch is approximately 5.5 cm from the anorectal junction. In the male neonate, peritoneum extends on to the front of the rectum as far as the lower limit of the prostate. Superiorly the peritoneum is firmly attached to the muscle layer of the sigmoid colon by fibrous connective tissue, but as it descends onto the rectum it is more loosely attached by fatty connective tissue, which allows for considerable expansion of the upper half of the rectum (Figs 67.35, 67.36).

There are no haustra in the rectum. When empty the mucosa forms a number of longitudinal folds in its lower part which become effaced during distension. The rectum commonly has three permanent semi-lunar transverse or horizontal folds (although the number can vary), which are most marked in rectal distension (Fig. 67.9). Two forms of horizontal fold have been recognized. One consists of the mucosa, a circular muscle layer and part of the longitudinal muscle, and is marked externally by an indentation. The other is devoid of longitudinal muscle and has no external marking. The most superior fold at the beginning of the rectum may be either on the left or right and occasionally encircles the rectal lumen. The middle fold is largest and most constant. It lies immediately above the rectal ampulla, projecting from the anterior and right wall just below the level of the anterior peritoneal reflection; the circular muscle is more marked in this fold than in the others. The most inferior and variable fold is found on the left below the middle fold. Sometimes a fourth fold is found on the left a little above the middle fold.

MESORECTUM, RECTAL FASCIAE AND ‘SPACES’

The mesorectum (mesentery of the rectum) and its contents are intimately related to the rectum down to the level of levator ani (Figs 67.37-67.39). It is a distinct compartment derived from the embryological hindgut. It contains the superior rectal artery and its branches, the superior rectal vein and its tributaries, the lymphatic vessels and nodes that lie along the superior rectal artery, branches from the inferior mesenteric plexus which descend to innervate the rectum, and loose adipose connective tissue.

The mesorectum is enclosed by mesorectal fascia, a distinct covering derived from the visceral peritoneum that is also called the visceral fascia of the mesorectum, fascia propria of the rectum or the presacral wing of the hypogastric sheath. The fascia bounds the mesorectum posteriorly and thus lies anterior to the retrorectal space and the pre-sacral fascia. The mesorectal fascia is surrounded by a very thin layer of loose areolar tissue which separates it from the posterior and lateral walls of the true pelvis. Superiorly, the mesorectal fascia blends with the connective tissue bounding the sigmoid mesentery. Laterally, it extends around the rectum and mesorectum and becomes continuous with a denser condensation of fascia anteriorly. In males this anterior fascia is known as the rectovesical fascia of Denonvillier, and in females it forms the fascia of the rectovaginal septum.

On MRI scanning, the mesorectum appears as a fat-containing envelope in which vessels are depicted as low signal due to signal void produced by blood flow. Lymph nodes appear as high signal ovoid structures. Small nerves within the mesorectum are not visualized, but interlacing connective tissue within the mesorectum can be seen as low signal intensity strands. The mesorectal fascia is demonstrated on axial views as a low signal layer that surrounds the mesorectum, and which corresponds to the distinct condensation of fascia seen on histological sections containing the mesorectum (Brown et al 1999). Identification of the involvement of this layer by malignant tumours of the rectum on MRI scanning may help plan preoperative radiotherapy, and predict the chance of successful surgical resection.

Anterolaterally, branches of the inferior hypogastric plexus and branches of the middle rectal artery and veins run into the mesorectum. They are ensheathed by fascia and are sometimes jointly referred to as the ‘lateral rectal ligaments’. The number and calibre of the middle rectal vessels are highly variable; they may be very small or even absent (Sato & Sato 1991). The ‘lateral ligaments’ are not seen on MRI or CT scanning, and only appear as an identifiable structure with surgical traction on the rectum. The fascia of the ‘ligaments’ is flimsy and they probably play very little role in support of the rectum.

The parietal fascia that covers levator ani and the muscles of the side-wall of the pelvis forms a denser condensation of fascial tissue overlying the sacrum (Fig. 67.40).

RELATIONS OF THE RECTUM

Posterior to the rectum and mesorectum, and separated from them by the presacral fascia, in the median plane are the lower three sacral vertebrae, coccyx, median sacral vessels, and the lowest portion of the sacral sympathetic chain. Laterally, the upper part of the rectum is related to the pararectal fossa and its contents (sigmoid colon or terminal ileum), while below the peritoneal reflection lie piriformis, the anterior rami of the lower three sacral and coccygeal nerves, the sympathetic trunk, lower lateral sacral vessels, and coccygei and levatores ani. Anteriorly, above the level of the peritoneal reflection, lie loops of sigmoid colon or terminal ileum (if these lie in the pelvis), otherwise the rectum is related to the upper parts of the base of the bladder in males, or to the cervix/body of the uterus and upper vagina in females. The lower parts of the base of the bladder, the seminal vesicles, vas deferens, terminal parts of the ureters, and the prostate in males (Figs 67.38, 67.39), or the lower part of the vagina in females, lie below the reflection. In females, the rectovaginal septum is composed of a condensation of connective tissue which is continuous with the connective tissue of the outer layers of the rectal and vaginal walls. In postmenopausal females, and following childbirth, the connective tissue of the rectovaginal septum may atrophy or be thinned, reducing the support for the anterior rectal and posterior vaginal walls.

RECTAL PROLAPSE

Prolapse of the rectum involving all layers of the rectal wall may occur: the precise aetiology is not known. During prolapse, the mid and upper rectum descends towards the pelvic floor on straining. This descent tends to occur within the lumen of the rectum as a form of intussusception, and may be a consequence of the large diameter of the lower rectal ampulla and relative fixation of the anorectal junction and anal canal. The upper mesorectum is formed by relatively loose adipose connective tissue, and so relatively little tissue actually fixes the mid and upper rectum in position within the pelvis. The 'lateral ligaments' are composed mainly of vascular structures and offer only limited support against rectal descent. Chronic enlargement of the anorectal space bound by levatores ani commonly occurs in patients suffering rectal prolapse, but it is thought to be a consequence rather than a cause of the prolapse. During prolapse, the recto-uterine pouch in females also descends with the anterior rectal wall, and in extreme cases may become everted through the anus between the layers of rectal wall. This rarely happens to the rectovesical pouch in males.

RECTOCELE

When the rectovaginal septum is grossly effaced, especially in postmenopausal females, the pressure of defecation transmitted forward along the sacral flexure of the rectum can eventually cause bulging of the rectal wall into the posterior vagina, and, in extreme cases, through the vaginal introitus. Failure of support of the rectum and perineum by the puborectalis and pubovaginalis muscles contributes to this prolapse by allowing descent of the posterior perineum during straining.

MESORECTAL EXCISION IN RECTAL CANCER

An important concept in the oncological treatment of adenocarcinoma of the rectum is the integrity of the rectum and its mesorectal tissue. The epirectal and pararectal lymphatic tissues are located throughout the mesorectum. If the mesorectum is divided or disrupted during surgical excision of rectal carcinoma, involved nodes may be left *in situ*, which may predispose to local recurrence of tumour (Heald et al 1982). Oncological excision of the rectum involves mobilization of the rectum in the plane formed by the mesorectal fascia posterolaterally around the mesorectum. This plane allows the rectum and mesorectum to be removed as a whole without disruption of the presacral fascia and its underlying venous plexus. It is continuous with the plane between the mesentery surrounding the origin of the superior rectal artery and the presacral fascia over the sacral promontory, which is opened during mobilization of the origin of the inferior mesenteric artery prior to ligation. The mesorectal plane extends laterally and anteriorly, disrupted only by small branches of the middle rectal vessels, and is continuous with the rectovesical or rectovaginal fascia, which provides a similar oncological plane of dissection. Since the inferior hypogastric nerves are closely related to the plane of the mesorectal fascia in its upper third, dissection must spare the nerves if a degree of pelvic autonomic disturbance (bladder dysfunction and erectile dysfunction in males) is to be avoided following surgery. Complete excision of the rectum – total mesorectal excision – involves mobilization of this plane to the level of levatores ani. During the excision it is important to follow the sacral curve of the rectum to prevent entry into the presacral fascia or anococcygeal ligament with subsequent bleeding from presacral vessels.

ABDOMINOPERINEAL EXCISION IN RECTAL CANCER

The posterior mesorectum is thinnest at its lowest extremity, where the mesorectal fascia becomes continuous with the periserosal tissues which condense on the outer muscle layer as it passes inside the fibres of puborectalis and it lies directly on the fascia of levator ani (endopelvic fascia) (see Fig. 63.4). Tumours penetrating through the rectal wall at this point may therefore lie in extremely close proximity to the mesorectal margin. Conventional dissection in the mesorectal plane as far as the pelvic floor may open this fascial space close to the tumour and abdominoperineal excision of the rectum should be conducted through the ischio-anal fossa, vertically through levator ani outside the puborectalis sling and into the mesorectal plane well above the area of contact with the pelvic floor to avoid opening this potential tumour plane.

LOCAL EXCISION OF THE RECTUM

Full thickness excision of lesions of the rectal wall is possible in those parts of the rectum lying in the extraperitoneal compartment, i.e. below the peritoneal reflections. The mesorectal adipose tissue contains any leakage of contents and provides support to the closure of the defect in the rectal wall. Since only the lower third of the rectum is wholly extraperitoneal, full thickness local excisions of the rectum should be avoided on the anterior wall of the middle third and anterolateral walls of the upper third of the rectum. The height to which such excision can be performed anteriorly in females is lower than in males, because the lower level of the peritoneal reflection makes entry into the peritoneal cavity more likely.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The principal arterial supply to the upper two-thirds of the rectum is the superior rectal artery. Branches of the middle rectal artery provide some additional supply to the middle third, and ascending branches of the inferior rectal artery supply the distal third. The median sacral artery (the terminal midline branch of the aorta), contributes a small branch which enters the posterior wall of the anorectal junction on the sacrorectal fascia (Fig. 67.41).

Fig. 67.41 The arterial supply of the rectum.

Superior rectal artery

The superior rectal artery is the principal continuation of the inferior mesenteric artery (Fig. 67.31). It descends into the pelvis in the sigmoid mesocolon, crosses the left common iliac vessels and passes over the sacral promontory usually just to the left of the midline. It is straddled by the inferior hypogastric nerves on either side. It lies anterior to the upper sacral vertebrae and passes into the upper mesorectum, then descends, initially in the midline, and divides into two branches at the level of the third sacral vertebra. These lie initially posterolateral, then lateral, to the rectal wall as they descend one on each side of the rectum. Terminal branches pierce the muscle wall from the level of the upper mesorectum to enter the rectal submucosa, where they anastomose with ascending branches of the inferior rectal arteries.

Middle rectal arteries

The middle rectal arteries arise either directly from the anterior division of the internal iliac artery or from the inferior vesical artery (vaginal artery in females). They enter the mesorectum anterolaterally in the ‘lateral rectal ligaments’, and are frequently either absent or may be very small in calibre (Sato & Sato 1991). When present, they provide an arterial supply to the muscle of the mid and lower rectum, but form only poor anastomoses with the superior and inferior rectal arteries.

Inferior rectal arteries

The inferior rectal arteries are terminal branches of the internal pudendal arteries. They cross the ischio-anal fossa to enter the upper anal canal laterally where they branch. They supply the internal and external anal sphincters, the anal canal and the perianal skin. Ascending branches pass superiorly in the submucosal plain, and anastomose with the terminal branches of the superior rectal artery.

Veins

Rectal venous plexus

The rectal venous plexus surrounds the rectum, and connects anteriorly with the vesical plexus in males or the uterovaginal plexus in females. It consists of an internal part, beneath the rectal and anal epithelium, and an external part outside the muscular wall. In the anal canal the internal plexus displays longitudinal dilatations, connected by transverse branches in circles immediately above the anal valves. The dilatations are most prominent in the left lateral, right anterolateral and right posterolateral sectors. The internal plexus drains mainly to the superior rectal vein but connects widely with the external plexus. The inferior portion of the external plexus is drained by the inferior rectal vein into the internal pudendal vein, the middle portion by one or more middle rectal veins into the internal iliac vein, and its superior part by the superior rectal vein, which drains into the inferior mesenteric vein. Communication between portal and systemic venous systems is thus established in the rectal plexus.

Superior rectal veins

The superior rectal veins are formed from the internal rectal plexus. The tributaries of the superior rectal vein ascend in the rectal submucosa as about six vessels of considerable size which pierce the rectal wall approximately 7.5 cm above the anus. The branches unite to form the superior rectal vein, which runs along the superior rectal artery in the root of the mesorectum and mesosigmoid, crosses the left common iliac vessels with the superior rectal artery, and continues upwards as the inferior mesenteric vein to the left of the midline (see Figs 67.14 and 67.43A).

glandular, vascular and fibromuscular structures and the conjoint longitudinal coat have been omitted for clarity.

Middle rectal veins

The middle rectal veins pass alongside the middle rectal arteries to drain into the anterior division of the internal iliac vein on the lateral wall of the pelvis.

Lymphatics

Lymphatics draining the rectum and the upper anal canal above the level of the dentate line pass superiorly, initially through the rectal wall, and then as a fine network over the surface of the rectum, before draining into nodes which lie in the loose adipose connective tissue of the mesorectum. Epirectal nodes lie very close to the outer fibres of the rectal longitudinal muscle while pararectal nodes lie within the mesorectum, a variable distance from the rectal wall. The overall direction of drainage is upwards along the branches of the superior rectal artery. Drainage to intermediate groups occurs up to the nodes near the origin of the inferior mesenteric artery (Fig. 67.42).

INNERVATION

The sympathetic supply to the rectum and upper anal canal originates in the first and second lumbar spinal segments. The fibres are distributed via the lumbar splanchnic nerves through the inferior mesenteric plexuses and via the sacral splanchnic nerves through the superior and inferior hypogastric plexuses: postganglionic axons reach the gut wall via periarterial plexuses on branches of the superior and middle rectal arteries, and are inhibitory to the muscle of the rectal wall.

The preganglionic parasympathetic supply to the rectum and upper anal canal is mediated via the pelvic splanchnic nerves, which travel through the inferior and superior hypogastric plexuses and along the nerve plexuses on the branches of the inferior mesenteric artery. Parasympathetic nerves are secretomotor to the colorectal glands, and motor to the rectal musculature, causing relaxation of the internal anal sphincter. Afferent impulses mediating sensations of distension are carried by visceral afferent fibres which travel with the parasympathetic nerves. Pain impulses pass in visceral afferents travelling with the sympathetic and parasympathetic nerves that supply the rectum and the upper part of the anal canal.

The role of rectal innervation in anorectal function and continence is described below.

ANAL CANAL

The anal canal begins at the anorectal junction and ends at the anal verge (Figs 67.43-67.45). It is angulated in relation to the rectum because the pull of the sling-like puborectalis produces the anorectal angle. It lies 2–3 cm in front of and slightly below the tip of the coccyx, which is opposite the apex of the prostate in males. The anal verge is marked by a sharp turn where the squamous epithelium which lines the lower anal canal becomes continuous with the skin of the perineum. The pigmentation of skin around the anal verge approximately corresponds to the extent of the external sphincter. Identification of the anal verge may be difficult, particularly in males in whom the perineum may ‘funnel’ upwards into the lower anal canal, however, the characteristic puckering of the external epithelium caused by the penetrating fibres of the conjoint longitudinal layer makes a useful landmark. The functional anal canal is represented by a zone of high pressure which roughly equates to the anatomical canal. The anal canal consists of an inner epithelial lining, a vascular subepithelium, the internal and external anal sphincters and fibromuscular supporting tissue as well as dense neuronal networks of both autonomic and somatic origin. It is between 2.5 and 5 cm long in adults although the anterior wall is slightly shorter than the posterior. It is usually shorter in females. At rest it forms an oval slit in the anteroposterior plane rather than a circular canal: the arrangement of the external anal sphincter and its attachments to the perineal body and coccyx create sites of maximum pressure within the anal canal in the anterior and posterior midline.

Anteriorly, the middle third of the anal canal is attached by dense connective tissue to the perineal body, which separates it from the membranous urethra and penile bulb in males or from the lower vagina in females. Laterally and posteriorly, the anal canal is surrounded by loose adipose tissue within the ischio-anal fossae; this offers a potential pathway for the spread of perianal sepsis from one side to the other (see Ch. 63). Posteriorly, the anal canal is attached to the coccyx by the anococcygeal ligament, a midline fibroelastic structure which may possess some skeletal muscle elements, and which runs between the posterior aspect of the middle portion of the external sphincter and the coccyx. Just above this is the raphe of the levator ani ‘plate’, the fusion of the two halves of iliococcygeus, which merges anteriorly with puborectalis. Between these two structures is a potential ‘postanal’ space.

The ischial spines may be palpated laterally by an examining finger in the upper anal canal. The pudendal nerves pass over the ischial spines at this point and pudendal nerve motor terminal latency may be measured digitally using a modified electrode worn on the examining glove.

LINING OF THE ANAL CANAL

The upper portion of the anal canal is lined by columnar epithelium similar to that of the rectum. It contains secretory and absorptive cells with numerous tubular glands or crypts. The subepithelial tissues are mobile and relatively distensible and possess profuse submucosal arterial and venous plexuses. Terminal branches of the superior rectal vessels pass downwards towards the anal columns. The submucosal veins drain into the submucosal rectal venous plexus and also through the fibres of the upper internal anal sphincter into an intermuscular venous plexus.

There are 6–10 vertical folds, the anal columns, in the mid anal canal. They tend to be obvious in children but less well-defined in adults. Each column contains a terminal radicle of the superior rectal artery and vein: the vessels are largest in the left-lateral, right-posterior and right-anterior quadrants of the wall of the canal where the subepithelial tissues expand into three ‘anal cushions’ (Fig. 67.46). The cushions help to seal the anal canal, to maintain continence to flatus and fluid, and are also important in the pathogenesis of haemorrhoids. The lower ends of the columns may form small crescentic folds, called the anal valves, between which lie small recesses referred to as anal sinuses. The anal valves and sinuses together form the dentate (or pectinate) line. About six anal glands open into small depressions, anal crypts, in the anal valves. The glands are branched and lined by stratified columnar epithelium. Cystic dilatations in the glands may extend through the internal sphincter and even into the external sphincter (Seow-Cheon & Ho 1994).

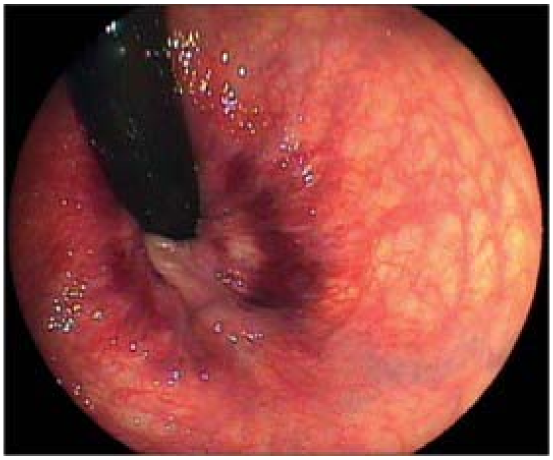

Fig. 67.46 Endoscopic appearance of the anorectal junction.

The mucosa below the dentate line is smooth, and termed the pectin. It is non-keratinized stratified squamous epithelium which lacks sweat and sebaceous glands and hair follicles, but contains numerous somatic nerve endings. It extends down to the intersphincteric groove, a depression at the lower border of the internal sphincter. The canal below the intersphincteric groove is lined by hair-bearing, keratinizing, stratified epithelium which is continuous with the perianal skin. The submucosa in this region contains profuse arterial and venous plexuses and has more connective tissue than the upper canal. It may be tethered to fibres of the conjoint longitudinal layer in the region of the intersphincteric groove.

The junction between the columnar and squamous epithelia is referred to as the anal transition zone (ATZ). It is variable in height and position and often contains islands of squamous epithelium extending up into the columnar mucosa; it is not the same as the dentate line which is an indistinct line observed in the anal canal. Nerve endings including thermoreceptors exist in the submucosa around the upper ATZ; they probably play a role in continence by providing a highly specialized ‘sampling’ mechanism to identify the contents of the lower rectum when the upper anal canal relaxes to allow rectal contents to come into contact with the upper anal canal epithelium (Duthie & Gairns 1960).

The well-defined muscularis mucosae of the rectum continues into the upper canal. Fibres from the longitudinal muscle pass through the internal sphincter and surround the submucosal venous plexus before turning upwards to merge with the muscularis mucosae and form the musculus submucosae ani.

Haemorrhoids

Haemorrhoids represent abnormal enlargement of the anal cushions. The partial drainage of the venous plexus into the intermuscular plane may play a role in this chronic engorgement as a result of obstruction of the venous flow during prolonged straining and defecation. Since the subepithelial vascular cushions of the upper, mid and lower anal canal form a continuous plexus, the differentiation of haemorrhoids into ‘internal’ and ‘external’ is somewhat arbitrary. The laxity of the upper anal canal submucosa is probably responsible for the fact that internal haemorrhoids may form more easily, although engorgement of the plexus deep to the lower anal epithelium may also occur. Since the epithelium in the lower canal is well supplied with sensory nerve endings, acute distension or invasive treatment to haemorrhoids in this area causes profound discomfort, whereas invasive or destructive therapy with relatively few symptoms is possible in the upper canal because the latter is lined with insensate columnar mucosa.

Anal fissures

Acute, transient, vertical breaks in the anal epithelium are not uncommon. The development of chronic, non-healing fissures is less common. They are more likely to develop in the anterior, and particularly the posterior, midline of the anus, possibly because stress within the anal canal is concentrated in these regions by the arrangement of the fibres of the external sphincter: the relative paucity of the arterial supply in these regions probably contributes to poor healing. Persistent hypertonicity of the anal sphincter is a primary pathogenic factor, possibly developing as a consequence of disordered local reflex mechanisms between the lower rectum and internal anal sphincter.

Cryptoglandular sepsis and fistula in ano

Infection of the anal glands is the main cause of anal sepsis and cryptogenic fistula formation (Parks et al 1976). Because many of these glands extend into the intersphincteric plane, so-called cryptoglandular sepsis may readily spread into the same plane. The commonest route of drainage of this sepsis is downwards between the internal and external anal sphincters, appearing beneath the skin at the anal verge. Rupture or drainage of the sepsis at this point will form a fistula *in ano* in the intersphincteric plane. Less commonly, the infection drains outwards from the intersphincteric plane and passes through the fibres of the external anal sphincter, possibly along the spreading septa of the conjoint longitudinal coat, and appears in the perianal skin outside the external anal sphincter as a transphincteric fistula. If the sepsis does not originate in the intersphincteric plane, drainage is likely to be beneath the anal mucosa alone and a submucous fistula forms. Sepsis within the ischio-anal fossa surrounding the lower anal canal can spread with relative ease because the connective tissue is mostly loose adipose tissue. Pus may spread posteriorly, behind the lower anal canal into the contralateral ischio-anal fossa, because the lower anal canal lacks any ligamentous attachments (Parkes 1961).

MUSCLES OF THE ANAL CANAL

The anal canal is encircled by internal and external anal sphincters, separated by the longitudinal layer, and has connections superiorly to puborectalis and the transverse perineii (Fig. 67.47).

Internal anal sphincter

The internal anal sphincter is a well-defined ring of obliquely orientated smooth muscle fibres that is continuous with the circular muscle of the rectum, and which terminates at the junction of the superficial and subcutaneous components of the external sphincter. Its thickness varies between 1.5 and 3.5 mm, depending upon the height within the anal canal and whether the canal is distended. It is usually thinner in females and becomes thicker with age. It may also be thickened in disease processes such as rectal prolapse and chronic constipation. The lower portion of the sphincter is crossed by fibres from the conjoint longitudinal coat which pass into the submucosa of the lower canal.

Vascular supply

The internal anal sphincter is supplied from the terminal branches of the superior rectal vessels and branches of the inferior rectal vessels.

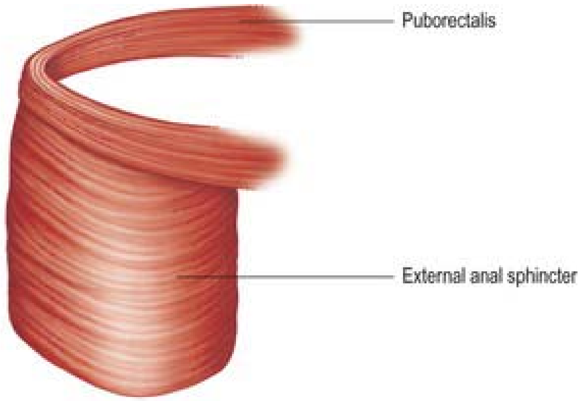
Innervation

The internal anal sphincter is supplied by the sympathetic and parasympathetic systems by fibres that extend down from the lower rectum. Sympathetic fibres originate in the lower two lumbar spinal segments, are distributed via the inferior hypogastric plexus, and cause contraction of the sphincter. Parasympathetic fibres originate in the second to fourth sacral spinal segments, are distributed via the inferior hypogastric plexus, and cause relaxation of the sphincter.

External anal sphincter

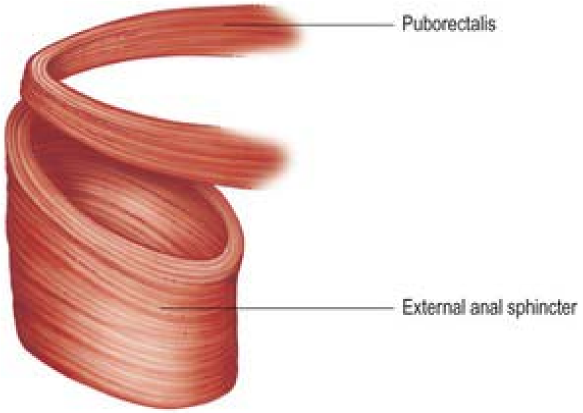
The external anal sphincter is an oval tube-shaped complex of striated muscle, composed mainly of type 1 (slow twitch) skeletal muscle fibres, which are well suited to prolonged contraction. It has been described as consisting of deep, superficial and subcutaneous parts but the external anal sphincter should be considered as a single functional and anatomical entity although the upper middle and lower thirds show different features and attachments. Endoanal ultrasound and magnetic resonance imaging reveal that the uppermost fibres blend with the lowest fibres of puborectalis. In the upper third some of these upper fibres decussate anteriorly into the superficial transverse perineal muscles and posteriorly some fibres are attached to the anococcygeal raphe. The majority of the fibres of the middle third of the external anal sphincter surround the lower part of the internal sphincter. The middle third is attached anteriorly to the perineal body and posteriorly to the coccyx via the anococcygeal ligament: some fibres from each side of the sphincter decussate in these areas to form a commissure in the anterior and posterior midline. The fibres of the lower third lie below the level of the internal anal sphincter and are separated from the lowest anal epithelium by submucosa.

The length and thickness of the external anal sphincter varies between the sexes. In females, the anterior portion tends to be shorter, the wall may be slightly thinner, and the tube may take the form of an asymmetrical cone (Rociu et al 2000) and the transverse perineii and bulbospongiosus fuse with the external sphincter in the lower part of the perineum. In males, the external sphincter is more anular and is separate from the central point of the perineum into which the transverse perineii and bulbospongiosus fuse, so that there is a surgical plane of cleavage between the external sphincter and perineum (Fig. 67.48).



Puborectalis
External anal sphincter

Male



Puborectalis
External anal sphincter

Female

Fig. 67.48 Typical anatomy of male and female external anal sphincters. Puborectalis is shown in isolation with the external anal sphincter viewed from the superolateral aspect. The anterior portion of the external anal sphincter is typically shorter and thinner in females.

Vascular supply

The external anal sphincter is supplied from the terminal branches of the inferior rectal vessels with a small contribution from the median sacral artery.

Innervation

The external anal sphincter is innervated mainly by the inferior rectal branch of the pudendal nerve (anterior divisions of the second, third and fourth sacral spinal nerves). It may also receive some direct supply via fibres which leave the ventral rami of these nerves as they exit the sacral foramina and run beneath the fascia over levator ani to reach the anorectal junction.

FIBROMUSCULAR STRUCTURES OF THE ANAL CANAL

Longitudinal layer and conjoint longitudinal coat

The longitudinal layer is situated between the internal and external sphincters. It contains a fibromuscular layer, the conjoint longitudinal coat, and the intersphincteric space with its connective tissue components (Lunniss & Phillips 1992). The longitudinal layer has muscular and fibroelastic components. The muscular element is formed by fusion of striated muscle fibres from puboanalis, which is the innermost part of puborectalis, with smooth muscle from the longitudinal muscle of the rectum. Endoanal ultrasound and magnetic resonance imaging demonstrate either bundles or incomplete sheets of muscle extending down between the sphincters in the upper canal in both sexes: in men these often end just above the lower border of the internal sphincter. The layer then becomes completely fibroelastic, and splits into septa running between bundles of the subcutaneous external sphincter to terminate in the perianal skin. The area bounded by these septa is generally referred to as the perianal space. The most peripheral of the septa extend between the fibres of the external sphincter into the ischio-anal fat. The most central septa pass through the fibres of the internal sphincter to reach the anal lining and may help to form the intersphincteric groove. The conjoint longitudinal coat is innervated by autonomic fibres that share an origin with the fibres that innervate the internal sphincter.

Other fibromuscular structures

A layer of smooth muscle, yellow elastic fibres, and collagenous connective tissue is found in the anal submucosa, inferior to the anal sinuses. It is derived mainly from strands of the conjoint longitudinal coat, which descend inwards between the fibres of the internal sphincter. Some of the strands end by turning outwards around the lower edge of the internal sphincter to rejoin the main longitudinal layer. Most continue obliquely downwards and insert into the dermis below the intersphincteric groove. These attachments may help to form the corrugations seen in the perianal skin. The septa end in a honeycomb-like arrangement of fibres, which prevents easy distension of the lowest anal lining. This may explain the severe pain produced by pus or blood which collects here, since small volumes of fluid rapidly produce high pressure within the subepithelium.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply to the anal canal is derived from terminal branches of the superior rectal artery, the inferior rectal branch of the pudendal artery and branches of the median sacral artery. The supply to the anal canal lining is not distributed uniformly. The arterial supply of the anterior and, more particularly, the posterior, midline epithelia is less good than that lining the lateral portions of the canal (Klosterhalfen et al 1989), which is relevant to the perpetuation of chronic anal fissures.

Veins

The venous drainage of the upper anal canal mucosa, internal anal sphincter and conjoint longitudinal coat passes via the terminal branches of the superior rectal veins into the inferior mesenteric vein. The lower anal canal and external sphincter drain via the inferior rectal branch of the pudenal vein into the internal iliac vein.

Lymphatics

Lymphatics from the upper anal mucosa, internal anal sphincter and conjoint longitudinal coat drain upwards into the submucosal and intramural lymphatics of the rectum. The lower anal canal epithelium and external anal sphincter lymphatics drain downwards via perianal plexuses into vessels that drain into the external inguinal lymph nodes. The lymphatics of puborectalis drain into the internal iliac lymph nodes. This arrangement has considerable importance for tumours of the lower rectum and upper anal canal. If the tumour is confined to the tissue of origin, malignant spread is confined to the mesorectal lymph nodes. However, if the tumour involves puborectalis or tissues associated with the external anal sphincter, the possibility of lymph node spread to these other groups may require radical excision and much more extensive surgery.

INNERVATION

The anal canal is innervated by both autonomic and somatic nervous systems. Preganglionic sympathetic fibres originate in the lower two lumbar segments, run via the lumbar sympathetic chain into the upper two sacral sympathetic ganglia, and into the inferior hypogastric plexus via the sacral splanchnic nerves. Parasympathetic fibres originate in the second to fourth sacral spinal segments and also run to the inferior hypogastric plexus via the pelvic splanchnic nerves. From the inferior hypogastric plexus both sympathetic and parasympathetic fibres run together in nerves of the ‘pelvic plexus’ and enter the lower rectal wall via the ‘lateral ligaments’ of the rectum and anorectal junction via the endopelvic fascia over levator ani. They are distributed to the submucosal and myenteric plexuses where most fibres terminate on interstitial cells (of Cajal).

The autonomic supply to the anus innervates the upper anal mucosa (rich in thermoreceptors), the internal anal sphincter and the conjoint longitudinal coat. Sympathetic fibres cause relaxation of the lower rectal muscle but contraction of the conjoined longitudinal coat and internal anal sphincter fibres via α-adrenergic receptors. Parasympathetic fibres cause relaxation of the internal sphincter via muscarinic receptors which stimulate release of nitric oxide from intramural nitrergic neurones (Brading & Ramalingam 2006).

The external anal sphincter and lower half of the anal mucosa and perianal skin (which are both rich in nocioceptors and pressure receptors) receive a somatic innervation from the anterior divisions of the second, third and fourth sacral spinal nerves which is mainly distributed via the inferior rectal branch of the pudendal nerve. There may also be some direct supply via fibres which leave the ventral rami of the second to fourth sacral nerves as they exit the sacral foramina and run beneath the fascia over levator ani to reach the anorectal junction (because some somatic reflexes are not abolished by division of the pudendal nerves).

Referred pain

Pain in the lower two thirds of the anus is usually felt with a high degree of acuity and is well localized to the perineum and anal canal itself.

Reflexes, control of anorectal function and continence

Local reflex arcs exist within the anorectal intramural plexuses and also within the sacral segments of the spinal cord a spinal centre for co-ordination of anorectal function has not yet been identified. These reflex arcs involve both autonomic and somatic elements because the co-ordination of continence and the initiation of defecation requires that the lower rectum, internal and external anal sphincters act together.

The internal anal sphincter often relaxes following distension of the rectum (Recto-Anal Inhibitory Reflex or 'RAIR'), suggesting that local reflex pathways exist between the lower rectal sensory fibres and sphincteric motor fibres. This relaxation also occurs on stimulation of somatic sensory nerves, even after the rectum has been excised completely, and is presumably mediated via proprioceptors present in the pelvic floor and an additional reflex pathway via the sacral spinal segments. Integrating the sensory input from the anal canal so as to control the activity of the anal musculature occurs at many levels in the nervous system, including the spinal cord, brain stem, thalamus and cortex. Neural activity not only monitors and regulates defecation, but also other more subtle behaviours within the rectum and anal canal, such as the separation of faeces from rectal gas; local adjustments to faecal consistency and quantities; self-cleansing movements in the rectum and anal canal; coordination with other actions of the perineal and abdominal muscles.

To keep the anal canal closed, the pressure within the anal canal has to be higher than that in the rectum. The resting pressure in the canal is maintained mainly by tonic activity of the internal sphincter as a result of sympathetic tone: sudden increases of intrarectal pressure, e.g. during coughing or exertion, are compensated for by rapid contraction of the external sphincter and puborectalis via spinal reflexes. Angulation of the anorectal junction and the 'flap valve' theory is no longer considered important in continence since dynamic imaging of the process of defecation (proctography) has demonstrated that there is a wide range of angulation which does not correlate with function. The internal sphincter does not close the canal completely; the gap (approximately 7 mm) is sealed by the distensible, vascular subepithelial tissues.

Defecation

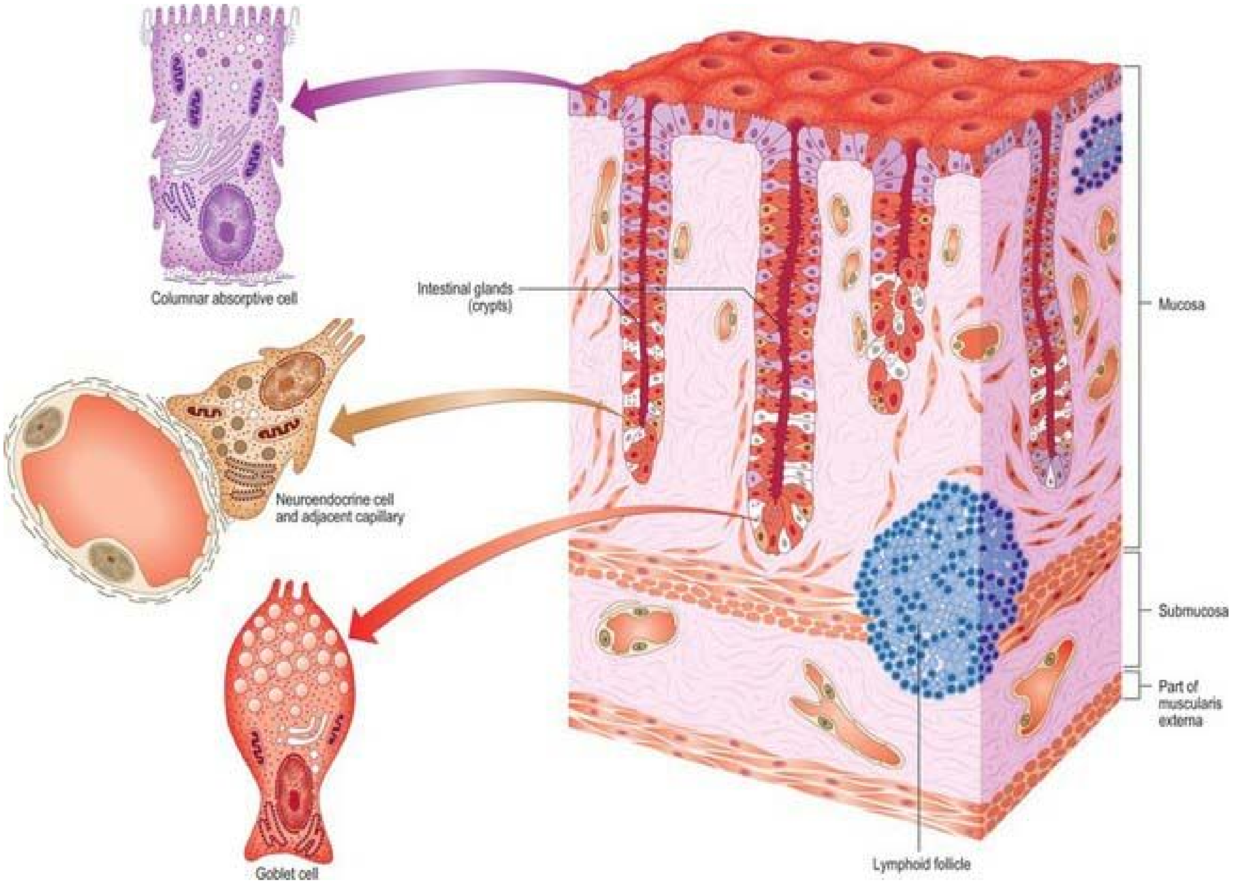
Defecation is a conscious physiological act in response to feeling the need to pass stool in the rectum: it requires coordinated relaxation of the pelvic floor muscles and anal sphincter. The dynamics have been studied using pressure measurements in the colon, rectum and anus (Herbst et al 1997), and by various imaging techniques including fluoroscopy, ultrasonography and magnetic resonance imaging (Kruyt et al 1991). The process is initiated by mass colonic contractions which drive faeces into the rectum. Rectal distension occurs progressively; there is little increase in intra-rectal pressure because the rectal musculature relaxes as a result of either local intramural or spinal reflexes mediated via sympathetic and parasympathetic fibres. The RAIR is probably involved in allowing the descent of rectal contents into the upper anal canal where it can be ‘sampled’ by contact with the mucosal receptors (particularly thermoreceptors). Defecation may be deferred by conscious contraction of the external anal sphincter until contractions cease and retrograde rectal peristalsis moves stool out of the distal rectum, so that the sensation to defecate passes off. Initiation of defecation involves conscious relaxation of the pelvic floor muscles and external sphincter, so that the pelvic floor descends slightly allowing the anorectal angle to straighten. Reflex relaxation of the internal anal sphincter and conjoint longitudinal coat allows the anal canal to open. Abdominal muscle contraction will aid expulsion from the rectum, but continuing mass colonic contractions push more faeces down into the rectum, so that the entire left colon may be emptied.

Anorectal incontinence

Anal incontinence is common and may occur for a variety of reasons. Abnormally high rectal pressures, as occur in severe diarrhoea, may overcome a normal sphincter, and autonomic disorders may produce abnormal motor activity or loss of normal sensation, so that there is no awareness of the presence of stool. Damage to the anal sphincter may result from vaginal delivery due to stretch, instrumentation or surgical procedures. Atrophy of the external sphincter may occur secondary to pudendal nerve damage during delivery (and may also occur in diabetics, neurological disease and the elderly) A damaged sphincter will not be able to overcome normal fluctuations of intrarectal pressures, or there may be a combination of damage and rectal dysfunction resulting in anal incontinence.

MICROSTRUCTURE

The layers of tissue in the large intestinal wall (see Fig. 67.3; Fig. 67.49) resemble those in the small intestine (Ch. 66), except that villi and circular folds are absent and the glands (crypts) are longer.



Columnar absorptive cell
Intestinal glands (crypts)
Mucosa
Neuroendocrine cell and adjacent capillary
Submucosa
Part of muscularis externa
Goblet cell
Lymphoid follicle

Fig. 67.49 The microstructure of the colonic wall and its epithelial cells. Note the aggregations of lymphocytes (blue) and undifferentiated epithelial cells (white).

Mucosa

The mucosa is pale, smooth, and, in the colon, raised into numerous crescent-shaped folds between the sacculi. In the rectum it is thicker, darker, more vascular, and more loosely attached to the submucosa.

Epithelium

The luminal surface of all but the anorectal junction is lined by columnar cells, mucous (goblet) cells, and occasional microfold (M) cells that are restricted to the epithelium overlying lymphoid follicles. Columnar and mucous cells are also present in the intestinal glands (crypts) which additionally contain stem cells and neuroendocrine cells. In general, the glands lack Paneth cells, but some may be present in the caecum.

Columnar (absorptive) cells

Columnar (absorptive) cells are the most numerous of the epithelial cell types. They are responsible for ion exchange and other transepithelial transport functions including water resorption, particularly in the colon. Although there is some variation in their structure, they all bear apical microvilli, which are shorter and less regular than those on enterocytes in the small intestine. All cells have typical junctional complexes around their apices, and these limit extracellular diffusion from the lumen across the intestine wall.

Mucous (goblet) cells

Mucous cells have a similar structure to those of the small intestine, but are more numerous. They are outnumbered by absorptive cells for most of the length of the colon, but they are equally frequent towards the rectum, where their numbers increase further.

Microfold (M) cells

Microfold cells are similar to those of the small intestine: they are flattened or cuboidal cells with long, blunt microfolds rather than typical microvilli, and they are restricted to epithelium overlying lymphoid follicles.

Stem cells

Stem cells are the source of the other epithelial cell types in the large intestine. They are located at or near the bases of the intestinal glands, where they divide by mitosis. They provide cells that migrate towards the luminal surface of the intestine: their progeny differentiate, undergo apoptosis and are shed after approximately 5 days.

Neuroendocrine cells

Neuroendocrine cells are situated mainly at the bases of the glands, and secrete basally into the lamina propria.

Intestinal glands (crypts)

The crypts are narrow perpendicular tubular glands which are longer, more numerous and closer together than those of the small intestine. Their openings give a cribriform appearance to the mucosa in surface view. The glands are lined by low columnar epithelial cells, mainly goblet cells, between which are columnar absorptive cells and neuroendocrine cells. Epithelial stem cells at their bases give rise to all three cell types.

Lamina propria

The lamina propria is composed of connective tissue that supports the epithelium. It forms a specialized pericryptal myofibroblast sheath around each intestinal gland. Solitary lymphoid follicles within the lamina propria are most abundant in the caecum, appendix and rectum, but are also present scattered along the rest of the large intestine. They are similar to those of the small intestine; efferent lymphatic vessels originate within them. Lymphatic vessels are absent from the lamina propria core between crypts.

Muscularis mucosae

The muscularis mucosae of the large intestine is essentially similar to that of the small intestine: it has prominent longitudinal and circular layers.

Submucosa

The submucosa of the large intestine is similar to that of the small intestine.

Muscularis externa

The muscularis externa has outer longitudinal and inner circular layers of smooth muscle. The longitudinal fibres form a continuous layer but, with the exception of the uniform outer muscle layer of most of the appendix, macroscopically these are aggregated as longitudinal bands or taeniae coli (see Figs 67.3 and 67.12). Between the taeniae coli the longitudinal layer is much thinner, less than half the circular layer in thickness. The circular fibres form a thin layer over the caecum and colon, and are aggregated particularly in the intervals between the sacculi. In the rectum they form a thick layer and in the anal canal they form the internal anal sphincter. There is an interchange of fascicles between circular and longitudinal layers, especially near the taeniae coli. Deviation of longitudinal fibres from the taeniae to the circular layer may, in some instances, explain the haustration of the colon.

Serosa

The serosa or visceral peritoneum is variable in extent. Along the colon the peritoneum forms small fat-filled appendices epiploicae which are most numerous on the sigmoid and transverse colon but generally absent from the rectum. Subserous loose connective tissue attaches the peritoneum to the muscularis externa.

CHAPTER 68

Liver

The liver is the largest of the abdominal viscera, occupying a substantial portion of the upper abdominal cavity. It occupies most of the right hypochondrium and epigastrium, and frequently extends into the left hypochondrium as far as the left lateral line (Fig. 68.1). As the body grows from infancy to adulthood the liver rapidly increases in size. This period of growth reaches a plateau around 18 years and is followed by a gradual decrease in the liver weight from middle age. The ratio of liver to body weight decreases with growth from infancy to adulthood. The liver weighs approximately 5% of the body weight in infancy and it decreases to approximately 2% in adulthood. The size of the liver also varies according to sex, age and body size. It has an overall wedge shape, which is in part determined by the form of the upper abdominal cavity into which it grows. The narrow end of the wedge lies towards the left hypochondrium, and the anterior edge points anteriorly and inferiorly. The superior and right lateral aspects are shaped by the anterolateral abdominal and chest wall as well as the diaphragm. The inferior aspect is shaped by the adjacent viscera. The capsule is no longer thought to play an important part in maintaining the integrity of the shape of the liver.

Fig. 68.1 The ‘bed’ of the liver. The outline of the liver is shaded green. The central bare area is unshaded.

Throughout life the liver is reddish brown in colour, although this can vary depending upon the fat content. Obesity is the most common cause of excess fat in the liver (also known as steatosis): the liver assumes a more yellowish tinge as its fat content increases. The texture is usually soft to firm, although it depends partly on the volume of blood the liver contains and the fat content.

The liver performs a wide range of metabolic activities required for homeostasis, nutrition and immune defence. For example, it is important in the removal and breakdown of toxic, or potentially toxic, materials from the blood and the regulation of blood glucose and lipids, the storage of certain vitamins, iron, and other micronutrients, and in breaking down or modifying amino acids. It is involved in a plethora of other biochemical reactions. Since the majority of these processes are exothermic, a substantial part of the thermal energy production of the body, especially at rest, is provided by the liver. The liver is populated by phagocytic macrophages, components of the mononuclear phagocyte system capable of removing particulates from the blood stream. It is an important site of haemopoiesis in the fetus.

SURFACES OF THE LIVER

The liver is usually described as having superior, anterior, right, posterior and inferior surfaces, and has a distinct inferior border (Figs 68.2, 68.3). However, the superior, anterior and right surfaces are continuous and no definable borders separate them. It would be more appropriate to group them as the diaphragmatic surface, which is mostly separated from the inferior, or visceral surface, by a narrow inferior border. At the infrasternal angle the inferior border is related to the anterior abdominal wall and is accessible to examination by percussion, but is not usually palpable. In the midline, the inferior border of the liver is near the transpyloric plane, about a hand's breadth below the xiphisternal joint. In women and children the border often projects a little below the right costal margin.

Fig. 68.3 Relations of the liver. **A**, superior view; **B**, posterior view; **C**, anterior view; **D**, inferior view.

Superior surface

The superior surface is the largest surface and lies immediately below the diaphragm, separated from it by peritoneum except for a small triangular area where the two layers of the falciform ligament diverge. The majority of the superior surface lies beneath the right dome, but there is a shallow cardiac impression centrally that corresponds to the position of the heart above the central tendon of the diaphragm. The left side of the superior surface lies beneath part of the left dome of the diaphragm.

Anterior surface

The anterior surface is approximately triangular and convex and is covered by peritoneum except at the attachment of the falciform ligament. Much of it is in contact with the anterior attachment of the diaphragm. On the right the diaphragm separates it from the pleura and sixth to tenth ribs and cartilages, and on the left from the seventh and eighth costal cartilages.

Right surface

The right surface is covered by peritoneum and lies adjacent to the right dome of the diaphragm which separates it from the right lung and pleura and the seventh to 11th ribs. The right lung and basal pleura both lie above and lateral to its upper third, between the diaphragm and the seventh and eighth ribs. The diaphragm, the costodiaphragmatic recess lined by pleura, and the ninth and tenth ribs all lie lateral to the middle third of the right surface. Lateral to the lower third, the diaphragm and thoracic wall are in direct contact. Rarely, the hepatic flexure and proximal transverse colon may lie on a long mesentery over the right and superior surfaces of the liver, referred to as Chilaiditi syndrome.

Posterior surface

The posterior surface is convex, wide on the right, but narrow on the left. A deep median concavity corresponds to the forward convexity of the vertebral column close to the attachment of the ligamentum venosum. Much of the posterior surface is attached to the diaphragm by loose connective tissue, forming the triangular ‘bare area’. The inferior vena cava lies in a groove or tunnel in the medial end of the ‘bare area’. To the left of the caval groove the posterior surface of the liver is formed by the caudate lobe, and covered by a layer of peritoneum continuous with that of the inferior layer of the coronary ligament and the layers of the lesser omentum. The caudate lobe is related to the diaphragmatic crura above the aortic opening and the right inferior phrenic artery, and separated by these structures from the descending thoracic aorta.

The fissure for the ligamentum venosum separates the posterior aspect of the caudate lobe from the main part of the left lobe. The fissure cuts deeply in front of the caudate lobe and contains the two layers of the lesser omentum. The posterior surface over the left lobe bears a shallow impression near the upper end of the fissure for the ligamentum venosum that is caused by the abdominal part of the oesophagus. The posterior surface of the left lobe to the left of this impression is related to part of the fundus of the stomach. Together these posterior relations make up what is sometimes referred to as the ‘bed’ of the liver (Fig. 68.1).

Inferior surface

The inferior surface is bounded by the inferior edge of the liver. It blends with the posterior surface in the region of the origin of the lesser omentum, the porta hepatis and the lower layer of the coronary ligament, and is marked near the midline by a sharp fissure which contains the ligamentum teres (the obliterated fetal left umbilical vein). The gallbladder usually lies in a shallow fossa, but this is variable: it may have a short mesentery or be completely intrahepatic and lie within a cleft in the liver parenchyma. The quadrate lobe lies between the fissure for the ligamentum teres and the gallbladder.

The inferior surface of the left lobe is related inferiorly to the fundus of the stomach and the upper lesser omentum. The quadrate lobe lies adjacent to the pylorus, first part of the duodenum and the lower part of the lesser omentum. Occasionally the transverse colon lies between the duodenum and the quadrate lobe. To the right of the gallbladder, the inferior surface is related to the hepatic flexure of the colon, the right suprarenal gland and right kidney, and the first part of the duodenum.

GROSS ANATOMICAL LOBES

Historically, the liver has been considered to be divided into right, left, caudate and quadrate lobes by the surface peritoneal and ligamentous attachments.

Right lobe

The right lobe is the largest in volume and contributes to all surfaces of the liver. It is divided from the left lobe by the falciform ligament superiorly and the ligamentum venosum inferiorly. On the inferior face to the right of the groove formed by the ligamentum venosum there are two prominences separated by the porta hepatis: the caudate lobe lies posterior, and the quadrate lobe anterior, to the porta hepatis. The gallbladder lies in a shallow fossa to the right of the quadrate lobe.

Left lobe

The left lobe is the smaller of the two main lobes, although it is nearly as large as the right lobe in young children.

It lies to the left of the falciform ligament with no subdivisions, and is substantially thinner than the right lobe, having a thin apex that points into the left upper quadrant.

Quadrate lobe

The quadrate lobe is visible as a prominence on the inferior surface of the liver, to the right of the groove formed by the ligamentum venosum (and thus is incorrectly said to arise from the right lobe although it is functionally related to the left lobe). It lies anterior to the porta hepatis and is bounded by the gallbladder fossa to the right, a short portion of the inferior border anteriorly, the fissure for the ligamentum teres to the left, and the porta hepatis posteriorly.

Caudate lobe

The caudate lobe is visible as a prominence on the inferior and posterior surfaces to the right of the groove formed by the ligamentum venosum: it lies posterior to the porta hepatis. To its right is the groove for the inferior vena cava. Above, it continues into the superior surface on the right of the upper end of the fissure for the ligamentum venosum. In gross anatomical descriptions this lobe is said to arise from the right lobe, but it is functionally separate.

FUNCTIONAL ANATOMICAL DIVISIONS

Current understanding of the functional anatomy of the liver is based on Couinaud's division of the liver into eight (subsequently nine) functional segments, based upon the distribution of portal venous branches and the location of the hepatic veins in the parenchyma (Couinaud 1957). Further understanding of the intrahepatic biliary anatomy, especially of the right ductal system, was enhanced by contributions from Hjortsjo (1948) and Healey & Schroy (1953) using the biliary system as the main guide for division of the liver (Fig. 68.4).

Fig. 68.4 The fissures and sectors of the liver. (Right lateral = right posterior; right medial = right anterior.)

The liver is divided into four portal sectors by the four main branches of the portal vein. These are right lateral, right medial, left medial and left lateral (sometimes the term posterior is used in place of lateral and anterior in place of medial). The three main hepatic veins lie between these sectors as intersectorial veins. These intersectoral planes are also called portal fissures (scissures). The fissures containing portal pedicles are called hepatic fissures. Each sector is sub-divided into segments (usually two) based on their supply by tertiary divisions of the vascular biliary sheaths.

Fissures of the liver

Knowledge of the fissures of the liver is essential for understanding liver surgery. Three major fissures, not visible on the surface, run through the liver parenchyma and harbour the three main hepatic veins (main, left and right portal fissures). Three minor fissures are visible as physical clefts of the liver surface (umbilical, venous and fissure of Gans).

Main portal fissure

The main fissure extends from the tip of the gallbladder back to the midpoint of the inferior vena cava and contains the middle (main) hepatic vein. It separates the liver into right and left hemi-livers. Segments V and VIII lie to the right and segment IV to the left of the fissure.

Left portal fissure

The left fissure divides the left hemi-liver into medial (anterior) and lateral (posterior) sectors. It extends from the mid point of the anterior edge of the liver between the falciform ligament and the left triangular ligament to the point which marks the confluence of the left and middle hepatic veins. It contains the left hepatic vein and separates the left anterior and left posterior sectors: segment III lies anteriorly and segment II posteriorly.

Right portal fissure

The right portal fissure divides the right hemi-liver into lateral (posterior) and medial (anterior) sectors. The plane of the right fissure is the most variable amongst the main fissures and runs approximately diagonally through the gross right lobe from the lateral end of the anterior border to the confluence of the left and middle hepatic veins. The fissure divides the right anterior sector to its left (segments V and VIII) from the right posterior sector to its right (segments VI and VII), and contains the right hepatic vein. The right fissure marks the thickest point of liver parenchyma which is commonly transected during liver resection.

Umbilical fissure

The umbilical fissure separates segment III from segment VI within the left anterior sector and contains a main branch of the left hepatic vein (the umbilical fissure vein). It is marked by the attachment of the falciform ligament and sometimes covered by a ridge of liver tissue extending between the segments: it is often avascular and can be divided safely with diathermy during a surgical approach. It contains the umbilical portion of the left portal vein and the final divisions of the left hepatic duct and the left hepatic artery branches. The umbilical portion of the left portal vein is an important landmark: access to this vein and mobilization of the left portal vein are essential steps in surgery for hilar cholangiocarcinoma. A knowledge of the arrangement of the portal vein, hepatic artery and bile duct within the umbilical fissure is also essential when splitting the liver for an adult and paediatric recipient and for live donor liver transplantation for a child recipient.

Venous fissure

The venous fissure is a continuation of the umbilical fissure on the under surface of the liver and contains the ligamentum venosum. It lies between the caudate lobe and segment IV. The deeper continuation of this plane is the dorsal fissure.

Fissure of Gans

The fissure of Gans lies on the undersurface of the right lobe of the liver behind the gallbladder fossa. It often contains the portal pedicle to the right posterior sector and is thought to correspond to the right fissure as it relates to the separation of the sectors of the liver.

Sectors and segments of the liver

Sectors

The sectors of the liver are made up of between one and three segments: right lateral sector = segments VI and VII; right medial sector = segments V and VIII; left medial sector = segments III and IV (and part of I); left lateral sector = segment II (Fig. 68.5). Segments are numbered in an ante-clockwise spiral centered on the portal vein with the liver viewed from beneath, starting with segment I up to segment VI, and then back clockwise for the most cranial two segments VII and VIII (Fig. 68.6).

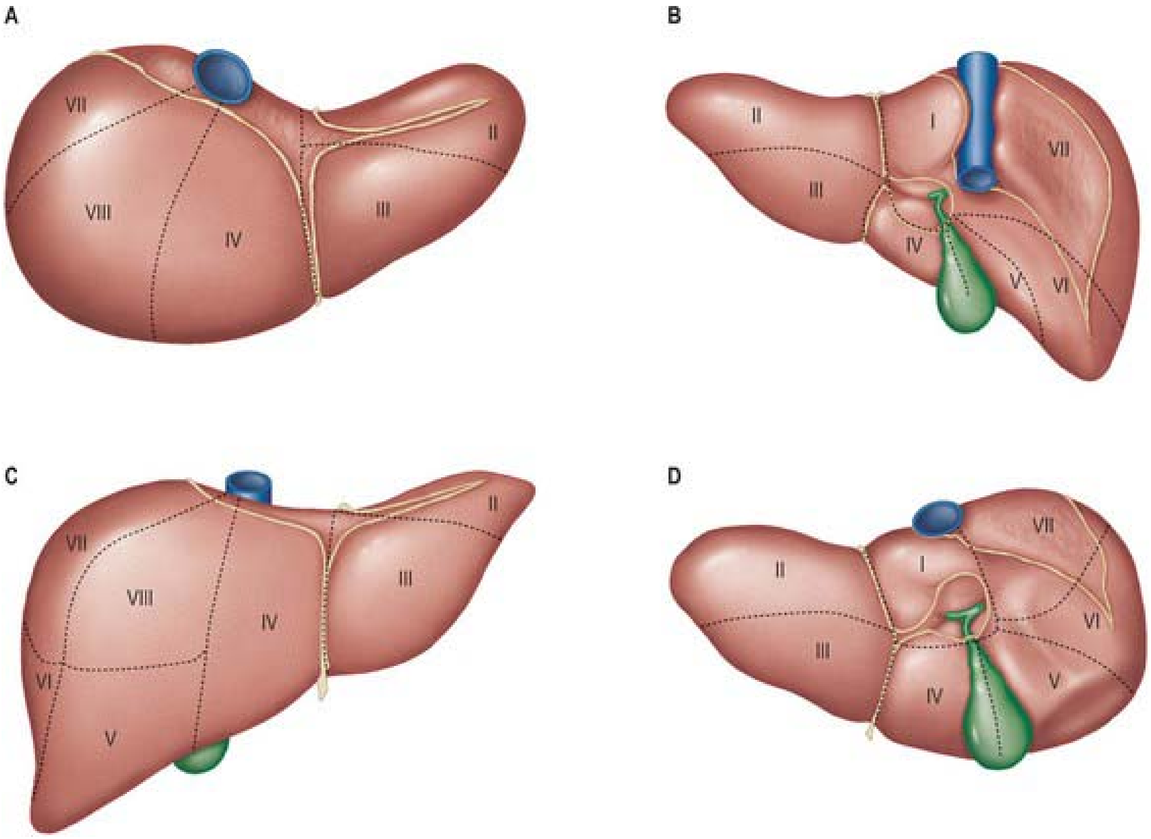

Fig. 68.5 Segments of the liver (after Couinaud). **A**, superior view; **B**, posterior view; **C**, anterior view; **D**, inferior view. The segments are sometimes referred to by number (name) – I (caudate) (sometimes subdivided into left and right parts called segment IX); II (left lateral superior); III (left medial inferior); IV (left medial superior) (sometimes subdivided into superior and inferior parts); V (right medial inferior); VI

(right lateral inferior); VII (right lateral superior); VIII (right medial superior).

The left portal vein (LPV) separates segment II superiorly from segment III inferiorly. **C**, The right portal vein (RPV) divides segments V and VI inferiorly (**C**) from segments VII and VIII superiorly (**B**).

Segment I

Segment I corresponds to the anatomical caudate lobe and lies posterior (dorsal) to segment IV with its left half directly posterior to segments II and II and its medial half surrounded by major vascular branches. The Glissonian sheaths to segment I arise from both right and left main sheaths: the segment therefore receives vessels independently from the left and right portal veins and hepatic arteries, and it drains independently into the inferior vena cava by multiple small branches (referred to as the lower group). They nearly always arise in the lower and occasionally from the middle third, but never from the upper third of the segment. The bile ducts draining the segment are closely related to the confluence of the right and left hepatic ducts such that excision of central bile duct tumours usually requires removal of segment IV.

Segment II

Segment II is the only segment in the left lateral sector of the liver and lies postero-lateral to the left fissure. It often has only one Glissonian sheath and drains into the left hepatic vein. Rarely, a separate vein drains directly into the inferior vena cava.

Segment III

Segment III lies between the umbilical fissure and the left fissure and is often supplied by one to three Glissonian sheaths: it drains into the left hepatic vein. The vein of the falciform ligament can provide an alternative drainage route for segment III.

Segment IV

Segment IV lies between the umbilical fissure and the main fissure, anterior to the dorsal fissure and segment I. Segment IV is supplied by three to five Glissonian sheaths, of which the majority arise in the umbilical fissure; their origins are often close to those that supply to segments II and III. Occasionally segment IV is supplied by branches from the main left pedicle. The main venous drainage segment is into the middle hepatic vein; the segment can also drain into the left hepatic vein through the vein of the falciform ligament.

Segment V

Segment V is the inferior segment of the right medial sector and lies between the middle and the right hepatic veins. Its size is variable, as are the number of Glissonian sheaths that supply it. Venous drainage is into the right and middle hepatic veins.

Segment VI

Segment VI forms the inferior part of the right lateral sector posterior to the right portal fissure. It is often supplied by two to three branches from the right posterior Glisson’s sheath, but occasionally the Glisson’s sheath to segment VI can arise directly from the right pedicle. Venous drainage is normally into the right hepatic vein, but may be via the right inferior hepatic vein directly into the inferior vena cava.

Segment VII

Segment VII forms the superior part of the posterior sector and lies behind the right hepatic vein. The sheaths to segment VII are often single. The venous drainage is into the right hepatic vein; occasionally the segment can drain through the right middle hepatic vein directly into the inferior vena cava.

Segment VIII

Segment VIII is the superior part of the right anterior sector. The right anterior sectoral sheaths end in segment VIII and supply it after giving off branches to segment V. The venous drainage is to the right and middle hepatic veins.

Segment IX

Segment IX is a recent subdivision of segment I, and describes that part of the segment that lies posterior to segment VIII.

Supports of the liver

The liver is stabilized and maintained in its position in the right upper quadrant of the abdomen by both static and dynamic factors. Richelme & Bourgeon (1973) suggested a three-tier classification of the anatomical factors: the suspensory attachments at the posterior abdominal wall to the inferior vena cava, hepatic veins, coronary and triangular ligaments (primary factors); the support provided by the right kidney, right colonic angle and duodenopancreatic complex (secondary factors); the attachment to the anterior abdominal wall and diaphragm by the falciform ligament (tertiary factors).

The surgical implications of these different factors are important for traumatologists in terms of achieving a better understanding of the pathophysiology of liver trauma. The inferior vena cava and the supra-hepatic veins, especially the right hepatic vein, appear to be the most important anatomical structures that support the bulk of the liver. Other factors which are responsible for the maintenance of the position of the liver within the abdominal cavity include positive intra-abdominal pressure and the movement of the diaphragm during respiration.

Peritoneal attachments and ligaments of the liver

The liver is attached to the anterior abdominal wall, diaphragm and other viscera by several ligaments which are formed from condensations of the peritoneum.

Falciform ligament

The liver is attached in front to the anterior abdominal wall by the falciform ligament. The two layers of this ligament descend from the posterior surface of the anterior abdominal wall and diaphragm and turn onto the anterior and superior surfaces of the liver. On the dome of the superior surface, the right leaf runs laterally and is continuous with the upper layer of the coronary ligament. The left layer of the falciform ligament turns medially and is continuous with the anterior layer of the left triangular ligament. The ligamentum teres, which represents the obliterated left umbilical vein, runs in the lower free border of the falciform ligament and continues into a fissure on the inferior surface of the liver. In fetal life the left umbilical vein opens into the left portal vein: it is supposed to be obliterated in adult life, but frequently remains partially patent. This lumen may open up in conditions such as portal hypertension to form a collateral channel. The ligamentum teres has importance in abdominal surgery for several reasons. It is quite often divided in upper abdominal surgery to optimize access to the upper abdominal viscera or as the first step in the mobilization of the liver. The ligament is vascularized by numerous arterial branches, mainly from the segment IV artery, and these form an anastomotic connection with the branches of the internal thoracic artery: it is therefore important to ligate or coagulate the ligament during its division. The ligamentum teres is a landmark and guide to the segment III hepatic duct used in hepatocojejunostomy formation, and to the left portal vein lying in the umbilical fissure during creation of a mesentericoportal shunt.

Coronary ligament

The coronary ligament is formed by the reflection of the peritoneum from the diaphragm onto the posterior surfaces of the right lobe of the liver. A large triangular area of liver devoid of peritoneal covering, the ‘bare area’ of the liver, is defined between the two layers of the coronary ligament. Here the liver is attached to the diaphragm by areolar tissue and is in continuity inferiorly with the anterior pararenal space. The coronary ligament is continuous on the right with the right triangular ligament. On the left, the two layers become closely applied, and form the left triangular ligament. The upper layer of the coronary ligament is reflected superiorly onto the inferior surface of the diaphragm and inferiorly onto the right and superior surface of the liver. The lower layer of the coronary ligament is reflected inferiorly over the right suprarenal gland and right kidney, and superiorly onto the inferior surface of the liver. Surgical division of the right triangular and coronary ligaments allows the right lobe of the liver to be brought forward, and exposes the lateral aspect of the inferior vena cava behind the liver.

Triangular ligaments

The left triangular ligament is a double layer of peritoneum which extends to a variable length over the superior border of the left lobe of the liver. Medially the anterior leaf is continuous with the left layer of the falciform ligament and the posterior layer is continuous with the left layer of the lesser omentum. The left triangular ligament lies in front of the abdominal part of the oesophagus, the upper end of the lesser omentum and part of the fundus of the stomach. Division of the left triangular ligament allows the left lobe of the liver to be mobilized for exposure of the abdominal oesophagus and crura of the diaphragm. The left triangular ligament is an important stabilizing factor for the left lobe in operations involving removal of the right lobe of the liver. Its division will result in the left lobe being unstable to the extent that it can rotate and displace into the space vacated under the right hemidiaphragm: this extreme degree of rotation can compromise the venous outflow of the liver with consequent liver dysfunction. If it is divided, the left triangular ligament must be fixed at the end of the surgery, in addition to fixing back the falciform ligament.

The right triangular ligament is a short structure which lies at the apex of the ‘bare area’ of the liver and is continuous with the layers of the coronary ligament.

Lesser omentum

The lesser omentum is a fold of peritoneum which extends from the lesser curve of the stomach and proximal duodenum to the inferior surface of the liver. Its attachment to the inferior surface of the liver is L-shaped. The vertical component follows the line of the fissure for the ligamentum venosum, the fibrous remnant of the ductus venosus. More inferiorly the attachment runs horizontally to complete the L in the porta hepatis. At its upper end, the superior layer of the lesser omentum is continuous on the left with the posterior layer of the left triangular ligament, and the inferior layer is continuous on the right with the coronary ligament as it encloses the inferior vena cava. At its lower end, the two layers diverge to surround the structures of the porta hepatis. A thin fibrous condensation of fascia usually runs from the medial end of the porta hepatis into the fissure in the inferior surface which contains the ligamentum teres. This fascia is continuous with the lower border of the falciform ligament when the ligamentum teres re-emerges at the inferior border of the liver. Care should be taken when dividing the lesser omentum, because an aberrant left hepatic artery may run in the medial end: when present, it invariably extends to the liver at the base of the umbilical fissure, and may be identified by a pulsation in the lesser omentum close to the umbilical fissure.

Ligamentum venosum

The ligamentum venosum represents the obliterated venous connection that existed between the left portal vein and the left hepatic vein in fetal life. It is used as a guide and aid to control the left hepatic vein extrahepatically during surgery. By dividing the ligament close to its insertion into the left hepatic vein and retracting it laterally, the angle between the left and the middle hepatic veins, required for dissection and control of the left hepatic vein, may be accessed.

Porta hepatis, hepatoduodenal ligament and hilar plate

The porta hepatis is a deep fissure on the inferior surface of the liver. It is situated between the quadrate lobe in front and the caudate process behind, and contains the portal vein, hepatic artery and hepatic nervous plexuses as they ascend into the parenchyma of the liver, and the right and left bile ducts and some lymph vessels as they emerge from the liver. The hepatic ducts lie anterior to the portal vein and its branches, and the hepatic artery with its branches lies between the two (Fig. 68.7). All these structures are enveloped in the perivascular fibrous capsule, the hepatobiliary capsule of Glisson, a sheath of loose connective tissue which surrounds the vessels as they course through the portal canals in the liver and is also continuous with the fibrous hepatic capsule. The dense aggregation of vessels, supporting connective tissue, and liver parenchyma just above the porta hepatis is often referred to as the 'hilar plate' of the liver (Fig. 68.8). Understanding of the concept of hilar plate is important in surgical approaches to the hilar structures. Division or lowering of the hilar plate are essential for surgical access to the left hepatic duct. The hepatic artery, bile duct and portal vein extend from the porta hepatis towards the duodenum in the free edge of the hepatoduodenal ligament, which forms the anterior boundary of the epiploic foramen. Rapid control of the vessels entering the porta hepatis can be obtained by dividing the lesser omentum to the left of these structures and passing a tape around them from left to right through the epiploic foramen (a 'Pringle' manoeuvre).

Fig. 68.7 Cross-section of the structures at the porta hepatis.

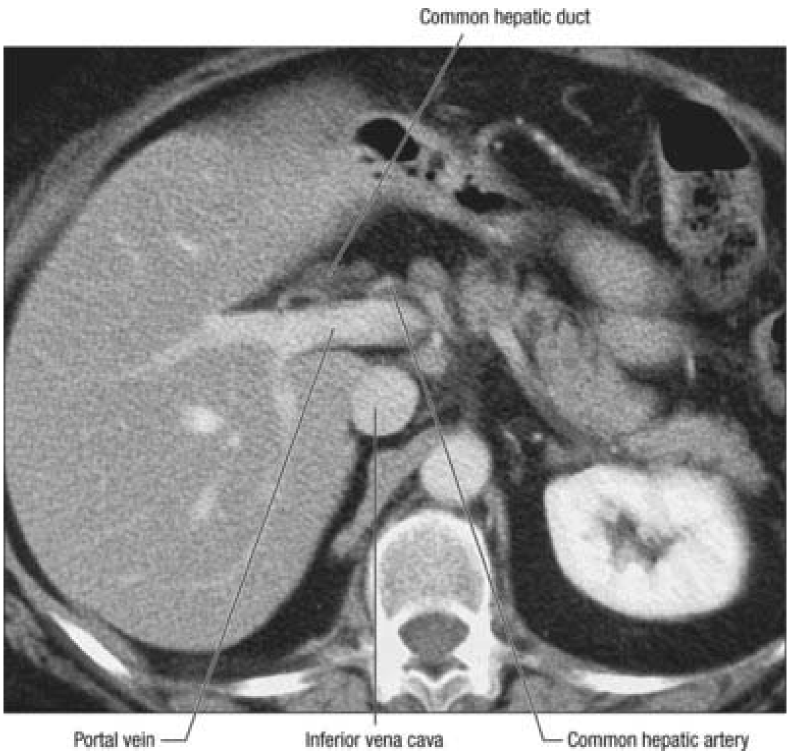

Fig. 68.8 Axial CT of the porta hepatis. The hepatic ducts lie anteriorly, the portal vein posteriorly, and hepatic artery between the two.

The left hepatic duct remains extrahepatic as it runs down to the bifurcation along the base of segment IV (the quadrate lobe). This extrahepatic length of duct is particularly useful when performing high biliary duct reconstructions where a length of jejunum is anastomosed to form a biliary-enteric bypass, to treat strictures of the common hepatic duct.

Glisson’s sheath

Glisson’s capsule condenses around the branches of the portal triad structures as Glissonian sheaths as they enter the liver parenchyma and extends as far the individual segments of the liver. This arrangement facilitates surgical control of both the main right and left pedicles of the liver as well as all the structures (biliary, autonomic and lymphatic elements) that supply individual sectors and segments in liver complex resectional surgery.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The vessels connected with the liver are the portal vein, hepatic artery and hepatic veins. The portal vein and hepatic artery ascend in the lesser omentum to the porta hepatis, where each bifurcates. The hepatic bile duct and lymphatic vessels descend from the porta hepatis in the same omentum (Figs 68.7 and 68.8). The hepatic veins leave the liver via its posterior surface and run directly into the inferior vena cava.

Hepatic artery

In adults the hepatic artery is intermediate in size between the left gastric and splenic arteries. In fetal and early postnatal life it is the largest branch of the coeliac axis. The hepatic artery gives off right gastric, gastroduodenal and cystic branches as well as direct branches to the bile duct from the right hepatic and sometimes the supraduodenal artery (Fig. 68.9A). After its origin from the coeliac axis, the hepatic artery passes anteriorly and laterally below the epiploic foramen to the upper aspect of the first part of the duodenum. It may be subdivided into the common hepatic artery, from the coeliac trunk to the origin of the gastroduodenal artery, and the hepatic artery ‘proper’, from that point to its bifurcation. It passes anterior to the portal vein and ascends anterior to the epiploic foramen between the layers of the lesser omentum. Within the free border of the lesser omentum the hepatic artery is medial to the common bile duct and anterior to the portal vein. At the porta hepatis it divides into right and left branches before these run into the parenchyma of the liver. The right hepatic artery usually crosses posterior (occasionally anterior) to the common hepatic duct (Fig. 68.9B). This close proximity often means that the right hepatic artery is involved in bile duct cancer earlier than the left hepatic artery. Occasionally the right hepatic artery crosses in front of the common bile duct and may be injured in surgery of the common bile duct. It almost always divides into an anterior branch supplying segments V and VIII, and a posterior branch supplying segments VI and VII. The anterior division often supplies a branch to segment I and the gallbladder. The segmental arteries are macroscopically end-arteries although some collateral circulation occurs between segments via fine terminal branches.

A small number of normal variants are important to demonstrate angiographically because they may influence surgical and interventional radiological procedures. A vessel that supplies a lobe in addition to its normal vessel is defined as an accessory artery. A replaced hepatic artery is a vessel that does not originate from an orthodox position and provides the sole supply to that lobe. Rarely a replaced common hepatic artery arises from the superior mesenteric artery (Fig. 68.10) and is identified at surgery by a relatively superficial portal vein (reflecting the absence of a common hepatic artery that would normally cross in front of the vein). More commonly a replaced right hepatic artery or an accessory right hepatic artery arises from the superior mesenteric artery (Fig. 68.11). In this case they run behind the portal vein and bile duct in the lesser omentum and can be identified at surgery by pulsation behind the portal vein. The accessory right hepatic artery may be injured during resections of the pancreatic head because the artery lies in close proximity to the portal vein. Occasionally, a replaced left hepatic artery or an accessory branch arises from the left gastric artery: these vessels provides a source of collateral arterial circulation in cases of occlusion of the vessels in the porta hepatis but may also be injured during mobilization of the stomach as it lies in the upper portion of the lesser omentum. Rarely, accessory left or right hepatic arteries may arise from the gastroduodenal artery or aorta. The presence of replaced arteries can be lifesaving in patients with bile duct cancer: because they are further away from the bile duct they tend to be spared from the cancer, making excision of the tumour feasible. Knowledge of these variations is also important in planning whole and split liver transplantation.

Variations in the intrahepatic arteries are common and may be surgically important. For example, the segment VI artery most commonly arises from the left hepatic artery, but in about 10–20% of cases it arises from the right hepatic artery or the main hepatic artery. Failure to recognize this variation may compromise the blood supply to segment IV following right hepatectomy, and is especially important following right lobe donation for live donor liver transplantation.

Veins

The liver has two venous systems. The portal system conveys venous blood from the majority of the gastrointestinal tract and its associated organs to the liver (see Ch. 60). The hepatic venous system drains blood from the liver parenchyma into the inferior vena cava.

Portal vein

The portal vein begins at the level of the second lumbar vertebra and is formed from the convergence of the superior mesenteric and splenic veins (Fig. 68.12; see also Fig. 71.4 and Fig. 60.8. It is approximately 8 cm long and lies anterior to the inferior vena cava and posterior to the neck of the pancreas. It lies obliquely to the right and ascends behind the first part of the duodenum, the common bile duct and gastroduodenal artery. At this point it is directly anterior to the inferior vena cava. It enters the right border of the lesser omentum, ascends anterior to the epiploic foramen to reach the right end of the porta hepatis and then divides into right and left main branches which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum the portal vein lies posterior to both the common bile duct and hepatic artery. It is surrounded by the hepatic nerve plexus and accompanied by many lymph vessels and some lymph nodes.

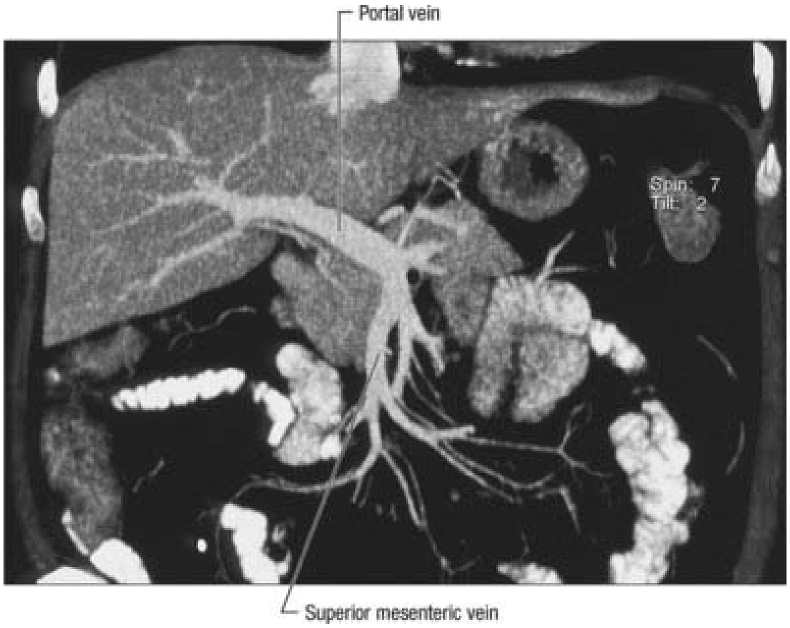

Fig. 68.12 Coronal CT of the portal vein and superior mesenteric vein.

The main extrahepatic tributaries of the portal vein are the coronary or the left gastric vein, which ends in the left margin of the portal vein, and the posterior superior pancreatoduodenal vein nearer to the head of the pancreas. The portal vein divides into right and left branches at the hilum (Fig. 68.13). The left portal vein has a longer extraparenchymal course (4–5 cm) and tends to lie slightly more horizontally than the right portal vein, but is often of smaller calibre. It has horizontal and vertical portions. The horizontal portion runs along the base of segment VI and often gives branches to segment I and sometimes to segment VI in this part of its course. The branch to segment II continues laterally but the main left portal vein takes a more anterior and vertical course in the umbilical fissure (the vein of the umbilical fissure) where it gives branches to segments III and IV and receives the obliterated left umbilical vein (ligamentum teres). The majority of the supply to segment IV comes from the left portal vein, and only occasionally from the right via proximal branches of the main vein or branches from veins to segments V or VIII. The right portal vein is only 2–3 cm in length and usually divides into a right medial (anterior) sectoral division supplying segments V and VIII, and a right lateral (posterior) sectoral division supplying segments VI and VII. The medial division may give a branch to segment I.

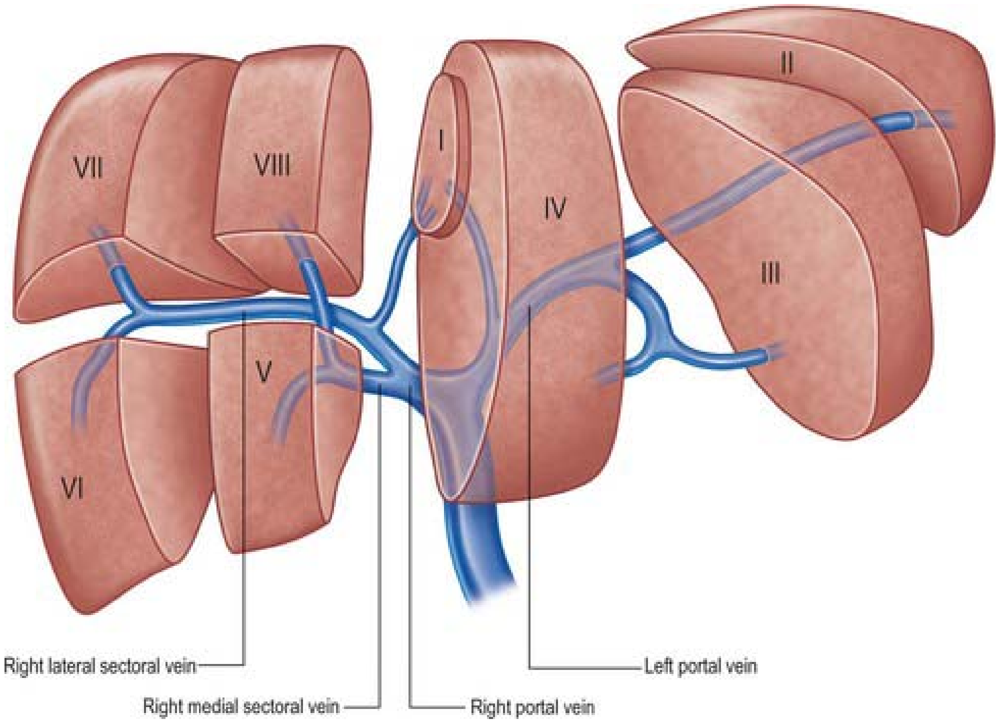

Fig. 68.13 The main portal vein and its intraheptic branches. (Right lateral = right posterior; right medial = right anterior.)

Variations usually involve the right portal vein: absence of a right portal vein with the resulting portal trifurcation in the form of left portal vein, right medial and right lateral portal veins, is present in 10–15% of livers. Occasionally the right medial vein arises from the left portal vein, a variant which is important to remember during left sided liver resection. The portal trifurcation has implications for split liver and live donor liver transplantation, where its presence might be considered as a relative contra-indication. On rare occasions, the portal bifurcation is absent, in which case the main portal vein enters the liver giving off the right segmental branches and then turns left to supply the left lobe of the liver (a contraindication to major liver surgery). Occasionally one or more of the segmental branches of the right lobe (especially segment IV) arises proximally.

Porto-systemic shunts

Increased pressure within the portal venous system may result in dilatation of the portal venous tributaries: a reversal of flow may occur where these veins form anastomoses with veins which drain into the systemic venous circulation. The common sites where porto-systemic shunts may occur, and the associated clinical implications, are listed in Table 68.1.

Table 68.1 Common sites of occurrence of porto-systemic shunts, and associated clinical implications.

Portal veins	**Systemic veins**	**Clinical presentations**
Left gastric and lower oesophageal veins	Lower branches of oesophageal veins that drain into azygos and accessory hemiazygos veins	Oesophageal or gastric varices
Superior rectal veins	Middle and inferior rectal veins that drain into internal iliac and pudendal veins	Rectal varices
Persistent tributaries of left branch of portal vein, running in ligamentum teres	Peri-umbilical branches of superior and inferior epigastric veins	‘Caput medusae’
Intraparenchymal branches of right branch of portal vein, lying in liver tissue exposed in ‘bare area’	Retroperitoneal veins that drain into lumbar, azygos and hemiazygos veins	Retroperitoneal dilated veins are at risk during surgery or interventional procedures
Omental and colonic veins in the region of the hepatic and splenic flexure	Retroperitoneal veins in the region of the hepatic and splenic flexure	
Patent ductus venosus connected to the left branch of the portal vein	Inferior vena cava	Is rare

Hepatic veins

The liver is drained by three major hepatic veins into the suprahepatic part of the inferior vena cava and a multitude of minor hepatic veins that drain into the intrahepatic inferior vena cava. The three major veins are located between the four major sectors of the liver (Figs 68.6A, 68.14 and 68.15).

Fig. 68.15 Arrangement of the hepatic venous territories. Multiple lower group veins may be present. Individual segments may drain into more than one hepatic venous territory.

Right hepatic vein

This is the longest and the largest vein and also the most variable. It is usually single, but occasionally it remains as two trunks until it terminates by draining into the inferior vena cava. The right hepatic vein runs into the intersectoral plane between the right medial and right lateral sectors. It drains the whole of segments VI and VII and parts of segments V and VIII. The extent of its contribution to the drainage of segments V and VIII is variable, and depends upon the size of the veins that drain these segments into the middle hepatic vein. The right hepatic vein is formed near the anterior and inferior edge of the liver and lies in a coronal plane through most of its course. It drains into the inferior vena cava near the upper border of the caudate lobe. Of all the three major veins the right hepatic vein is the one which is the most variable in its size not only due to the differential contribution to segments V and VIII drainage along with the middle hepatic vein but also due to the occasional presence of an accessory right middle and right inferior veins.

Middle hepatic vein

The middle hepatic vein lies along the plane between the right medial and the left medial sectors of the liver. It usually joins with the left hepatic vein and terminates into the inferior vena cava as a common trunk. It drains the central part of the liver receiving constant branches from segments IV, V and VIII. The sizes of the branches draining segments V and VIII are variable and are of surgical importance in terms of right lobe living donation.

Left hepatic vein

The left hepatic vein lies between the left medial and left lateral sectors of the liver. It drains segments II, III and occasionally IV. Small veins draining segment II and occasionally the superior part of segment IV may drain directly into the inferior vena cava in the minority of livers. Usually a major tributary of the left hepatic vein, the umbilical fissure vein runs in the intersegmental plane between segments III and IV and contributes to their drainage. Occasionally the vein draining segment III ends separately in the confluence of the left and middle hepatic veins. These variations in the venous drainage are of significance in terms of split liver transplantation and live donor liver transplantation.

Minor veins

Segment I veins drain directly into the inferior vena cava and vary in number from one to five. Since it has an independent drainage from the rest of the liver in patients with Budd–Chiari syndrome, where all the major hepatic veins are blocked, segment I often continues to drain effectively and undergoes compensatory hypertrophy. Rarely there is an accessory right middle or inferior hepatic vein. When they are present they are of surgical importance especially if they are of more than 5 mm in diameter; they drain segments V and VI independently of the three major veins and therefore any tumour involving the three major veins can be safely resected as long as venous drainage from the accessory veins is ensured. In live donor and split liver transplantation these veins must be individually anastomosed to the recipient inferior vena cava to ensure adequate venous drainage.

Transjugular intraparenchymal porto-systemic shunt (TIPS) procedure for portal hypertension

In extreme cases of chronic portal hypertension, large calibre anastomoses between portal and systemic circulations may be formed within the liver parenchyma using a balloon catheter, introduced via the internal jugular vein and under radiological control, to puncture across and rupture through a thinned strip of liver parenchyma between hepatic veins and dilated portal branches.

Lymphatics

Lymph from the liver has abundant protein content. Lymphatic drainage from the liver is wide and may pass to nodes above and below the diaphragm. Obstruction of the hepatic venous drainage increases the flow of lymph in the thoracic duct. Hepatic collecting vessels are divided into superficial and deep systems.

Superficial hepatic vessels

The superficial vessels run in subserosal areolar tissue over the whole surface of the liver and drain in four directions. Lymph vessels from the majority of the posterior surface, the surface of the caudate lobe, and the posterior part of the inferior surface of the right lobe, accompany the inferior vena cava and drain into pericaval nodes. Vessels in the coronary and right triangular ligaments may directly enter the thoracic duct without any intervening node. Vessels from the majority of the inferior surface, anterior surface and most of the superior surface all converge on the porta hepatis to drain into the hepatic nodes. A few lymph vessels from the posterior surface of the lateral end of the left lobe pass towards the oesophageal opening to drain into the para-cardiac nodes. One or two lymph trunks from the right surface and right end of the superior surface accompany the inferior phrenic artery across the right crus to drain into the coeliac nodes.

Deep hepatic vessels

The great majority of the liver parenchyma is drained by lymphatic vessels within the substance of the liver. Fine lymphatic vessels merge to form larger vessels. Some run superiorly through the parenchyma to form the ascending trunks which accompany the hepatic veins and pass through the caval opening in the diaphragm to drain into nodes around the end of the inferior vena cava. Vessels from the lower portion of the liver form descending trunks which emerge from the porta hepatis and drain into the hepatic nodes.

INNERVATION

The liver has a dual innervation. The parenchyma is supplied by hepatic nerves which arise from the hepatic plexus and contain sympathetic and parasympathetic (vagal) fibres. They enter the liver at the porta hepatis and most accompany the hepatic arteries and bile ducts. A very few may run directly within the liver parenchyma. The capsule is supplied by some fine branches of the lower intercostal nerves, which also supply the parietal peritoneum, particularly in the area of the ‘bare area’ and superior surface: distension or disruption of the liver capsule causes quite well localized sharp pain.

Hepatic plexus

The hepatic plexus is the largest derivative of the coeliac plexus and receives branches from the anterior and posterior vagi. It accompanies the hepatic artery and portal vein and their branches into the liver, where its fibres run close to the branches of the vessels, supplying vasomotor fibres to the hepatic vessels and biliary tree, and innervating the hepatocytes directly. Multiple fine branches from the plexus supply the common and hepatic bile ducts directly; branches to the gallbladder form a delicate cystic plexus. The vagal fibres are motor to the musculature of the gallbladder and bile ducts and inhibitory to the sphincter of the bile duct.

Nerves from the hepatic plexus run with the branches of the common hepatic artery to supply, or contribute to the supply of, foregut derivatives. Branches run inferiorly from the plexus with the right gastric artery to contribute to the supply of the pylorus, with the gastroduodenal artery and its branches to reach the pylorus and the first part of the duodenum, and with the right gastroepiploic artery to provide a small contribution to the supply the right side of the stomach and the greater curvature. The superior pancreaticoduodenal extension supplies the descending part of the duodenum, the pancreatic head and the intrapancreatic part of the common bile duct.

Referred pain

Pain arising from the parenchyma of the liver is poorly localized. In common with other structures of foregut origin, pain is referred to the central epigastrium. Stretch of or involvement of the liver capsule by inflammatory or neoplastic processes rapidly produces well-localized pain of a ‘somatic’ nature.

MICROSTRUCTURE

The liver is essentially an epithelial-mesenchymal outgrowth of the caudal part of the foregut, with which it retains its connection via the biliary tree. The surface of the liver facing the peritoneal cavity is covered by a typical serosa, the visceral peritoneum. Beneath this, and enclosing the whole structure, is a thin (50–100 µm) layer of connective tissue from which extensions pass into the liver as connective tissue septa and trabeculae. Branches of the hepatic artery and hepatic portal vein, together with bile ductules and ducts, run within these connective tissue trabeculae which are termed portal tracts (portal canals). The combination of the two types of vessel and a bile duct is termed a portal triad (Fig. 68.16); these structures are usually accompanied by one or more lymphatic vessels.

Fig. 68.16 The structural organization of human liver tissue. **A**, Lobules bordered by delicate connective tissue septa (arrows) in which run branches of the hepatic portal vein, hepatic artery and bile duct, grouped as portal triads. A central vein drains each lobule. **B**, A portal triad containing branches of the hepatic portal vein (PV; generally the largest profile), the hepatic artery (A) and a bile duct (B), with typical round epithelial nuclei. Other small bile ductule and arteriolar branches are also visible. **C**, A functional view in which the territories of the hepatic lobules are shown as regular hexagons (unlike their real appearance, which is highly variable). The different functions, such as blood flow from the territory of the acinus to sectors of adjacent hepatic lobules, are shown in different lobules, though in reality all occur in each lobule.

(By permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.) (By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

The liver parenchyma consists of a complex network of epithelial cells, supported by connective tissue, and perfused by a rich blood supply from the hepatic portal vein and hepatic artery. The epithelial cells, hepatocytes, carry out the major metabolic activities of this organ, but additional cell types possess storage, phagocytic and mechanically supportive functions. In the mature liver, hepatocytes are arranged mainly in plates (or cords, as seen in two-dimensional sections) that are usually only one cell thick and separated by venous sinusoids which anastomose with each other via gaps in the plates. Until about seven years of age, plates are normally two cells thick.

Bile secreted by the hepatocytes is collected in a network of minute tubes (canaliculi). The hepatocytes can therefore be regarded as exocrine cells, secreting bile into the alimentary tract via the hepatic ducts and bile duct. Their other metabolic functions involve complex biochemical exchanges with the blood.

The fetal liver is a major haemopoietic organ: erythrocytes, leukocytes and platelets develop from the mesenchyme covering the sinusoidal endothelium.

Lobulation of the liver

The structural unit of the liver is the lobule: a roughly hexagonal arrangement of plates of hepatocytes, separated by intervening sinusoids which radiate outward from a central vein, with portal triads at the vertices of each hexagon (Fig. 68.16). The central vein is a tributary of the hepatic vein that drains the tissue. In some species, the classic lobular units are delimited microscopically by distinct connective tissue septa. However, the lobular organization of the human liver is not immediately evident in histological sections: the lobules do not have distinct boundaries, and connective tissue is sparse. The plates do not pass straight to the periphery of a lobule like the spokes of a wheel but run irregularly as they anastomose and branch.

Detailed studies of human liver, using three-dimensional reconstruction and morphometric analysis combined with histopathological observations, have revealed a highly ordered arrangement of functional units, the hepatic (portal) acini. Each acinus is an approximately oval mass of tissue, oriented around the afferent vascular system, i.e. a terminal branch of a hepatic arteriole and portal venule, and with its long axis defined by the territory between two adjacent central veins. It includes the hepatic tissue served by these afferent vessels, and is bounded by the territories of other acini.

The acinar definition of hepatic micro-organization has clarified important problems of liver histopathology, especially the development of zones of anoxic damage, glycogen deposition and removal, and of toxic trauma, which are all related to the direction of blood flow and thus tend to follow the acinar pattern. There are also real metabolic differences between hepatocytes within the acini, and they have been divided into three zones: zone 1 (periportal) is nearest to the terminal branches of afferent vessels; zone 2 is the intermediate zone; and zone 3 is the area closest to the central venous drainage.

Blood supply

Preterminal hepatic arterioles in the portal canals branch to convey arterial blood to the sinusoids by several routes. The main pattern is via a fine capillary plexus which drains to branches of the portal veins. Some arterial blood passes directly to the hepatic sinusoids, bypassing these capillary plexuses, but this represents only a small part of the total flow. Sinusoids thus contain mixed venous and arterial blood. Central veins from adjacent lobules form interlobular veins which unite as hepatic veins and drain to the inferior vena cava. Hepatic veins draining the tissue run quite separately with respect to the portal triad system, freely crossing the boundaries of triad territories.

Hepatic plates (cords)

The endothelial linings of the sinusoids are separated from hepatocytes forming the hepatic plates by a narrow gap, the perisinusoidal space of Disse, which is normally about 0.2–0.5 μm wide, but which distends in anoxic conditions. The space contains fine collagen fibres (mostly type III, with some types I and IV), the microvilli of adjacent hepatocytes, and occasional non-myelinated nerve terminals. There is no basal lamina within the space of Disse.

Minute bile canaliculi form nets with polygonal meshes in the hepatic plates. Each polygonal hepatocyte is surrounded by canaliculi (see below) except on the surfaces, at least two per cell, that face sinusoids. Hepatic plates thus enclose a network of canaliculi that pass to the lobular periphery, where they join to form narrow intralobular ductules (terminal ductules or the canals of Hering) lined by squamous or cuboidal epithelium. The intralobular ductules enter bile ductules, lined by cuboidal or columnar cells, in the portal canals. The flow of bile is thus towards the periphery of lobules, in the opposite direction to the blood flow, which is centripetal.

Cells of the liver

Cells of the liver include hepatocytes, hepatic stellate cells (also known as perisinusoidal lipocytes, or Ito cells), sinusoidal endothelial cells, macrophages (Kupffer cells), the cells of the biliary tree (cuboidal to columnar epithelium) and connective tissue cells of the capsule and portal tracts (Figs 68.16B and 68.17).

Hepatocytes

About 80% of the liver volume and 60% of its cell number are formed by hepatocytes (parenchymal cells) (Fig. 68.17). They are polyhedral, with 5–12 sides and are from 20 to 30 μm across. Their nuclei are round, euchromatic and often tetraploid, polyploid or multiple, with two or more in each cell. Their cytoplasm typically contains a considerable amount of rough and smooth endoplasmic reticulum, many mitochondria, lysosomes and well-developed Golgi apparatus, which are all features that indicate a high metabolic activity. Glycogen granules and lipid vacuoles are usually prominent. Numerous large peroxisomes and vacuoles containing enzymes, e.g. urease in distinctive crystalline forms, indicate the complex metabolism of these cells. Their role in iron metabolism is reflected by the presence of storage vacuoles containing crystals of ferritin and haemosiderin.

The surfaces of hepatocytes facing the sinusoids exhibit numerous microvilli, approximately 0.5 μm long, creating a large area of membrane, 70% of the hepatocyte surface, exposed to blood plasma. Elsewhere, hepatocytes are linked by numerous gap junctions and desmosomes. Lateral plasma membranes of adjacent hepatocytes form microscopic channels, the bile canaliculi, which are specialized regions of intercellular space formed by apposing grooves in hepatocyte plasma membranes, sealed from extraneous interstitial space by tight junctions. Numerous membrane-bound exocytotic vesicles cluster near the lumen of the canaliculi because the secretion of bile components is targeted to the canalicular plasma membrane. These canaliculi form the origins of the biliary tree and their tight junctions prevent bile from entering interstitial fluid or blood plasma: this is the blood–bile barrier.

Hepatic stellate cells

Hepatic stellate cells are much less numerous than hepatocytes. They are irregular in outline and lie within the hepatic plates, between the bases of hepatocytes. They are thought to be mesenchymal in origin and are characterized by numerous cytoplasmic lipid droplets. These cells secrete most of the intralobular matrix components, including collagen type III (reticular) fibres. They store the fat-soluble vitamin A in their lipid droplets and are a significant source of growth factors active in liver homeostasis and regeneration. Hepatic stellate cells also play a major role in pathological processes. In response to liver damage, they become activated and predominantly myofibroblast-like. They are responsible for the replacement of toxically damaged hepatocytes with collagenous scar tissue, a process called hepatic fibrosis, that is seen initially in zone 3, around central veins. Fibrosis can progress to cirrhosis, where the parenchymal architecture and pattern of blood flow are destroyed, with major systemic consequences.

Sinusoidal endothelial cells

Hepatic venous sinusoids are generally wider than blood capillaries and are lined by a thin but highly fenestrated endothelium that lacks a basal lamina. The endothelial cells are typically flattened, each with a central nucleus and joined to each other by junctional complexes. The fenestrae are grouped in clusters with a mean diameter of 100 nm, allowing plasma direct access to the basal plasma membranes of hepatocytes. Their cytoplasm contains numerous typical transcytotic vesicles.

Kupffer cells

Kupffer cells are hepatic macrophages derived from circulating blood monocytes and originate in the bone marrow. They are long-term hepatic residents and lie within the sinusoidal lumen attached to the endothelial surface. Kupffer cells are irregular in shape, and have long processes that extend into the sinusoidal lumen. They form a major part of the mononuclear phagocyte system which is responsible for removing cellular and microbial debris from the circulation, and for secreting cytokines involved in defence. They remove aged and damaged red cells from the hepatic circulation, a function normally shared with the spleen, but fulfilled entirely by the liver after splenectomy.

CHAPTER 69

Gallbladder and biliary tree

The biliary tree consists of the system of vessels and ducts which collect and deliver bile from the liver parenchyma to the second part of the duodenum. It is conventionally divided into intrahepatic and extrahepatic biliary trees. The intrahepatic ducts are formed from the larger bile canaliculi which come together to form segmental ducts. These fuse close to the porta hepatis into right and left hepatic ducts. The extrahepatic biliary tree consists of the right and left hepatic ducts, the common hepatic duct, the cystic duct and gallbladder and the common bile duct (Fig. 69.1).

Fig. 69.1 Overall arrangement of the intrahepatic and extrahepatic biliary tree. The segmental ducts often branch just before, or are multiple, as they enter the main ducts, but for clarity are shown here as single ducts. Note that segment I usually has drainage from both right and left hepatic ducts. The level of the liver parenchyma at the porta hepatis is shown by the dashed brown line.

GALLBLADDER

The gallbladder is a flask-shaped, blind-ending diverticulum attached to the common bile duct by the cystic duct. In life, it is grey-blue in colour and usually lies attached to the inferior surface of the right lobe of the liver by connective tissue (Fig. 69.2). In the adult the gallbladder is between 7 and 10 cm long with a capacity of up to 50 ml. It usually lies in a shallow fossa in the liver parenchyma covered by peritoneum continued from the liver surface. This attachment can vary widely. At one extreme the gallbladder may be almost completely buried within the liver surface, having no peritoneal covering (intraparenchymal pattern); at the other extreme it may hang from a short mesentery formed by the two layers of peritoneum separated only by connective tissue and a few small vessels (mesenteric pattern). The gallbladder is described as having a fundus, body and neck. The neck lies at the medial end close to the porta hepatis, and almost always has a short peritoneal-covered attachment to the liver (mesentery); this mesentery usually contains the cystic artery. The mucosa at the medial end of the neck is obliquely ridged, forming a spiral groove continuous with the spiral valve of the cystic duct. At its lateral end the neck widens out to form the body of the gallbladder and this widening is often referred to in clinical practice as ‘Hartmann’s pouch’. The neck lies anterior to the second part of the duodenum.

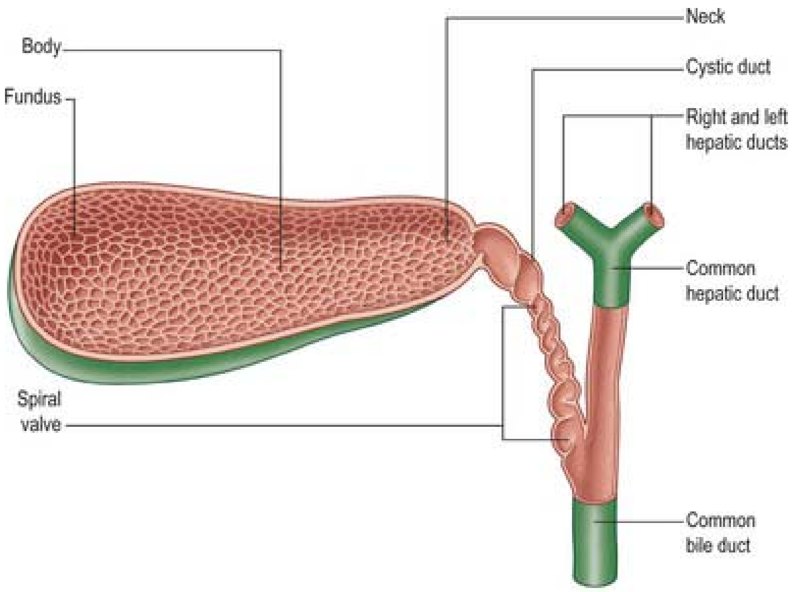

Fig. 69.2 Interior of the gallbladder and bile ducts.

The body of the gallbladder normally lies in contact with the liver surface. When the neck possesses a mesentery, this rapidly shortens along the length of the body as it comes to lie in the gallbladder fossa. It lies anterior to the second part of the duodenum and the right end of the transverse colon. The fundus lies at the lateral end of the body and usually projects past the inferior border of the liver to a variable length. It often lies in contact with the anterior abdominal wall behind the ninth costal cartilage where the lateral edge of the right rectus abdominis crosses the costal margin. This is the location where enlargement of the gallbladder is best sought on clinical examination. The fundus commonly lies adjacent to the transverse colon.

The gallbladder varies in size and shape. The fundus may be elongated and highly mobile. Rarely, the fundus is folded back upon the body of the gallbladder, the so-called Phrygian cap: on ultrasound, this may be wrongly interpreted as an apparent septum within an otherwise normal gallbladder. Again, rarely, the gallbladder may be bifid or completely duplicated, usually with a duplicated cystic duct.

INTRAHEPATIC BILIARY TREE

SEGMENTAL AND SECTORAL DUCTS

The segmental ducts of the left liver have a relatively constant pattern, although several segmental ducts may drain each particular segment. The left hepatic duct is formed by the union of segment II and III ducts behind the umbilical portion of the left portal vein (Fig. 69.1). The segment IV duct is more variable, but usually drains into the left hepatic duct. The right hepatic duct is formed by the union of the right medial (anterior) and lateral (posterior) sectoral ducts. These sectoral ducts in turn are formed by the segmental ducts: VII and VI from the lateral, and VIII and V from the medial duct. The right lateral sectoral duct is often identified on a cholangiogram as curving around the right medial duct before joining the medial side of the medial sectoral duct: this is often described as Hjortsjo’s crook, and has surgical importance for liver resections. The right hepatic duct and its branches are subject to more variations than the left ductal system, and these variations have been classified by Blumgart into six main types (Table 69.1).

Table 69.1 Variations of the right hepatic duct and its branches

Type	Percentage of population	Description
A	55	Anatomy is normal.
B	15	There is no right hepatic duct and the common hepatic duct is formed by the right anterior, right posterior and left hepatic ducts as a trifurcation.
C	20	There is a low drainage of one the right sectoral ducts into the common hepatic duct.
D	5	One of the right sectoral ducts joins the left hepatic duct.
E	5	The common hepatic duct is formed by the union of two or more ducts from either lobe.
F	5	The right posterior sectoral duct drains into the cystic duct.

EXTRAHEPATIC BILIARY TREE

CYSTIC DUCT

The cystic duct drains the gallbladder into the common bile duct. It is between 3 and 4 cm long, passes posteriorly to the left from the neck of the gallbladder, and joins the common hepatic duct to form the common bile duct. It almost always runs parallel to, and is adherent to, the common hepatic duct for a short distance before joining it. The junction usually occurs near the porta hepatis but may be lower down in the free edge of the lesser omentum. The cystic duct may have several important variations in its anatomy (Fig. 69.3). Rarely, the cystic duct lies along the right edge of the lesser omentum all the way down to the level of the duodenum before the junction is formed, but in these cases the cystic and common bile ducts are usually closely adherent. The cystic duct occasionally drains into the right hepatic duct, in which case it may be elongated, lie anterior or posterior to the common hepatic duct, and join the right hepatic duct on its left border. Rarely, the duct is double or even absent, in which case the gallbladder drains directly into the common bile duct. One or more accessory hepatic ducts occasionally emerge from segment V of the liver and join either the right hepatic duct, the common hepatic duct, the common bile duct, the cystic duct, or the gallbladder directly. These variations in cystic duct anatomy are of considerable importance during surgical excision of the gallbladder. Ligation or clip occlusion of the cystic duct must be performed at an adequate distance from the common bile duct to prevent angulation or damage to it. Accessory ducts must not be confused with the right hepatic or common hepatic ducts.

Fig. 69.3 Variations in the anatomy of the cystic and intrahepatic bile ducts. The cystic duct variations are labelled A1–A3 and the letters B–F are used for the variants of the intrahepatic ducts to ensure consistency with the Blumgart nomenclature.

The mucosa of the cystic duct bears 5–12 crescentic folds, continuous with those in the neck of the gallbladder. They project obliquely in regular succession, appearing to form a spiral valve when the duct is cut in longitudinal section. When the duct is distended, the spaces between the folds dilate and externally it appears twisted like the neck of the gallbladder.

HEPATIC BILE DUCTS

The main right and left hepatic ducts emerge from the liver and unite near the right end of the porta hepatis as the common hepatic duct. The extrahepatic right duct is short and nearly vertical while the left is more horizontal and lies along the base of segment IV. The common hepatic duct descends approximately 3 cm before being joined on its right at an acute angle by the cystic duct to form the common bile duct. The common hepatic duct lies to the right of the hepatic artery and anterior to the portal vein in the free edge of the lesser omentum.

COMMON BILE DUCT

The common bile duct is formed near the porta hepatis, by the junction of the cystic and common hepatic ducts (Figs 69.4 and 69.5), and is usually between 6 and 8 cm long. Its diameter tends to increase somewhat with age but is usually around 6 mm in adults. It descends posteriorly and slightly to the left, anterior to the epiploic foramen, in the right border of the lesser omentum, where it lies anterior and to the right of the portal vein and to the right of the hepatic artery. It passes behind the first part of the duodenum with the gastroduodenal artery on its left, and then runs in a groove on the superolateral part of the posterior surface of the head of the pancreas. The duct lies anterior to the inferior vena cava and is sometimes embedded in the pancreatic tissue. It may lie close to the medial wall of the second part of the duodenum or as much as 2 cm from it: even when it is embedded in the pancreas, a groove in the gland marking its position can be palpated behind the second part of the duodenum.

Hepatopancreatic ampulla (of Vater)

As it lies medial to the second part of the duodenum, the common bile duct approaches the right end of the pancreatic duct. The ducts enter the duodenal wall together, and usually unite to form the hepatopancreatic ampulla. Rarely the common bile duct and pancreatic duct drain into the duodenum separately. Circular muscle usually surrounds the lower part of the common bile duct (bile duct sphincter) and frequently also surrounds the terminal part of the main pancreatic duct (pancreatic duct sphincter) and the hepatopancreatic ampulla (sphincter of Oddi). When all elements are present, this arrangement may allow for separate control of pancreatic and common bile duct emptying. Division of the upper part of the ampulla and ampullary sphincter (sphincterotomy) may be required to allow access to the common bile duct during endoscopic retrograde cholangiography.

Calot’s triangle

The near triangular space formed between the cystic duct, the common hepatic duct and the inferior surface of segment V of the liver (Suzuki et al 2000), is commonly referred to as Calot’s triangle. It is enclosed by the double layer of peritoneum which forms the short mesentery of the cystic duct. Since the two layers are not closely opposed, there is an appreciable amount of loose connective tissue within the triangle. It is perhaps better described as a pyramidal ‘space’ with one apex lying at the junction of the cystic duct and fundus of the gallbladder, one at the porta hepatis, and two closer apices at the attachments of the gallbladder to the liver bed. The base of the triangle thus lies on the inferior surface of the liver. This space usually contains the cystic artery as it approaches the gallbladder, the cystic lymph node and lymphatics from the gallbladder, one or two small cystic veins, the autonomic nerves running to the gallbladder, and some loose adipose tissue. It may contain any accessory ducts which drain into the gallbladder from the liver. Appreciation of the variations in ductal and arterial anatomy as they relate to the triangle are of considerable importance during excision of the gallbladder in order to avoid mistakenly ligating the common hepatic or common bile duct.

BILIARY STONES

Gallstones usually form in the gallbladder. As the gallbladder empties, gallstones move towards the cystic duct. When small stones enter the cystic duct they may irritate the columnar mucosa, this leads to spasm of the smooth muscle in the cystic duct wall, and the spasm generates pain known as biliary colic, which is often very severe. The mucosal folds in the neck of the gallbladder and the cystic duct provide a common site of entrapment of gallstones. Stones occluding the neck of the gallbladder may cause a sterile distension of the gallbladder: providing the gallbladder has not undergone acute inflammation previously it remains non-fibrotic and readily distensible, and an enlarged fundus often becomes palpable below the costal margin. Stones lodged in the distal cystic duct may cause swelling in the tissues around the duct. The close relationship of the distal cystic duct to the common hepatic duct means that this swelling may cause secondary compression of the common hepatic duct, resulting in partial obstruction to the flow of bile and the appearance of mild jaundice, the so called ‘Mirizzi syndrome’. Once stones have passed through the cystic duct they often become impacted at the junction of the common bile duct and pancreatic duct just proximal to the hepatopancreatic ampulla, producing obstructive jaundice and/or acute pancreatitis.

ENDOSCOPIC CHOLANGIOGRAPHY

The common bile duct may be accessed endoscopically from the duodenum for diagnostic cholangiography and therapeutic interventions. The angled relationship of the distal common bile duct and pancreatic duct may make direct cannulation of the bile duct difficult. When the duct lies in a more vertical position, embedded within the wall of the duodenum, a direct incision in the base of the hepatopancreatic ampulla and the adjacent wall of the duodenum (pre-cut sphincterotomy) may expose the duct to allow cannulation. This is occasionally associated with haemorrhage from the duodenal wall vessels. Division of the smooth muscle fibres of the common bile duct sphincter may be necessary for endoscopic access to the bile duct, but it often results in uncontrolled reflux of duodenal contents into the distal common bile duct, and this may result in recurrent biliary infections.

BILIARY DRAINAGE

The proximity of the fundus of the gallbladder to the anterior abdominal wall provides a useful route of access for percutaneous drainage of a distended, obstructed gallbladder. It is rarely obscured by liver tissue, can often be accessed below the costal margin, and is most often performed under ultrasound guidance. Because of the small calibre and spiral conformation of the cystic duct, drainage of the gallbladder is rarely adequate to decompress the biliary tree if it is blocked, and this must be achieved endoscopically, surgically or by a percutaneous, transhepatic approach. This latter technique requires the identification of dilated intrahepatic bile ducts, usually by ultrasound imaging with direct guided puncture via a right subcostal approach. Percutaneous access is obtained via segment III in the left lobe of the liver and via segments V and VI in the right lobe of the liver.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Cystic artery

The cystic artery usually arises from the right hepatic artery (Fig. 69.6). It usually passes posterior to the common hepatic duct and anterior to the cystic duct to reach the superior aspect of the neck of the gallbladder and divides into superficial and deep branches. The superficial branch ramifies on the inferior aspect of the body of the gallbladder, the deep branch on the superior aspect. These arteries anastomose over the surface of the body and fundus. The origin of the cystic artery frequently varies (Fig. 69.7). The most common variant is an origin from the common hepatic artery (occasionally low down), sometimes from the left hepatic or gastroduodenal artery, and rarely from the superior pancreaticoduodenal, coeliac, right gastric or superior mesenteric arteries. In these cases, it crosses anterior (or less commonly posterior) to the common bile duct or common hepatic duct to reach the gallbladder. An accessory cystic artery may arise from the common hepatic artery or one of its branches and the cystic artery often bifurcates close to its origin, giving rise to two vessels which approach the gallbladder. Multiple fine arterial branches may arise from the parenchyma of segments IV or V of the liver and contribute to the supply of the body, particularly when the gallbladder is substantially intrahepatic. This makes the gallbladder relatively resistant to necrosis during inflammation which otherwise occludes the cystic artery.

C Gastroduodenal artery
D Superior pancreaticoduodenal, coeliac or right gastric arteries
E Left hepatic artery
F Accessory deep artery
G Multiple non-dominant arteries

Fig. 69.7 Variant anatomy of the cystic artery origin and distribution.

The cystic artery gives rise to multiple fine branches which supply the common and lobar hepatic ducts and upper part of the common bile duct. These fine branches form a network which anastomoses with the vessels ascending around the common bile duct and with the vessels from the liver parenchyma which descend with the right and left hepatic ducts.

Ductal arteries

The common bile duct and hepatic ducts are supplied by a fine network of vessels which usually receives contributions from several sources, and which lies in close proximity to the ducts. Disruption of the network during surgical exposure of the bile ducts over a long length frequently causes chronic ischaemia and resultant stenosis of the duct. Approaches which spare the network are necessary to avoid this complication.

The common bile duct is fairly consistently supplied by two to four ascending and descending arteries which form long narrow anastomotic channels along the length of the duct: the most prominent of these are disposed into medial and lateral ‘trunks’, although they may lie more anterolateral and posteromedial. The largest contributions usually arise as one or two branches from the retroduodenal branch of the gastroduodenal artery as it crosses the anterior surface of the duct at the upper border of the duodenum. Three or four descending branches supply this network from the right hepatic and cystic arteries as these vessels pass close to the lower common hepatic duct: occasionally they are the dominant supply to the common bile duct.

Posteriorly, a retroportal artery often arises from the coeliac axis, superior mesenteric artery or one of their major branches close to the origin from the aorta, and runs upwards on the posterior surface of the portal vein. It usually ends by joining the retroduodenal artery close to the lower end of the supraduodenal bile duct, but occasionally it passes up behind the bile duct to join the right hepatic artery. When present, the retroportal artery contributes to the arterial network supplying the supraduodenal bile duct system.

The hilar and intrahepatic ducts are supplied by a fine network of periductal arteries that arise from the segmental arteries within the Glissonian sheaths.

Cystic veins

The venous drainage of the gallbladder is rarely by a single cystic vein. There are usually multiple small veins. Those arising from the superior surface of the body and neck lie in areolar tissue between the gallbladder and liver and enter the liver parenchyma to drain into the segmental portal veins. The remainder form one or two small cystic veins, which enter the liver either directly or after joining the veins that drain the hepatic ducts and upper bile duct. Only rarely does a single or double cystic vein drain into the right portal branch.

Lymphatics

Numerous lymphatic vessels run from the submucosal and subserosal plexuses on all aspects of the gallbladder and cystic duct. Those on the hepatic aspect of the gallbladder connect with the intrahepatic lymph vessels. The remainder drain into the cystic node, which usually lies above the cystic duct in the tissue of Calot’s triangle. This node, and some lymphatic channels which bypass the cystic node, drain into a node lying in the anterior border of the free edge of the lesser omentum. Hepatic nodes lying in the porta hepatis collect lymph from vessels that accompany the hepatic ducts and the upper part of the bile duct. Lymphatics from the lower part of the common bile duct drain into the inferior hepatic and upper pancreaticosplenic nodes.

INNERVATION

The gallbladder and the extrahepatic biliary tree are innervated by branches from the hepatic plexus. The retroduodenal part of the common bile duct and the smooth muscle of the hepatopancreatic ampulla are also innervated by twigs from the pyloric branches of the vagi.

Referred pain

In common with other structures of foregut origin, pain caused by stretch of the common bile duct or gallbladder is referred to the central epigastrium. Involvement of the overlying somatic peritoneum produces pain which is more localized to the right upper quadrant.

MICROSTRUCTURE

GALLBLADDER

The fundus of the gallbladder is completely covered by a serosa, and the inferior surfaces and sides of the body and neck of the gallbladder are usually covered by a serosa. If the gallbladder possesses a mesentery the serosa extends around the sides of the body and neck onto the superior surface and continues into the serosa of the mesentery, whereas the serosa is limited to the inferior surfaces only if the gallbladder is intrahepatic. Beneath the serosa is subserous loose connective and adipose peritoneal tissue. The gallbladder wall microstructure generally resembles that of the small intestine. The mucosa is yellowish-brown and elevated into minute rugae with a honeycomb appearance (Fig. 69.2). In section, projections of the mucosa into the gallbladder lumen resemble intestinal villi, but they are not fixed structures and the surface flattens as the gallbladder fills with bile. The epithelium is a single layer of columnar cells with apical microvilli; basally, the spaces between epithelial cells are dilated (Fig. 69.8). Many capillaries lie beneath the basement membrane. The epithelial cells actively absorb water and solutes from the bile and concentrate it up to ten-fold. There are no goblet cells in the epithelium. The thin fibromuscular layer is composed of fibrous tissue mixed with smooth muscle cells arranged loosely in longitudinal, circular and oblique bundles.

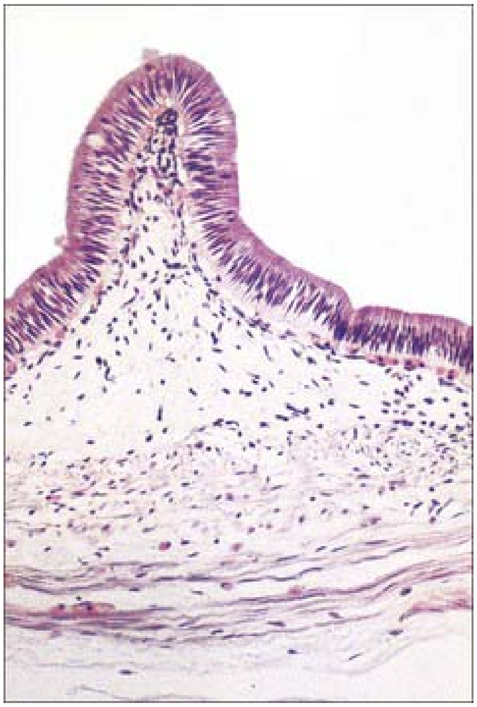

Fig. 69.8 Low power micrograph showing the gallbladder wall, with a mucosal projection which flattens in the full gallbladder, and the thin muscular layer.

BILE DUCTS

The walls of the large biliary ducts consist of external fibrous and internal mucosal layers (Fig. 69.9). The outer layer is fibrous connective tissue containing a variable amount of longitudinal, oblique and circular smooth muscle cells. The mucosa is continuous with that in the hepatic ducts, gallbladder and duodenum. The epithelium is columnar and there are numerous tubuloalveolar mucous glands in the duct walls.

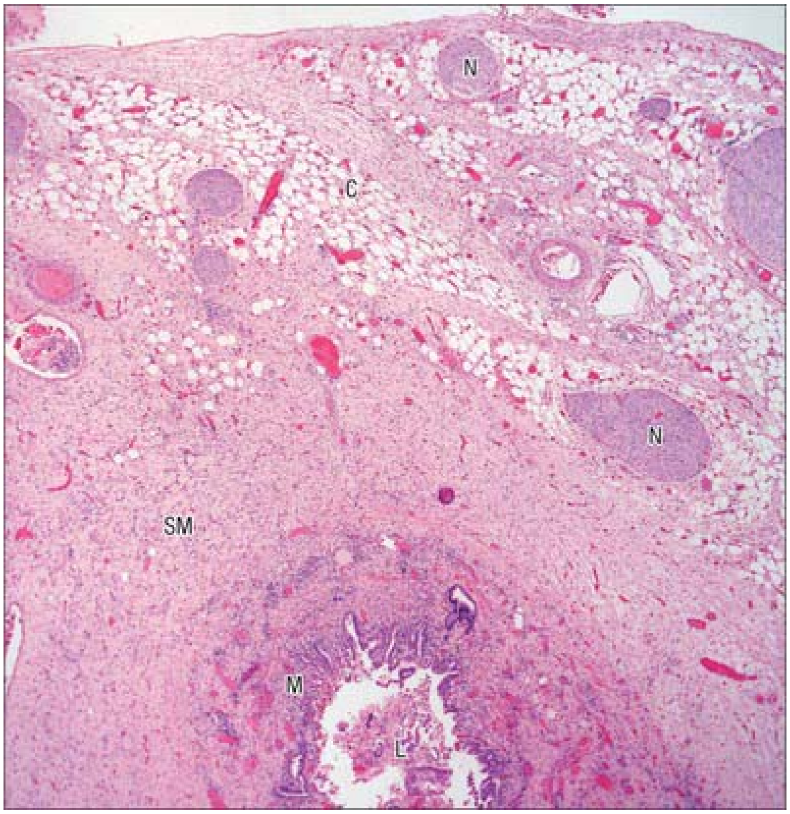

Fig. 69.9 Low power micrograph showing the human common bile duct structure. Shown are the lumen (L), mucosal lining (m), smooth muscle coat (SM) and outer connective tissue (C), with numerous nerve fibre bundles (N).

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Expulsion of gallbladder contents is under neuroendocrine control. Fat in the duodenum causes the release of cholecystokinin (CCK), which stimulates the gallbladder to contract because muscle cells in its walls bear surface receptors for CCK. When the pressure exceeds 100 mm H_2O of bile, the sphincter of Oddi relaxes and bile enters the duodenum. The termination of the united bile and pancreatic ducts is packed with villous, valvular folds of mucosa that contain muscle cells in their connective tissue cores. Contraction is thought to result in retraction and clumping of these folds, so preventing reflux of duodenal contents and controlling the exit of bile.

CHAPTER 70

Pancreas

The pancreas is the largest of the digestive glands and performs a range of both endocrine and exocrine functions. The major part of the gland is exocrine, secreting a range of enzymes involved in the digestion of lipids, carbohydrates and proteins. The endocrine function of the pancreas is derived from cells scattered throughout the substance of the gland: they take part in glucose homeostasis and are also involved in the control of upper gastrointestinal motility and function.

The pancreas is salmon pink in colour with a firm, lobulated smooth surface. The main portion is divided into four parts, head, neck, body and tail, purely on the basis of anatomical relations: there are only very minor functional or anatomical differences between each part (Figs 70.1 and 70.2). The pancreas also possesses one accessory lobe (the uncinate process), which is anatomically and embryologically distinct. In adults the pancreas measures between 12 and 15 cm long and is shaped as a flattened ‘tongue’ of tissue, thicker at its medial end (head) and thinner towards the lateral end (tail). With age, the amount of exocrine tissue tends to decline, as does the amount of fatty connective tissue within the substance of the gland, and this leads to a progressive thinning atrophy which is particularly noticeable on CT scanning. The pancreas lies within the curve of the first, second and third parts of the duodenum, and extends transversely and slightly upwards across the posterior abdominal wall to the hilum of the spleen, behind the stomach. It does not lie in one plane but is effectively ‘draped’ over the other structures in the retroperitoneum and the vertebral column and so forms a distinct shallow curve, of which the neck and medial body are the most anterior parts. Because of its flattened shape, the parts of the pancreas, particularly the body, are often referred to as having surfaces and borders.

HEAD

The head of the pancreas lies to the right of the midline, anterior and to the right side of the vertebral column, within the curve of the duodenum. It is the thickest and broadest part of the pancreas but is still flattened in the anteroposterior plane. Superiorly it lies adjacent to the first part of the duodenum, but close to the pylorus the duodenum is on a short mesentery, and here the duodenum lies anterior to the upper part of the head. The duodenal border of the head is flattened and slightly concave, and is firmly adherent to the second part of the duodenum; occasionally a small part of the head is actually embedded in the wall of the second part of the duodenum. The superior and inferior pancreaticoduodenal arteries lie between the head and the duodenum in this area. The inferior border lies superior to the third part of the duodenum and is continuous with the uncinate process. Close to the midline, the head is continuous with the neck. The boundary between head and neck is often marked anteriorly by a groove for the gastroduodenal artery and posteriorly by a similar but deeper deep groove that contains the union of the superior mesenteric and splenic veins as they form the portal vein.

Anterior surface

The anterior surface of the head (Fig. 70.3) is covered in peritoneum and is related to the origin of the transverse mesocolon.

Areas covered in peritoneum are shown in blue and structures overlying these areas are separated from the pancreas by peritoneal ‘spaces’. The spleen in relation to the tail lies anterior to the anterior leaf of the splenorenal ligament and not in direct contact with the pancreatic tissue. D1, first part of the duodenum; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

Posterior surface

The posterior surface of the head is related to the inferior vena cava, which ascends behind it and covers almost all of this aspect. It is also related to the right renal vein, the right crus of the diaphragm and usually the origin of the right gonadal vein (see Ch. 76, Fig. 76.7).

NECK

The neck of the pancreas is approximately 2 cm wide and links the head and body. It is often the most anterior portion of the gland and is defined as the portion of the pancreas that lies anterior to the portal vein, which is closely related to the upper posterior surface (see Fig. 70.8). The lower part of the neck lies anterior to the superior mesenteric vein just before the formation of the portal vein. These are important relations during surgery for pancreatic cancer because malignant involvement of these vessels may make resection impossible. The anterior surface of the neck is covered with peritoneum and lies adjacent to the pylorus just inferior to the epiploic foramen. The gastroduodenal and anterior superior pancreaticoduodenal arteries descend in front of the gland in the region of the junction of the neck and head.

BODY

The body of the pancreas is the longest portion of the gland and runs from the left side of the neck to the tail. It is slightly triangular in cross-section, becoming progressively thinner and less broad towards the tail. The body is described as having three surfaces, anterosuperior, posterior and anteroinferior.

Anterosuperior surface

The anterosuperior surface of the pancreas makes up most of the anterior aspect of the gland close to the neck. Laterally, it narrows and lies slightly more superiorly to share the anterior aspect with the anteroinferior surface. It is covered by peritoneum, which runs anteroinferiorly from the surface of the gland to be continuous with the anterior, ascending layer of the greater omentum (see Fig. 64.4). The superior leaf of the transverse mesocolon is reflected and is continuous with the descending, posterior leaf of the greater omentum just above the anterior border and so forms virtually none of the covering of the anterosuperior surface. It is separated from the stomach by the lesser sac.

Posterior surface

The posterior surface of the pancreas is devoid of peritoneum. It lies anterior to the aorta and the origin of the superior mesenteric artery, the left crus of the diaphragm, left suprarenal gland and the left kidney and renal vessels, particularly the left renal vein (Fig. 70.4). It is closely related to the splenic vein which lies between the posterior surface and the other posterior relations and runs from left to right forming anything from a shallow groove to a near enveloped ‘tunnel’ in the substance of the gland. The left kidney is also separated from the posterior surface by perirenal fascia and fat.

Anteroinferior surface

The anteroinferior surface of the pancreas begins as a narrow strip just to the left of the neck. As the body runs laterally, it broadens out to form more of the anterior aspect of the body. It is covered by peritoneum which is continuous with that of the posteroinferior layer of the transverse mesocolon. The fourth part of the duodenum, the duodenojejunal flexure and coils of jejunum all lie inferiorly. The lateral end of the inferior border often lies superior and posterior to the splenic flexure. The peritoneum of the anterosuperior layer of the transverse mesocolon is reflected onto the upper part of the anteroinferior surface at the line of the anterior border where it is continuous with the posterior leaf of the greater omentum. The apex of the ligament of Treitz may form an anterior relation of this surface of the body laterally.

Superior border

On the right side, the superior border of the pancreas is initially blunt and somewhat flat, but as the gland is followed to the left, the surface changes to become narrower and sharper. An omental tuberosity usually projects from the right end of the superior border above the level of the lesser curvature of the stomach, in contact with the posterior surface of the lesser omentum. The superior border is related to the coeliac artery. The common hepatic artery runs to the right just above the gland. The splenic artery runs a course that is often highly tortuous to the left along the superior border; it tends to rise above the level of the superior border at several points along its course.

Anterior border

The anterior border of the pancreas separates the anterosuperior from the anteroinferior surfaces. The two layers of the transverse mesocolon diverge along this border. The upper is reflected inferiorly after a very short distance into the descending (posterior) leaf of the greater omentum whilst the other runs downwards and backwards over the anteroinferior surface.

Inferior border

The inferior border of the pancreas separates the posterior from the anteroinferior surfaces. At the medial end of the inferior border, adjacent to the neck of the pancreas, the superior mesenteric vessels emerge from behind the gland. More laterally, the inferior mesenteric vein runs under the border to join the splenic vein on the posterior surface. This is a useful site of identification of the inferior mesenteric vein during left-sided colonic resections and on CT imaging.

TAIL

The tail of the pancreas is the narrowest, most lateral portion of the gland and lies between the layers of the splenorenal ligament. It is continuous medially with the body and is between 1.5 and 3.5 cm long in adults. It may finish at the base of the splenorenal ligament or extend up nearly as far as the splenic hilum, in which case it is prone to injury at splenectomy during ligation of the splenic vessels. Posteriorly it is related to the splenic branches of the splenic artery and the splenic vein and its tributaries. The tip of the tail may lie in contact with the splenic hilum.

UNCINATE PROCESS

The uncinate process of the pancreas extends from the inferior lateral end of the head of the gland (Fig. 70.5). Embryologically it is separate from the rest of the gland, and so it lies posterior to the superior mesenteric vein and occasionally the artery as they descend and run forward into the root of the ileal mesentery, in close contact with its anterior surface. Posteriorly it lies in front of the aorta, and inferiorly it lies on the upper surface of the third part of the duodenum. Tumours of the uncinate process do not cause obstruction to the common bile duct, but frequently compress the third part of the duodenum as a result of this close relationship.

PANCREATIC DUCTS

The exocrine pancreatic tissue drains into multiple small lobular ducts. The arrangement of the main ducts draining the pancreas is subject to some variation but the commonest arrangement is a single main and a single accessory duct (Fig. 70.6). This arrangement reflects the embryological development of the dorsal and ventral pancreatic ducts (see Ch. 73). The main duct is derived from the distal part of the dorsal duct in the body and tail but fuses with the more posteriorly placed ventral duct in the region where the dorsal bud fuses with the ventral bud (because the latter forms the posterior portion of the head of the pancreas and uncinate process). The accessory duct is the remnant of the duct of the dorsal pancreatic bud lying in the anterior pancreatic head after the principle part has joined with the ventral bud duct.

divisum’. **D**, Absence of accessory duct (20%). **E**, Conjoined drainage of persistant ventral and dorsal ducts (<5%).

The main pancreatic duct (of Wirsung) usually runs within the substance of the gland from left to right. It tends to lie more towards the posterior than the anterior surface and is formed by the junction of several lobular (secondary) ducts in the tail. It increases in calibre as it runs within the body because it receives further lobular ducts which join it almost at right angles to its axis, forming a ‘herringbone pattern’. On ultrasound the duct can often be demonstrated, measuring approximately 3mm in diameter in the head, 2mm in the body, and 1mm in the tail in adults. As it reaches the neck of the gland it usually turns inferiorly and posteriorly towards the bile duct, which lies on its right side. The two ducts enter the wall of the descending part of the duodenum obliquely and unite in a short dilated hepatopancreatic ampulla (see Ch. 69).

The accessory pancreatic duct (of Santorini) usually drains the upper part of the anterior portion of the head of the pancreas. Much smaller in calibre than the main duct, it is formed within the substance of the head from several lobular ducts and ascends anterior to the main duct; it usually communicates with it through several small branches although these are rarely large enough to fill the accessory duct on a pancreatogram via the main ampulla. The accessory duct usually opens onto a small rounded minor duodenal papilla, which lies about 2cm anterosuperior to the major papilla. If the duodenal end of the accessory duct fails to develop, the lobular ducts drain via a small channel(s) into the main duct.

The main and accessory pancreatic ducts demonstrate some variability in their anatomy reflecting variations in the development and fusion of the dorsal and ventral ducts (Fig. 70.6). One clinically important variation is ‘pancreas divisum’, where entirely separate drainage occurs for different portions of the pancreas and which may allow some forms of pancreatitis to affect only one portion of the gland.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The pancreas has a rich arterial supply derived from the coeliac axis and superior mesenteric artery via both named vessels and multiple small unnamed vessels (Fig. 70.7).

Right branch, dorsal pancreatic artery
Jejunal branches

Fig. 70.7 Arterial supply of the pancreas.

Inferior pancreaticoduodenal artery

The inferior pancreaticoduodenal artery arises from the superior mesenteric artery or its first jejunal branch, near the superior border of the third part of the duodenum. It usually divides directly into anterior and posterior branches. The anterior branch passes to the right, anterior to the lower border of the head of the pancreas, and runs superiorly to anastomose with the anterior superior pancreaticoduodenal artery. The posterior branch runs posteriorly and superiorly to the right, lying posterior to the lower border of the head of the pancreas and anastomoses with the posterior superior pancreaticoduodenal artery. Both branches supply the pancreatic head, its uncinate process and the second and third parts of the duodenum.

Superior pancreaticoduodenal artery

The superior pancreaticoduodenal artery is usually double. The anterior artery is a terminal branch of the gastroduodenal artery and descends in the anterior groove between the second part of the duodenum and head of the pancreas. It supplies branches to the head of the pancreas and anastomoses with the anterior division of the inferior pancreaticoduodenal artery. The posterior artery is usually a separate branch of the gastroduodenal artery arising at the upper border of the first part of the duodenum. It descends to the right, anterior to the portal vein and common bile duct, where the duct passes behind the first part of the duodenum. The artery next runs posterior to the head of the pancreas and crosses posterior to the common bile duct embedded in the head of the pancreas. It enters the duodenal wall and anastomoses with the posterior division of the inferior pancreaticoduodenal artery. The posterior superior artery supplies branches to the head of the pancreas and the first and second parts of the duodenum. (See Kimura 2000.)

Pancreatic branches

The pancreas is supplied by numerous small arterial branches which usually run into the gland directly from their arteries of origin. They are particularly numerous in the region of the neck, body and tail. Most originate from the splenic artery as it runs along the superior border of the gland and supply the left part of the body and tail. A dorsal branch descends posterior to the pancreas, dividing into right and left branches. It sometimes arises from the superior mesenteric, middle colic, hepatic or rarely, the coeliac artery. The right branch is often double and runs between the neck and uncinate process to form a prepancreatic arterial arch as it anastomoses with a branch from the anterior superior pancreaticoduodenal artery. The left branch runs along the inferior border to the pancreatic tail where it anastomoses with the greater pancreatic artery (*arteria pancreatica magna*) and the artery to tail of the pancreas (*arteria caudae pancreatis*).

Small un-named branches also arise from the first jejunal arcade of the superior mesenteric artery and the arterial branches of the retroperitoneal vessels.

Small arteries characteristically run along the inferior and superior borders of the gland, either lying in a deep groove or within the tissue of the gland. They receive contributions from many of the arteries supplying the gland, but mainly from the inferior and superior pancreaticoduodenal arteries, and supply branches which penetrate the substance of the gland at right angles to the vessel. They may bleed profusely on cutting the parenchyma of the gland during resection and usually require ligation.

Veins

The venous drainage of the pancreas is primarily into the portal system (Fig. 70.8). The head and neck drain primarily via superior and inferior pancreaticoduodenal veins. The body and tail drain mostly via small veins that run directly into the splenic vein along the posterior aspect of the gland, or occasionally directly into the portal vein. The veins are numerous and short, features that may lead to troublesome bleeding during surgical mobilization of the head and neck of the gland. Small venous channels exist between all parts of the gland and the retroperitoneal veins, and ultimately drain into the lumbar veins: they may hypertrophy and become clinically significant in cases of portal hypertension.

Lymphatics

The lymphatic drainage of the pancreas is extensive; multiple groups of nodes may receive drainage from each region of the gland (see Fig. 65.12B) which in part explains the poor prognosis following resection of pancreatic tumours. Lymph capillaries commence around the pancreatic acini. The larger lymph vessels follow the arterial supply and drain into the lymph nodes around the pancreas and adjacent node groups. Lymphatics from the tail and body drain mostly into the pancreaticosplenic nodes, although some drain directly to pre-aortic nodes. Lymphatics from the neck and head drain more widely into nodes along the pancreaticoduodenal, superior mesenteric and hepatic arteries, and some also drain to the pre-aortic nodes and coeliac axis nodes. There is no evidence of lymphatic channels within the pancreatic islets.

INNERVATION OF THE EXOCRINE PANCREAS

The exocrine lobules of the pancreas are innervated by a fine network of sympathetic and parasympathetic fibres. The sympathetic supply originates from the sixth to tenth thoracic spinal segments and is mainly distributed to the pancreas via the sympathetic contribution to the coeliac ganglia. The postganglionic fibres are distributed to the gland via the arterial supply as periarterial plexuses. The parasympathetic supply is from the posterior vagus nerve and the parasympathetic component of the coeliac plexus. The supply to the gland is both vasomotor (sympathetic) and parenchymal (sympathetic and parasympathetic). The exocrine lobules are innervated by a fine network of parasympathetic and sympathetic fibres. Sensory fibres running from the gland run in both the sympathetic and parasympathetic systems: they mediate the sensation of pain arising from the gland and may also carry other sensory information. In chronic inflammation or inoperable tumours of the gland, thermal or chemical ablation of the coeliac plexus may be required to control chronic pain mediated by these fibres.

Referred pain

Pain arising in the pancreas is poorly localized. In common with other foregut structures, the majority of pain arising from the pancreas is referred to the epigastrium. Inflammatory or infiltrative processes arising from the gland rapidly involve the tissues of the retroperitoneum that are innervated by somatic nerves: pain is referred to the posterior paravertebral region around the lower thoracic spine.

PANCREATITIS AND PSEUDOCYST

Pancreatitis is one of the major pathological processes affecting the pancreas. Gallstones lying within the common bile duct are associated with pancreatitis. The presence of a common drainage for the common bile duct and the pancreatic duct may allow reflux of bile or pancreatic enzymes into the pancreatic duct during the passage of a gallstone through the ampulla. Reflux may also occur if the wall of the common bile duct becomes oedematous even though the gallstones have not entered the common ampulla.

Inflammation in the pancreas may cause a range of secondary pathologies. The course of the superior mesenteric artery and vein behind the neck and between the inferior border and uncinate process makes these vessels vulnerable to compression and secondary inflammation, which may result in an inflammatory aneurysm of the superior mesenteric artery or thrombosis of the superior mesenteric vein. Inflammatory aneurysms may rupture producing major haemorrhage. Thrombosis of the superior mesenteric vein may cause potentially lethal venous ischaemia of the small intestine. Thrombosis of smaller arterial branches such as the origin of the middle colic artery may cause ischaemia of individual organs such as the transverse colon.

In acute episodes, the profuse arterial and venous supply to the gland makes it particularly prone to haemorrhage. The extravasated blood collects in the retroperitoneal tissues because the neck and body of the gland lie largely in the loose connective tissue of the retroperitoneum. The pancreas lies anterior to the thoracolumbar and perirenal fasciae and the blood-stained fluid can track freely in the retroperitoneal tissues to appear in either the flanks (Grey–Turner’s sign), groins, or above the iliac crest where the iliac fascia is attached. Blood-stained fluid tracking laterally from the head of the pancreas may enter the lesser omentum and the ‘bare area’ of the liver, from where it may run forward into the falciform ligament and appear around the skin of the umbilicus (Cullen’s sign).

During acute episodes of inflammation, the close anterior relationship of the stomach may contribute to gastric stasis and vomiting. The origin of the superior mesenteric plexus also lies close to the pancreas and secondary inflammation in the tissues around the pancreas may affect the autonomic supply to the midgut and contribute to the paralytic ileus that frequently develops.

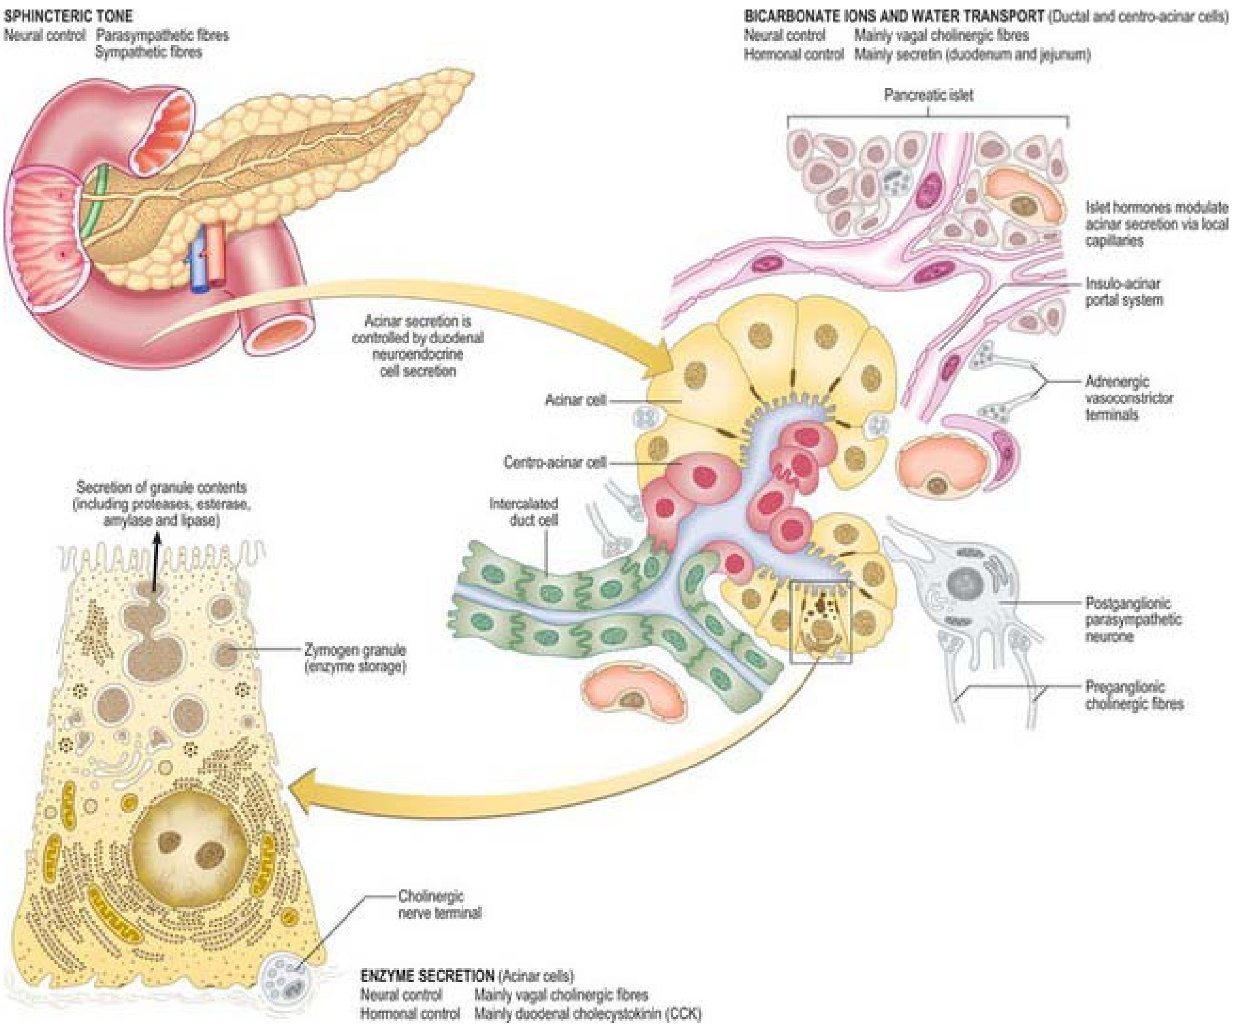
In severe cases, pancreatic inflammation may cause the collection of fluid within and around the pancreatic tissue. Intrapancreatic collections frequently resolve spontaneously over time, but coalescence of the fluid may occur anterior to the pancreas beneath the layer of peritoneum covering its anterior surfaces (although this actually lies beneath the posterior wall of the lesser sac). If this collection persists and grows, the peritoneum anterior and superior to the pancreas is stretched and comes to lie in contact with the anterior wall of the lesser sac. This collection is referred to as a pseudocyst. The anterior wall of the pseudocyst is formed of the twin layers of peritoneum lying adjacent to the posterior wall of the stomach, the lesser omentum and, occasionally, the gastrosplenic ligament. The lateral wall of the pseudocyst includes the splenorenal ligament. The posterior wall is a mixture of fibrous tissue resulting from previous inflammation, the anterior surface of the pancreas and the retroperitoneal tissues. Treatment of the pseudocyst usually involves drainage of the contents into the lumen of the stomach. This may be established endoscopically by placement of a drain through the posterior stomach wall and the two thickened layers of peritoneum into the cyst. Alternatively, the drain may be placed using radiological guidance, via the anterior abdominal wall and the anterior stomach wall.

PANCREATIC RESECTION

Resection of the pancreas is complicated by several factors. The extensive vascular supply requires careful haemostasis. Spleen-preserving resections may be undertaken if the underlying pathology does not involve the splenic vein where it lies in the groove on the posterior surface of the gland, although the multiple small pancreatic veins draining into it may cause troublesome bleeding. Resection of the head and neck is possible provided the plane between the neck and the portal vein has not been involved by disease. Occasional small venous branches may enter the portal vein directly and may also cause bleeding during this mobilization. Resection of the head and neck are almost always accompanied by resection of the distal first and second parts of the duodenum because of the dense adherence between the two and the common arterial supply. Resection without removal of the proximal part of the first part of the duodenum and pylorus, pylorus-preserving pancreatectomy, may be possible provided there is an adequate arterial supply to the pylorus from the stomach, and directly from the pre-pyloric vessels.

MICROSTRUCTURE

The pancreas is composed of two different types of glandular tissue. The main tissue mass is exocrine, in which pancreatic islets of endocrine cells are embedded (Figs 70.9-70.11).



SPHINCTERIC TONE
Neural control Parasympathetic fibres
Sympathetic fibres
BICARBONATE IONS AND WATER TRANSPORT (Ductal and centro-acinar cells)
Neural control Mainly vagal cholinergic fibres
Hormonal control Mainly secretin (duodenum and jejunum)
Pancreatic islet
Islet hormones modulate acinar secretion via local capillaries
Insulo-acinar portal system
Adrenergic vasoconstrictor terminals
Acinar secretion is controlled by duodenal neuroendocrine cell secretion

Fig. 70.11 Microstructure and control of function of the endocrine pancreas.

Exocrine pancreas

The exocrine pancreas isa branched acinar gland, surrounded and incompletely lobulated by delicate loose connective tissue. It is formed of pyramidal, secretory cells arranged mainly as spherical clusters, or acini. A narrow intercalated, intralobular duct originates within each secretory acinus, lined initially by flattened or cuboidal centro-acinar cells. These small ductules form branching links which run within and between adjacent acini, explaining why structurally distinct intralobular pancreatic ducts are infrequent (see Kerr 1999, for details). More distally, these are replaced by taller cuboidal and eventually columnar epithelium in the larger interlobular ducts. The latter are surrounded by loose connective tissue of the septa, containing smooth muscle and autonomic nerve fibres. Neuroendocrine cells are present amongst the columnar ductal cells and mast cells are numerous in the surrounding connective tissue.

Acinar cells

Acinar cells of the exocrine pancreas have a basal nucleus and, in their basal cytoplasmic domain, abundant rough endoplasmic reticulum which results in their basophilic staining characteristics. Dense secretory zymogen granules stain deeply with eosin in the apical region. A prominent supranuclear Golgi complex is surrounded by large, membrane-bound granules containing the proteinaceous constituents of pancreatic secretion, including enzymes which are only active after release. Ganglionic neurones and cords of undifferentiated epithelial cells are also found within the acini. The structure of the exocrine pancreas and its functional regulation are summarized in Fig. 70.9.

Stellate cells

Pancreatic stellate cells, PaSCs, are one of several resident cells in the exocrine pancreas. They are regulated by autocrine and paracrine stimuli and share many features with their hepatic counterparts. PaSCs are myofibroblast-like cells and are found in the periacinar space, where their long cytoplasmic processes encircle the base of the acinus, and in perivascular and periductal regions of the pancreas. They have been implicated as key players in the pathobiology of the major disorders of the exocrine pancreas, including chronic pancreatitis and pancreatic cancer (Bishr Omary et al 2007).

Endocrine pancreas

The endocrine pancreas consists of pancreatic islets of Langerhans, composed of spherical or ellipsoid clusters of cells embedded in the exocrine tissue. The human pancreas may contain more than a million islets, usually most numerous in the tail. An islet is a mass of polyhedral cells, each in close proximity to fenestrated capillaries and a rich autonomic innervation. Specialized staining procedures or immunohistochemical techniques are necessary to distinguish the three major types of cell, designated alpha, beta and delta. Their general organization is shown in Fig. 70.11.

The most numerous cells, types alpha and beta, secrete glucagon and insulin respectively. Alpha cells tend to be concentrated at the periphery of islets, and beta cells more centrally. A third type, the delta cell, secretes somatostatin and gastrin, and like alpha cells, is peripherally placed within the islets. A minor cell type, the F cell, secretes pancreatic polypeptide (PP), which is stored in smaller secretory granules. The autonomic neurotransmitters acetylcholine (ACh) and noradrenaline affect islet cell secretion: ACh augments insulin and glucagon release, noradrenaline inhibits glucose-induced insulin release, and they may also affect somatostatin and PP secretion.

Innervation of endocrine pancreas

The innervation of the endocrine islets is almost exclusively from the parasympathetic system. Fine branches ramify among the cells and form plexuses around the islets. Fibres frequently synapse with acinar cells before innervating the islets, suggesting a close linkage between neural control of exocrine and endocrine components. Many fibres enter the islets with the arterioles. Parasympathetic ganglia lie in the connective tissue within and between lobules, and in the former case are frequently associated with islet cells, forming neuroinsular complexes. Both alpha and beta cells are involved in these neuroinsular complexes. Three types of nerve terminal are seen in islets. Cholinergic terminals have agranular vesicles with a diameter of 30–50 nm, adrenergic terminals have dense-cored vesicles with a diameter of 30–50 nm and a third, uncharacterized, type have dense-cored vesicles with a diameter of 60–200 nm (Smith & Porte 1976).

No selective link with any one type of insular cell has been found. Sometimes more than one type of terminal contacts a single cell and some of the chemical synapses between axon terminals and islet cells show narrow areas in the synaptic clefts suggesting an electrical synapse or gap junction. Such junctions also occur between islet cells, and electrical coupling of nerve supply to a functional network of islet cells may occur (Orci 1974).

CHAPTER 71

Spleen

The spleen consists of a large encapsulated mass of vascular and lymphoid tissue situated in the upper left quadrant of the abdominal cavity between the fundus of the stomach and the diaphragm. Its shape varies from a slightly curved wedge to a ‘domed’ tetrahedron. The shape is mostly determined by its relations to neighbouring structures during development. The superolateral aspect is shaped by the left dome of the diaphragm with the inferomedial aspect being influenced mostly by the neighbouring splenic flexure of the colon, the left kidney and stomach. Its long axis lies approximately in the plane of the tenth rib. Its posterior border is approximately 4 cm from the mid-dorsal line at the level of the tenth thoracic vertebral spine. Its anterior border usually reaches the mid-axillary line.

The size and weight of the spleen vary with age and sex. It can also vary slightly in the same individual under different conditions. In the adult it is usually 12 cm long, 7 cm broad, and 3–4 cm wide. It is comparatively largest in the young child, and although its weight increases during puberty, by adulthood it is relatively smaller in comparison to the neighbouring organs. It tends to diminish in size and weight in senescence. Its average adult weight is about 150 g, although the normal range is wide, between 80 g and 300 g, in part reflecting the amount of blood it contains. The normal-sized adult spleen fits comfortably in a cupped hand; the spleen has to be at least three times its normal size before it can be palpated.

Additional collections of fully functional splenic tissue may exist near the spleen, especially within the gastrosplenic ligament and greater omentum. These accessory spleens, or splenunculi, are usually isolated but can be connected to the spleen by thin bands of similar tissue. They may be numerous and widely scattered in the abdomen. The spleen may retain its fetal lobulated form or show deep notches on its diaphragmatic surface and inferior border in addition to those usually present on the superior border.

RELATIONS

The spleen has a superolateral diaphragmatic and an inferomedial visceral surface (Fig. 71.1). There are superior and inferior borders and anterior and posterior extremities or poles. The diaphragmatic surface is convex and smooth and faces mostly superiorly and laterally although the posterior part may face posteriorly and almost medially as it approaches the inferior border. The diaphragmatic surface is related to the abdominal surface of the left dome of the diaphragm which separates it from the basal pleura, the lower lobe of the left lung and the ninth to eleventh left ribs (Fig. 71.2). The pleural costodiaphragmatic recess extends down as far as its inferior border. The visceral surface faces inferomedially towards the abdominal cavity, and is irregular and marked by gastric, renal, pancreatic and colic impressions. The gastric impression faces anteromedially and is broad and concave where the spleen lies adjacent to the posterior aspect of the fundus, upper body and upper greater curvature of the stomach. It is separated from the stomach by a peritoneal recess, which is limited by the gastrosplenic ligament. The renal impression is slightly concave and lies on the lowest part of the visceral surface, separated from the gastric impression above by a raised strip of splenic tissue and the splenic hilum. It faces inferomedially and slightly backwards, being related to the upper and lateral area of the anterior surface of the left kidney and sometimes to the superior pole of the left suprarenal gland. The colic impression lies at the inferior pole of the spleen and is usually flat. It is related to the splenic flexure of the colon and the phrenicocolic ligament. The pancreatic impression is often small when present and lies between the colic impression and the lateral part of the hilum. It is related to the tail of the pancreas which lies in the splenorenal ligament. The hilum of the spleen is a long fissure pierced by several irregular apertures through which the branches of the splenic artery and vein as well as nerves and lymphatics enter and leave the spleen; it lies in the visceral surface closer to the inferior border and anterior border.

Fig. 71.2 The posterior relations (‘bed’) of the spleen.

(Adapted from Drake, Vogl and Mitchell 2005.)

The superior border separates the diaphragmatic surface from the gastric impression and is usually convex. Near the anterior extremity there may be one or two notches that have persisted from the lobulated form of the spleen in early fetal life. However, they are often absent and are not a reliable guide to the identification of the spleen during clinical examination. The inferior border separates the renal impression from the diaphragmatic surface and lies between the diaphragm and the upper part of the lateral border of the left kidney. It is more blunt and rounded than the superior border and corresponds in position to the lower margin of the eleventh rib. The posterior extremity, or superior pole, usually faces the rounded vertebral column. The anterior extremity, or inferior pole, is larger and less angulated than the posterior extremity and connects the lateral ends of the superior and inferior borders: it is related to the colic impression and may lie adjacent to the splenic flexure and the phrenicocolic ligament.

PERITONEAL CONNECTIONS OF THE SPLEEN

The spleen is almost entirely covered by peritoneum that adheres firmly to its capsule, and is separated from the stomach and left kidney by recesses of the greater sac. It develops in the upper dorsal mesogastrium (see Figs 73.6 to 73.7), and remains connected via folds of peritoneum to the posterior abdominal wall (by the splenorenal, phrenicocolic and phrenicosplenic ligaments) and to the anterolateral abdominal wall and stomach (by the gastrosplenic ligament) (Fig. 71.3A). The splenorenal ligament is formed from two layers of peritoneum. The anterior layer is continuous with the peritoneum of the posterior wall of the lesser sac over the left kidney and with peritoneum of the splenic hilum where it runs into the posterior layer of the gastrosplenic ligament. The posterior layer of the splenorenal ligament is continuous with the peritoneum over the inferior surface of the diaphragm and runs onto the splenic surface over the renal impression. The splenic vessels lie between the layers of the splenorenal ligament: the tail of the pancreas is usually present in its lower portion (see Fig. 64.5B). The length of the splenorenal ligament may vary. Longer ligaments tend to make the spleen more mobile and may predispose the spleen to injury due to rotational shear forces during trauma, however they also make the mobilization of the spleen easier during surgery. The presence of the pancreatic tail within the splenorenal ligament must be remembered because it can be injured during ligation of the splenic vessels, causing pancreatitis or a pancreatic duct fistula to form.

*(**A** and **B** adapted from Drake, Vogl and Mitchell 2005.)*

The gastrosplenic ligament also has two layers (Fig. 71.3B). The posterior layer is continuous with the peritoneum at the splenic hilum and over the posterior aspect of the stomach. The anterior layer is formed from the peritoneum that is reflected off the gastric impression and reaches the greater curvature of the stomach anteriorly. The short gastric and left gastroepiploic branches of the splenic artery pass between its layers. Division of the gastrosplenic ligament during surgery may be hazardous if the ligament is short because ligation of the short gastric vessels may risk injury to the greater curvature of the stomach.

The phrenicocolic ligament extends from the splenic flexure of the colon to the diaphragm at the level of the eleventh rib. It extends inferiorly and laterally and is continuous with the peritoneum of the lateral end of the transverse mesocolon at the lateral margin of the pancreatic tail, and the splenorenal ligament at the hilum of the spleen.

If the peritoneal attachments of the spleen are not recognized during surgery, the splenic capsule may be injured, with subsequent serious bleeding. Downward traction on the phrenicocolic ligament during handling of the descending colon, especially during mobilization of the splenic flexure, may cause rupture of the splenic capsule. This is less likely if traction on the phrenicocolic ligament is made laterally or medially. The superior border and anterior diaphragmatic surface are often adherent to the peritoneum of the greater omentum. Medial traction on the omentum during surgery may cause capsular injury, but this is less likely if any limited traction required is applied inferiorly. The diaphragmatic surface of the spleen is occasionally adherent to the peritoneum over the inferior surface of the diaphragm: these adhesions often occur after inflammation in the spleen, but may also be present congenitally.

SPLENOMEGALY

Splenic enlargement may accompany any massive immune response and occurs in many other systemic inflammatory and degenerative conditions. In splenomegaly, the anterior border, anterior diaphragmatic surface and notched superior border may become clearly palpable below the left costal margin. The notches are often exaggerated and may be clearly palpable, and the transverse colon and splenic flexure are displaced downward.

SPLENIC TRAUMA

The spleen is particularly prone to rotational injury during rapid deceleration or compression. Because it has relatively mobile peritoneal connections, tearing injuries to the splenic vessels at the hilum or burst injuries of the splenic pulp may occur. Fractures of the overlying lower left ribs may cause sharp penetrating injuries to the splenic capsule and pulp. The spleen may also be injured during surgical procedures by tearing of its capsule through peritoneal adhesions and connections (see above). Minor capsular tears may be treated by conservative management if from blunt trauma or by application of various haemostatic substances to the exposed pulp. Direct sutured repair of more extensive tears of the spleen is rarely successful because the splenic pulp is fragile. Moderately severe injuries may be treated by conservative management if from blunt trauma or by compression of the splenic tissue until haemostasis occurs if encountered at surgery, but extensive burst injuries or major injuries to the hilar vessels usually require splenectomy.

SPLENECTOMY

Partial splenectomy is followed by rapid regeneration of lost tissue and there is no significant loss in any of the functions of the spleen. Total splenectomy has few haematological consequences since the functions of the spleen are largely assumed by the liver. There is, however, a loss in immune function, particularly in the antibody response to systemic infections with encapsulated bacteria. This is referred to as ‘overwhelming post-splenectomy sepsis syndrome’, and is particularly a problem when the spleen is lost in early childhood, but is still a significant risk even if the spleen is lost in late adult life. Splenectomy in adults is usually followed by an increased white blood cell count with increased lymphocytic, neutrophil, eosinophil and platelet counts in the peripheral blood: these effects fade and disappear within a few weeks.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Splenic artery

The spleen is supplied exclusively from the splenic artery (see Fig. 70.7). This is the largest branch of the coeliac axis and its course is among the most tortuous in the body. From its origin the artery runs a little way inferiorly, then turns rapidly to the left to run initially horizontally above the level of the neck of the pancreas, before ascending as it passes more laterally. It is less steeply inclined than the body and tail of the pancreas and so comes to lie posterior to the superior border of the gland. It lies in multiple loops or even coils which appear above the superior border of the pancreas and descend to lie behind the gland. The splenic artery lies anterior to the left kidney and left suprarenal gland and runs in the splenorenal ligament posterior to the tail of the pancreas. It divides into two or three main branches before entering the hilum of the spleen (Fig. 71.1). As these branches enter the hilum they divide further into four or five segmental arteries that each supply a segment of the splenic tissue. There is relatively little arterial collateral circulation between the segments, which means that occlusion of a segmental vessel often leads to infarction of part of the spleen. There is, however, considerable venous collateral circulation between the segments, making segmental resection of the spleen practically impossible. The splenic artery gives off various branches to the pancreas in its course and gives off short gastric arteries to the stomach just prior to dividing or from its terminal branches.

Splenic vein

The splenic vein is formed within the splenorenal ligament, close to the tip of the tail of the pancreas, by five or six tributaries that emerge from the hilum of the spleen (Fig. 71.4). The tributaries are thin walled and often spread over several centimetres because the hilum is long and thin (Fig. 71.1). This must be remembered during surgical removal of the spleen because the venous tributaries must be divided close to the hilum to avoid injury to the pancreatic tail. They should be ligated in several groups to prevent the risk of avulsion of the veins from the splenic hilum and consequent profuse bleeding before the resection is complete.

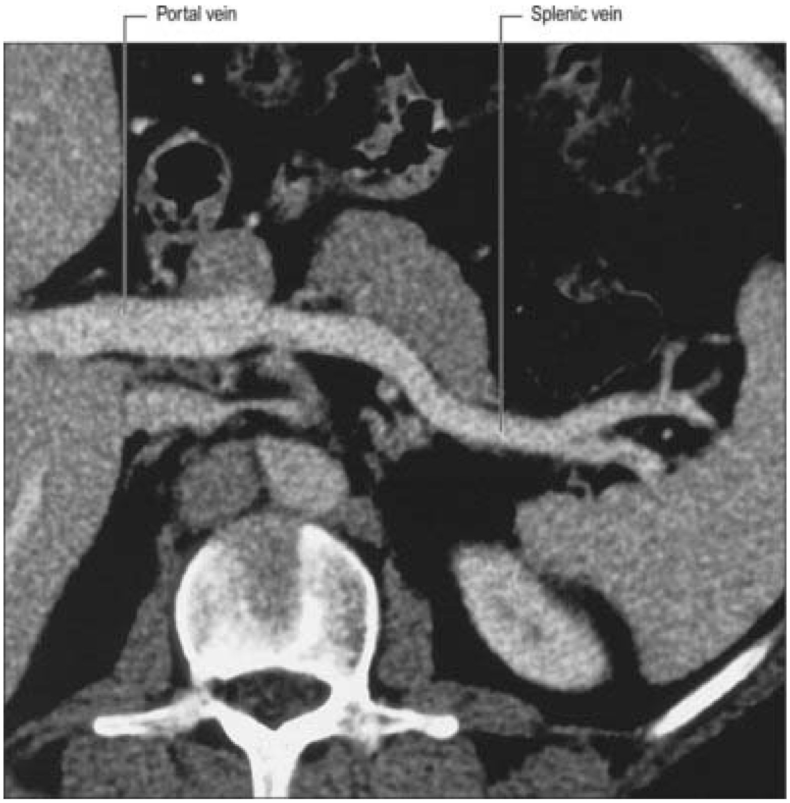

Fig. 71.4 Axial oblique CT slice of the portal vein and splenic vein.

The splenic vein runs in the splenorenal ligament below the splenic artery and posterior to the tail of the pancreas. It descends to the right, and crosses the posterior abdominal wall inferior to the splenic artery and posterior to the body of the pancreas, receiving numerous short tributaries from the gland as it does so. It crosses anterior to the left kidney and renal hilum and is separated from the left sympathetic trunk and left crus of the diaphragm by the left renal vessels, and from the abdominal aorta by the superior mesenteric artery and left renal vein. It ends behind the neck of the pancreas, where it joins the superior mesenteric vein to form the portal vein. The short gastric and left gastro-epiploic veins drain into the splenic vein through the folds of the gastrosplenic ligament near its origin.

Lymphatics

Lymphatic vessels drain along the splenic trabeculae and pass out of the hilum into lymphatic vessels that accompany the splenic artery and vein. They run posterior to the pancreas, close to the splenic artery, and drain into nodes at the hilum and along the splenic artery and into the coeliac nodes.

INNERVATION

The spleen is innervated by the splenic plexus, which consists of branches of the coeliac plexus, left coeliac ganglion and right vagus that accompany the splenic artery. The fibres are mainly sympathetic and terminate around blood vessels and in the non-striated muscle of the splenic capsule and trabeculae. Most appear to be noradrenergic, vasomotor, and are concerned with the regulation of blood flow through the spleen. Adrenergic agonists inhibit the concentration of red cells in the splenic blood (so called ‘plasma skimming’) indicating that sympathetic activity causes an increase in the ‘fast’ circulation of the spleen as opposed to slow filtration (Reilly 1985).

Referred pain

The sensation of pain arising from the pulp of the spleen is poorly localized and referred to the central epigastrium, as is the case for other structures derived from the foregut. Distension of the splenic capsule stretches the parietal layers of the peritoneum and produces pain that is localized to the posterior left upper quadrant.

MICROSTRUCTURE

The spleen is essentially concerned with phagocytosis and immune responses. In the fetus it is also an important site of haemopoiesis. Postnatally it may become haemopoietic in certain pathological conditions. Although important to the defence of the body it is not absolutely essential: if the spleen is removed, many of its functions can be assumed by the liver and by other lymphoid tissues.

Microscopically, the parenchymal tissue of the spleen consists of two major components, white pulp and red pulp, named on the basis of their appearance when a fresh spleen is transected (Fig. 71.5). The white pulp is composed of lymphoid tissue in which B and T lymphocytes mature and proliferate under antigenic stimulation (Fig. 71.6). The red pulp is a unique filtration device that enables the spleen to clear particulate material from the blood as it perfuses the spleen. It is composed of a complex system of interconnected spaces populated by large numbers of phagocytic macrophages that remove effete red blood cells, microorganisms, cellular debris and other particulate matter from the circulation.

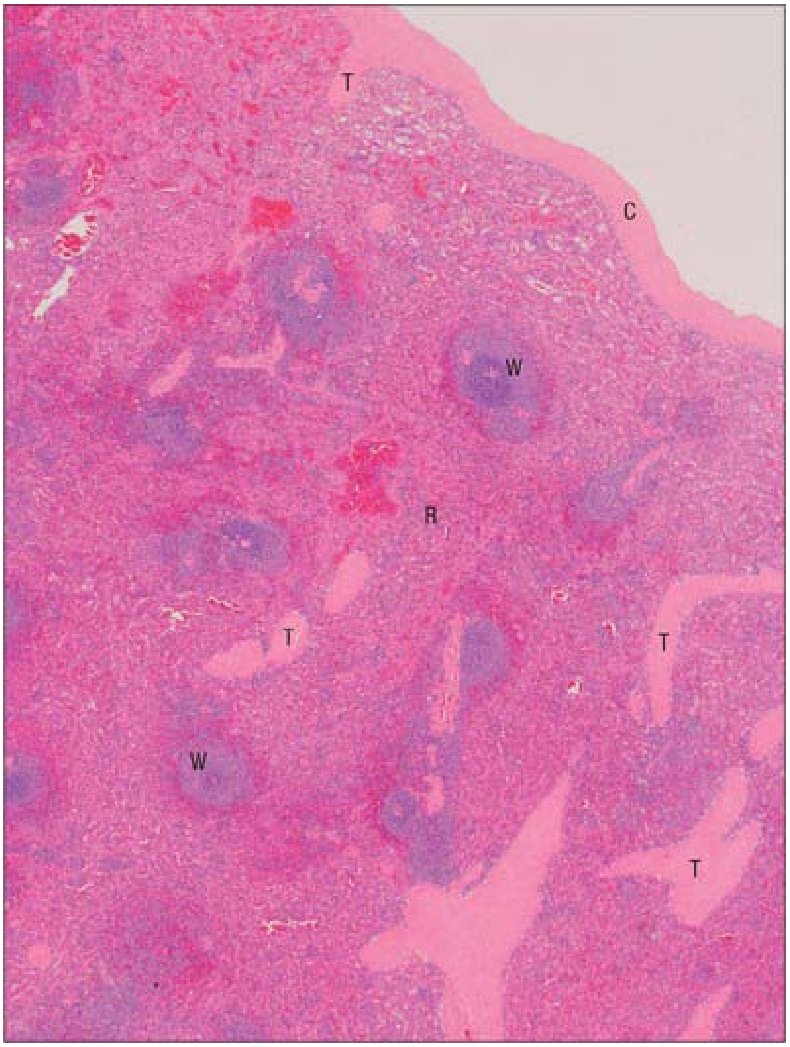

Fig. 71.5 A section through the spleen. White pulp (W) is present as ovoid areas of basophilic tissue. Red pulp (R) lies between white pulp tissue and consists of splenic sinusoids and intervening cellular cords. Part of the capsule (C) is seen top right, from which trabeculae (T) extend into the splenic tissue.

Fig. 71.6 The main features of splenic structure, not to scale. Shown are the capsule, trabeculae, reticular fibres and cells, the perivascular lymphoid sheaths and follicles (white pulp), and the cellular cords and venous sinusoids of the red pulp. The 'open' and 'closed' theories of splenic circulation are illustrated: it is likely that most of the circulation is of the open form. The venous sinusoids are lined by specialized endothelial 'stave' cells, the intercellular gaps of which have been over-emphasized for clarity.

Fibrous framework of the spleen

The serosa of the peritoneum covers the entire organ except at its hilum and along the lines of reflexion of the splenorenal and gastrosplenic ligaments. Deep to this layer is the connective tissue capsule, a continuous layer approximately 1.5 mm thick, containing abundant type I collagen fibres and some elastin fibres. The capsule has an outer and an inner lamina in which the directions of the collagen fibres differ, thereby increasing its strength. Numerous trabeculae extend from the capsule into the substance of the spleen, where they branch to form a supportive framework. The largest trabeculae enter at the hilum and provide a conduit for the splenic vessels and nerves, dividing into branches in the splenic pulp (Figs 71.6 and 71.7). Within the spleen, these branches become continuous with a delicate network of type III (reticular) collagen fibres that pervades both red and white pulps and is secreted by fibroblasts within its meshes.

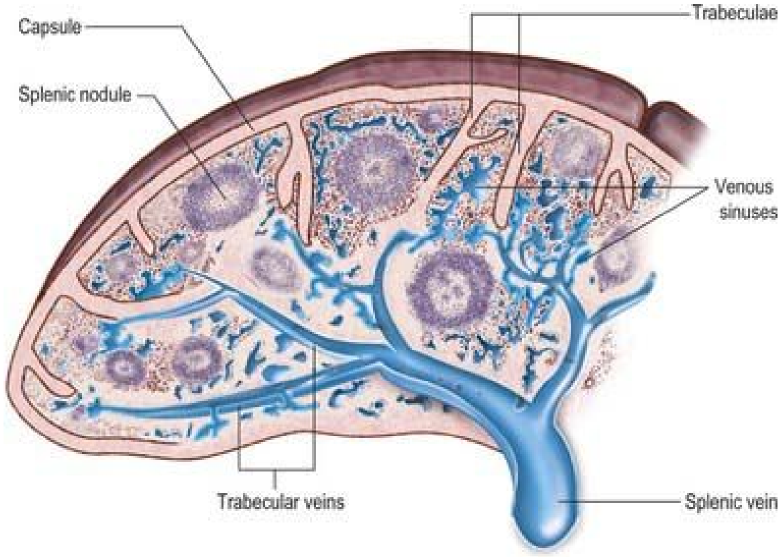

Fig. 71.7 Transverse section through the spleen, showing the trabecular tissue and the splenic vein and its tributaries.

White pulp

In the spleen parenchyma, branches of the splenic artery radiate out from the hilum within trabeculae, ramifying and narrowing to arterioles. In their terminal few millimetres, their connective tissue adventitia is replaced by a sheath of T-lymphocytes, the periarteriolar lymphatic sheath (PALS). This sheath is enlarged in places by lymphoid follicles, which are aggregations of B-lymphocytes, 0.25–1 mm in diameter and visible to the naked eye on the freshly cut spleen surface as white semi-opaque dots: they contrast with the surrounding deep reddish-purple of the red pulp. Follicles are usually situated near the terminal branches of arterioles and typically protrude to one side of a vessel, which consequently appears eccentrically placed within the follicle. Arterioles branch laterally within follicles to form a series of parallel terminal arterioles, called penicilli, or penicillar arterioles, from their resemblance to the penicillium mould.

Like the periarteriolar sheaths, follicles are centres of lymphocyte proliferation as well as aggregation, and when antigenically stimulated, the white pulp increases in size as lymphocytes proliferate. The primary follicles become intensely active in B-cell proliferation, and they develop germinal centres similar to those found in lymph nodes: the presentation of antigen by follicular dendritic cells is involved in this process. The germinal centres regress when the infection subsides. Follicles generally atrophy with increasing age and may be absent in the very elderly.

Red pulp

The red pulp constitutes the majority (75%) of the total splenic volume. It contains large numbers of venous sinusoids that ultimately drain into tributaries of the major splenic veins. The sinusoids are separated from each other by a fibrocellular network consisting of small bundles of delicate collagen type III fibres, the reticulum, and numerous reticular fibroblasts and splenic macrophages. Seen in two-dimensional sections, these intersinusoidal regions appear as strips of tissue, the splenic cords, which alternate with splenic sinuses (Fig. 71.6). In reality, they form a three-dimensional continuum around the venous spaces.

Venous sinusoids

Venous sinusoids are elongated ovoid vessels approximately 50 μm in diameter, lined by a characteristic, ‘incomplete’ endothelium that is unique to the spleen. Their endothelial cells are long and narrow, and aligned with the long axis of the sinusoid; they are often called stave cells, because they are reminiscent of planks in a barrel (Fig. 71.6). Stave cells are attached to their neighbours at intervals along their length by short stretches of intercellular junctions. These junctions alternate with intercellular slits which allow blood cells to squeeze into the lumen of the sinusoid from the surrounding splenic cords. A discontinuous basal lamina is present on the abluminal aspect of the sinus. The sinusoids are supported externally by circumferentially and longitudinally disposed reticular fibres, which are components of the fibrous reticulum.

Reticular tissue of the splenic cords

Large, stellate fibroblasts called reticular cells lie around the sinusoids. They synthesis the matrix components of the reticulum, including collagen and proteoglycans, and their cytoplasmic processes compartmentalize the reticular space. Blood is released from the ends of capillaries originating from penicillar arterioles and percolates through the reticular spaces within the splenic cords. As it does so, macrophages within the reticulum remove blood-borne particulate material, including ageing and damaged erythrocytes. When numbers of damaged erythrocytes increase, the reticular cells proliferate and the size of the red pulp increases considerably: this causes enlargement of the whole spleen, and in extreme cases, splenomegaly.

Marginal zone

The marginal zone lies at the interface between the white and red pulp. It is a region of great functional importance because it is where blood is delivered into the red pulp, and where many lymphocytes leave the circulation to migrate into their respective T- and B-lymphocyte areas in the white pulp. The lymphocytes are more loosely arranged than they are in the white pulp, and are held in a dense network of reticular fibres and cells. The arterioles leaving the white pulp are surrounded by a small aggregation of macrophages, the periarteriolar macrophage sheath.

Splenic microcirculation

The segmental splenic arteries enter the hilum and ramify in the trabeculae throughout the organ. The splenic vein forms in the splenorenal ligament from tributaries emerging from the hilum; they are similar in number to the arterial branches. Small arteries tapering to arterioles pass through the white pulp then turn abruptly to form penicillar branches which, after a course of approximately 0.5 mm, pass out of the white pulp into the marginal zone and red pulp. The passage of blood through the vascular compartments between the arterioles and splenic veins is referred to collectively as the intermediate circulation of the spleen. Ultimately, blood is passed to the venous sinusoids from which it enters venules leading to small veins that run within trabeculae, and thence into larger veins that drain the spleen at its hilum

Open and closed splenic circulations

Views on the intermediate circulation of the spleen differ on whether blood passes from the arterioles (or their terminal capillaries) directly into the venous sinuses (a closed circulation), or is instead discharged into a network of spaces in the splenic cords before entering the sinuses through the minute slits in their walls (an open circulation). In humans, evidence favours the presence of an anatomically and physiologically open circulation, in which blood percolates slowly through the reticular tissue of the splenic cords and filters through slits in the sinus walls before joining the majority of the blood flow (see Fig. 71.6). There is thought to be an additional closed vascular route, but this is likely to provide only a minor contribution to splenic circulation.

CHAPTER 72

Suprarenal (adrenal) gland

The suprarenal (adrenal) glands lie immediately superior and slightly anterior to the upper pole of either kidney (see Fig. 74.5A,B). Golden yellow in colour, each gland possesses two functionally and structurally distinct areas, an outer cortex and an inner medulla. The glands are surrounded by connective tissue containing perinephric fat, enclosed within the renal fascia, and separated from the kidneys by a small amount of fibrous tissue.

The dimensions of the suprarenal glands in adults *in vivo* have been defined by Vincent and colleagues (1994) using computed tomography (CT). The mean transverse dimensions of the body of the suprarenal gland are 61 mm (right) and 79 mm (left) and the mean transverse dimensions of suprarenal limbs are 28 mm (right) and 33 mm (left). No individual suprarenal limb should measure more than 6.5 mm in transverse section. The suprarenal glands each weigh approximately 5 g (the medulla contributes about one-tenth of the total weight).

The glands are macroscopically slightly different in external appearance (Fig. 72.1). The right gland is pyramidal in shape and has two well developed lower projections (limbs) giving a cross-sectional appearance similar to a broad-headed arrow. The left gland has a more semilunar form and is flattened in the anteroposterior plane. The left gland is marginally larger than the right. The bulk of the right suprarenal sits on the apex of the right kidney and usually lies slightly higher than the left gland, which sits on the anteromedial aspect of the upper pole of the left kidney.

Fig. 72.1 Suprarenal glands: anterior (**A**) and posterior (**B**) aspects.

At birth the glands are proportionately larger and are approximately one-third the size of the ipsilateral kidney. The cortex of each gland reduces in size immediately after birth and the medulla grows comparatively little. By the end of the second month the weight of the suprarenal has reduced by 50%. The glands begin to grow by the end of the second year and regain their weight at birth by puberty. There is little further weight increase in adult life.

Small accessory suprarenal glands, composed mainly of cortical tissue, may occur in the areolar tissue near the main suprarenal glands. Accessory glands, termed cortical bodies, may also occur in the spermatic cord, epididymis and broad ligament of the uterus.

RIGHT SUPRARENAL GLAND

The right suprarenal gland lies posterior to the inferior vena cava, from which it is only separated by a thin layer of fascia and connective tissue. It lies posterior to the right lobe of the liver and anterior to the right crus of the diaphragm and superior pole of the right kidney (Fig. 72.2). Its inferior surface is referred to as the base and adjoins the anterosuperior aspect of the superior pole of the right kidney. It often overlaps the apex of the upper pole of the right kidney as the two lower projections (limbs) straddle the renal tissue. The anterior surface faces slightly laterally and possesses two distinct facets. The medial facet is somewhat narrow, runs vertically and lies posterior to the inferior vena cava. The lateral facet is triangular and lies in contact with the bare area of the liver. The lowest part of the anterior surface may be covered by peritoneum, reflected onto it from the inferior layer of the coronary ligament. At this point it may lie posterior to the lateral border of the second part of the duodenum. Below the apex, near the anterior border of the gland, the hilum lies in a short sulcus from which the right suprarenal vein emerges to join the inferior vena cava. This vein is particularly short, which makes surgical resection of the gland potentially hazardous, because ligation may be difficult. The vein may be avulsed from the inferior vena cava during surgery or occasionally by high-energy deceleration injuries. The posterior surface is divided into upper and lower areas by a curved transverse ridge. The large upper area is slightly convex and rests on the diaphragm. The small lower area is concave and lies in contact with the superior aspect of the upper pole of the right kidney. The medial border of the gland is thin and lies lateral to the right coeliac ganglion and the right inferior phrenic artery as the artery runs over the right crus of the diaphragm.

LEFT SUPRARENAL GLAND

The left suprarenal gland lies closely applied to the left crus of the diaphragm and is separated from it only by a thin layer of fascia and connective tissue (Fig. 72.2). The medial aspect is convex whilst the lateral aspect is concave since it is shaped by the medial side of the superior pole of the left kidney. The superior border is sharply defined while the inferior surface is more rounded. The anterior surface has a large superior area covered by peritoneum on the posterior wall of the lesser sac, which separates it from the cardia of the stomach and sometimes from the posterior aspect of the spleen. The smaller inferior area is not covered by peritoneum and lies in contact with the pancreas and splenic artery. The hilum faces inferiorly from the medial aspect and is near the lower part of the anterior surface. The left suprarenal vein emerges from the hilum and runs inferomedially to join the left renal vein. The posterior surface is divided by a ridge into a lateral area adjoining the kidney and a smaller medial area which lies in contact with the left crus of the diaphragm. The convex medial border lies lateral to the left coeliac ganglion, and the left inferior phrenic and left gastric arteries, which ascend on the left crus of the diaphragm.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The suprarenal glands have an extensive vascular supply in relation to their size. Each gland is supplied by superior, middle and inferior suprarenal arteries, whose main branches may be duplicated or even multiple (Fig. 72.3). They ramify over the capsule before entering the gland to form a subcapsular plexus, from which fenestrated sinusoids pass around clustered glomerulosal cells and between columns in the zona fasciculata to a deep plexus in the zona reticularis. Venules from this plexus pass between medullary chromaffin cells to medullary veins, which they enter between prominent bundles of smooth muscle fibres. Some relatively large arteries bypass this indirect route and pass directly to the medulla (Fig. 72.4). At operation the arteries are rarely obvious, but the veins deserve specific attention (see below).

Fig. 72.4 The gross sectional appearance, microstructure, vasculature and ultrastructure of the suprarenal gland. Brief functional summaries are included.

Superior suprarenal arteries

The superior suprarenal artery arises from the inferior phrenic artery, a branch of the abdominal aorta: it is often small and may be absent.

Middle suprarenal arteries

The middle suprarenal artery arises from the lateral aspect of the abdominal aorta at the level of the superior mesenteric artery. It ascends slightly and runs over the crura of the diaphragm to the suprarenal glands, where it anastomoses with the suprarenal branches of the inferior phrenic and renal arteries. The right middle suprarenal artery passes behind the inferior vena cava and near the right coeliac ganglion and is frequently multiple. The left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas.

Inferior suprarenal arteries

The inferior suprarenal arteries arise from the renal arteries, usually from the main renal artery but occasionally from its upper pole branches.

Veins

Medullary veins emerge from the hilum to form a suprarenal vein, which is usually single. The right vein is very short, passing directly and horizontally into the posterior aspect of the inferior vena cava. An accessory vein is occasionally present and runs from the hilum superomedially to join the inferior vena cava above the right suprarenal vein. Their short course renders both right vessels liable to injury or even avulsion from the inferior vena cava during surgery if undue traction is applied, producing a side hole in the cava. The left suprarenal vein descends medially, anterior and lateral to the left coeliac ganglion. It passes posterior to the pancreatic body and drains into the left renal vein. Since the venous drainage from each gland is usually via a single vein, infarction of that gland is more likely to be caused by damage to a suprarenal vein than to one of the suprarenal arteries.

Lymphatic drainage

Small lymphatic channels from both cortex and medulla drain to the hilum, from where larger calibre lymphatics emerge to drain directly into the lateral groups of para-aortic nodes.

INNERVATION: SUPRARENAL PLEXUS

The suprarenal gland, relative to its size, has a larger autonomic supply than any other organ. On each side, the suprarenal plexus lies between the medial aspect of the gland and the coeliac and aorticorenal ganglia. It contains mostly preganglionic sympathetic fibres, which originate in the lower thoracic spinal segments and which reach the plexus via branches from the coeliac ganglion and plexus, and via the greater splanchnic nerve. These fibres synapse, often in deep invaginations, on large medullary chromaffin cells, which may therefore be considered to be homologous with postganglionic sympathetic neurones. A preponderance of non-myelinated axons has been described in the human suprarenal plexus. Both cortex and medulla also contain acetylcholinesterase (AChE)-positive axons that presumably reach the gland from the coeliac plexus: some synapse with ganglion cells in the zonae fasciculata and reticularis.

MICROSTRUCTURE

In section, the suprarenal gland has an outer cortex, which is yellowish in colour and forms the main mass, and a thin medulla, forming about one-tenth of the gland, which is dark red or greyish, depending on its content of blood (see Figs 72.4, 72.5). The medulla is completely enclosed by cortex, except at the hilum. The gland has a thick collagenous capsule from which trabeculae extend deep into the cortex. The capsule contains a rich arterial plexus which supplies branches to the gland.

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Suprarenal cortex

The suprarenal cortex consists of the zona glomerulosa, zona fasciculata and zona reticularis (Figs 72.4, 72.5). The outer subcapsular zona glomerulosa consists of a narrow region of small polyhedral cells in rounded clusters. The cells have deeply staining nuclei and a basophilic cytoplasm containing a few lipid droplets. Ultrastructurally, the cytoplasm displays abundant smooth endoplasmic reticulum, a feature typical of cells that synthesize steroids. The broader intermediate zona fasciculata consists of large polyhedral basophilic cells arranged in straight columns, two cells wide, with parallel fenestrated venous sinusoids between them. The cells contain many lipid droplets and large amounts of smooth endoplasmic reticulum. The innermost part of the cortex, the zona reticularis, consists of branching interconnected columns of rounded cells whose cytoplasm also contains smooth endoplasmic reticulum, many lysosomes and aggregates of brown lipofuscin pigment that accumulate with age.

Cortical cells produce several hormones and the cells of the zonae fasciculata and reticularis are also rich in ascorbic acid. Cells in the zona glomerulosa produce mineralocorticoids, e.g. aldosterone, which regulates electrolyte and water balance; cells in the zona fasciculata produce hormones maintaining carbohydrate balance (glucocorticoids) e.g. cortisol (hydrocortisone); cells in the zona reticularis produce sex hormones (progesterone, oestrogens and androgens). The cortex is essential to life and its complete removal is lethal without replacement therapy. It exerts considerable control over lymphocytes and lymphoid tissue: an increased secretion of corticosteroids can result in a marked reduction in lymphocyte numbers.

The deeper part of the zona fasciculata widens in pregnancy and in women of childbearing age in summer. Cortical atrophy in elderly males is greatest in the same region.

Suprarenal medulla

The suprarenal medulla is composed of groups and columns of chromaffin cells (phaeochromocytes) separated by wide venous sinusoids and supported by a network of reticular fibres. Chromaffin cells, so-called from their colour reaction to dichromate fixatives, form part of the neuroendocrine system and are functionally equivalent to postganglionic sympathetic neurones. They are neural crest derivatives and synthesize, store (as granules) and release the catecholamines noradrenaline (norepinephrine) and adrenaline (epinephrine) into the venous sinusoids. Release is under preganglionic sympathetic control, mediated by the sympathetic neurones that occur either singly or in small groups in the medulla.

The majority of chromaffin cells synthesize adrenaline and store it in small granules with a dense core. Less numerous noradrenaline-secreting cells have larger granules with a dense eccentric core. Some cells synthesize both hormones. Chromogranin proteins package catecholamines within the granules, which also contain enkephalins, opiate-like proteins that may have endogenous analgesic effects in some circumstances. All of the cells are large, with large nuclei and basophilic, faintly granular cytoplasm. They form single rows along the venous sinusoids. Sympathetic axon terminals synapse with the chromaffin cells on the surfaces that face away from the sinusoids.

The sinusoids are lined by fenestrated endothelium and drain to the central medullary vein and hilar suprarenal vein. Under normal circumstances, little adrenaline or noradrenaline is released; secretion is increased in response to fear, anger or stress. Unlike the cortex, the suprarenal medulla is not essential to life.

SUPRARENAL GLAND EXCISION

Removal of one or both suprarenal glands may be performed either through ‘open surgery’ or via a laparoscopic approach. There are essentially three ‘open surgical’ methods for removing the suprarenal glands. The posterior and lateral approaches involve removal of either the eleventh or twelfth ribs. The surgeon remains in the retroperitoneal plane and accesses the gland via the perirenal fat. This approach can be performed laparoscopically, but is difficult: landmarks are not easily identified because of the surrounding fat and the ‘workspace’ is frequently small. Not surprisingly, few surgeons employ this approach.

During laparoscopic surgery the anterior, transperitoneal approach is most commonly used. The patient is placed in the lateral decubitus position. On the left side, the splenic flexure is mobilized inferiorly, revealing the kidney. The lateral phrenicocolic ligament is then fully divided, which allows the spleen to be mobilized medially exposing the splenorenal ligament. Division of the splenorenal ligament (when the patient is in the lateral decubitus position) allows the spleen to ‘drop’ medially. This exposes the plane between the splenic hilum and medial border of the left kidney, and is where the pancreatic tail is identified as it runs to the hilum of the spleen. The renal fascia is divided to expose the suprarenal gland lying over the superomedial aspect of the upper pole of the kidney. On the right side, the right triangular ligament of the liver is divided, which allows the liver to be retracted caudally. In most individuals the inferior vena cava is easily identified behind the peritoneum lateral to the second part of the duodenum. The peritoneal reflection on the inferior border of the liver is divided from the inferior vena cava to the lateral border of the liver, exposing the suprarenal gland in the angle between the inferior vena cava and liver. The peritoneal reflection along the lateral aspect of the inferior vena cava is divided and the gland is then mobilized laterally exposing the suprarenal vein, which often emerges from the posterior aspect of the inferior vena cava. Once the suprarenal vein has been divided, the small middle suprarenal arteries, which run from the aorta to the gland behind the inferior vena cava, are easily identified. The gland is then usually mobilized very easily in a lateral direction. However, it can lie either behind the inferior vena cava or under the liver, in which case dissection at the junction of the liver and inferior vena cava often becomes very difficult.

In obese (or Cushingoid) patients, identification of a relatively normal sized suprarenal gland can be extremely difficult and time consuming. The suprarenal vein emerges from the lower medial border of the gland and it is often a very substantial structure. In contrast, the supplying arteries tend to be rather smaller in size and individual arteries are often difficult to identify during surgery.

The anterior open approach follows the procedure as described above through either a subcostal or a midline incision.

CHAPTER 73

Development of the peritoneal cavity, gastrointestinal tract and its adnexae

POSTPHARYNGEAL FOREGUT

The primitive gut is divided by head and tail folding into three main compartments. The foregut extends from the buccopharyngeal membrane to its continuation into the central midgut region via the cranial intestinal portal. The midgut extends between the intestinal portals, and in the early embryo is in wide communication with the yolk sac. The hindgut extends from the caudal intestinal portal to the cloacal membrane. The cranial end of the foregut, the embryonic pharynx, is intimately associated with head and neck development (see Ch. 35). The portion of foregut that passes dorsal to the pericardial cavity gives rise to the respiratory diverticulum and oesophagus within the thorax (see Chs 35 and 59). Caudal to the developing diaphragm, the enteric gut is conventionally subdivided into three embryological portions, fore- mid- and hindgut. There are no corresponding fundamental morphological and cytological distinctions between the three parts (Fig. 73.1), and so the foregut produces a portion of the duodenum, as does the midgut, and the midgut similarly produces large intestine, as does the hindgut. The differences between the portions of the gut develop as a result of interactions between the three embryonic tissue layers which give rise to the gut, namely the endodermal inner epithelium, the thick layer of splanchnopleuric mesenchyme, and the outer layer of proliferating splanchnopleuric coelomic epithelium.

Fig. 73.1 Major epithelial populations within the early embryo. The early gut tube is close to the notochord and neural tube dorsally. The splanchnopleuric layer of the intraembryonic coelomic epithelium is in contact with the foregut ventrally and laterally, with the midgut laterally and the hindgut ventrally and laterally.

The epithelial layer of the mucosa and connected ducts and glands are derived from the endodermal epithelium. The lamina propria and muscularis mucosa, the connective tissue of the submucosa, the muscularis externa and the external connective tissue are all derived from the splanchnopleuric mesenchyme. The outer peritoneal epithelium is derived from the splanchnopleuric coelomic epithelium.

Throughout the gut, blood vessels, lymphatics and lymph nodes develop from local populations of angiogenic mesenchyme. The nerves, which are distributed within the enteric and autonomic systems, are derived from the neural crest. There is a craniocaudal developmental gradient along the gut in that the stomach and small intestine develop in advance of the colon.

Figure 73.2 shows the gut in a stage 12 embryo in relation to the other developing viscera, especially the heart and liver. Figure 73.3 shows the overall development of the gut from stages 13–17. These diagrams should be compared. Figure 73.1 shows the fundamental relationship of the intraembryonic coelom to the developing gut.

Fig. 73.3 The shape of the endodermal epithelium of the gut at succeeding stages. The scale is constant illustrating the enormous growth of the gut over a 13-day period. **A**, stage 13; **B**, stage 14; **C**, stage 15; **D**, stage 16; and **E**, stage 17. Note the separation of the respiratory diverticulum, the

elongation of the foregut and expansion of the stomach, the formation of the hepatic and pancreatic diverticula, the lengthening of the midgut loop which protrudes into the umbilical cord, and the separation of the cloaca into enteric and allantoic portions.

(Modified from O'Rahilly and Müller. Developmental Stages in Human Embryos 1987 Carnegie Institution of Washington. Pub 637.)

All regions of the gut develop from epithelial/mesenchymal interactions which are dependent on the sequential expression of a range of basic and specific genes; on the regulation of the developmental clock, seen in all areas of development; on endogenous regulatory mechanisms and local environmental influences (Lebenthal 1989). Although all these factors pertain to the whole range of developing tissues, local differences in any one of these factors along the length of the developing gut promotes the differentiation of, for example, the gastric mucosa and hepatocytes; the rotation of the midgut; and the final disposition of the sessile portions of the fully formed gastrointestinal tract. The gut is functional prior to birth and able to interact with the extrauterine environment in preterm infants.

OESOPHAGUS

The oesophagus can be distinguished from the stomach at stage 13 (embryo 5 mm). It elongates during successive stages and its absolute length increases more rapidly than the embryo as a whole. Cranially it is invested by splanchnopleuric mesenchyme posterior to the developing trachea, and more caudally between the developing lungs and pericardioperitoneal canals posterior to the pericardium. (For details of tracheo-oesophageal fistulae see p. 1037). Caudal to the pericardium, the terminal, pregastric segment of the oesophagus has a short thick dorsal meso-oesophagus (from splanchnopleuric mesenchyme), while ventrally it is enclosed in the cranial stratum of the septum transversum mesenchyme. Each of the above are continuous caudally with their respective primitive dorsal and ventral mesogastria. Thus the oesophagus has only limited areas related to a primary coelomic epithelium. However, note the subsequent development of the para-oesophageal right and left pneumatoenteric recesses (see Fig. 73.7), the relation of the ventral aspect of the middle third of the oesophagus to the oblique sinus of the pericardium, and the relation of its lateral walls in the lower thorax to the mediastinal pleura. All the foregoing are secondary extensions from the primary coelom.

section (left column) and transverse section at the levels indicated by the arrows (right column). **D**, **E**, Three dimensional schematization of the lesser sac, dorsal and ventral mesogastria.

The oesophageal mucosa consists of two layers of cells by stage 15 (week 5), but the proliferation of the mucosa does not occlude the lumen at any time. The mucosa becomes ciliated at 10 weeks, and stratified squamous epithelium is present at the end of the 5th month: occasionally patches of ciliated epithelium may be present at birth. Circular muscle can be seen at stage 15 but longitudinal muscle has not been identified until stage 21. Neuroblasts can be demonstrated in the early stages; the myenteric plexuses have cholinesterase activity by 9.5 weeks and ganglion cells are differentiated by 13 weeks. It has been suggested that the oesophagus is capable of peristalsis in the first trimester. Oesophageal atresia is one of the more common obstructive conditions of the alimentary tract: fetuses swallow amniotic fluid, and so the condition may be indicated by polyhydramnios.

Oesophagus at birth

At birth the oesophagus extends 8–10 cm from the cricoid cartilage to the gastric cardiac orifice. It starts and ends one to two vertebrae higher than in the adult, extending from between the fourth to the sixth cervical vertebra to the level of the ninth thoracic vertebra (see Fig. 14.5). Its average diameter is 5 mm and it possesses the constrictions seen in the adult. The narrowest constriction is at its junction with the pharynx, where the inferior pharyngeal constrictor muscle functions to constrict the lumen: this region may be easily traumatized with instruments or catheters. In the neonate the mucosa may contain scattered areas of ciliated columnar epithelium, but these disappear soon after birth. Peristalsis along the oesophagus and at the lower oesophageal sphincter is immature at birth and results in frequent regurgitation of food in the newborn period. The pressure at the lower oesophageal sphincter approaches that of the adult at 3–6 weeks of age.

STOMACH

At the end of the fourth and beginning of the fifth week the stomach can be recognized as a fusiform dilation cranial to the wide opening of the midgut into the yolk sac (Figs 73.2 and 73.3). By the fifth week this opening has narrowed into a tubular vitelline intestinal duct, which soon loses its connection with the digestive tube. At this time the stomach is median in position and separated cranially from the pericardium by the septum transversum (see Fig. 73.5A), which extends caudally on to the cranial side of the vitelline intestinal duct and ventrally to the somatopleure. Dorsally, the stomach is related to the aorta and, reflecting the presence of the pleuroperitoneal canals on each side, is connected to the body wall by a short dorsal mesentery, the dorsal mesogastrium (see Fig. 73.6). The latter is directly continuous with the dorsal mesentery (mesenteron) of almost all of the remainder of the intestine, except its caudal short segment.

Fig. 73.6 Three-dimensional schematization of the major developmental sequences of the subdiaphragmatic embryonic and fetal gut, together with its associated major glands, peritoneum and mesenteries: left anterolateral aspect. The development sequence **A–F** spans 1.5 months to the perinatal period. Three-dimensional schematization of the major developmental sequences of the subdiaphragmatic embryonic and fetal gut, together with its associated major glands, peritoneum and mesenteries: left anterolateral aspect. The development sequence **A–F** spans 1.5 months to the perinatal period. **H** denotes the general disposition of the remaining viscera and mesenteric roots with their lines of attachment and principal contained vessels, which approximate to the adult state for comparison.

In human embryos of 10 mm (stage 15–16), the characteristic gastric curvatures are already recognizable. Growth is more active along the dorsal border of the viscus: its convexity markedly increases and the rudimentary fundus appears. Because of more rapid growth along the dorsal border, the pyloric end of the stomach turns ventrally and the concave lesser curvature becomes apparent (Fig. 73.3; see also Fig. 73.6). The stomach is now displaced to the left of the median plane and apparently becomes physically rotated, which means that its original right surface becomes dorsal and its left surface becomes ventral. Accordingly the right vagus is distributed mainly to the dorsal, and the left vagus mainly to the ventral, surfaces of the stomach. The dorsal mesogastrium increases in depth and becomes folded on itself. The ventral mesogastrium becomes more coronal than sagittal. The pancreaticoenteric recess (see Fig. 73.7B(ii)), hitherto usually described as a simple depression on the right side of the dorsal mesogastrium, becomes dorsal to the stomach and excavates downwards and to the left between the folded layers. It may now be termed the inferior recess of the bursa omentalis. Put simply, the stomach has undergone two ‘rotations’. The first is 90° clockwise, viewed from the cranial end, the second is 90° clockwise, about an anteroposterior axis. The displacement, morphological changes and apparent ‘rotation’ of the stomach have been attributed variously to its own and surrounding differential growth changes, extension of the pancreaticoenteric recess with changes in its mesenchymal walls, and pressure, particularly that exerted by the rapidly growing liver.

Mucosa

Mucosal and submucosal development can be seen in the eighth to ninth weeks. No villi form in the stomach, unlike other regions of the gut; instead glandular pits can be seen in the body and fundus. These develop in the pylorus and cardia by weeks 10 and 11 when parietal cells can be demonstrated. Although acid secretion has not been demonstrated in the fetal stomach before 32 weeks’ gestation, preterm infants from 26 weeks’ gestation onwards are able to secrete acid soon after birth. Intrinsic factor has been detected after 11 weeks. This increases from the 14th to 25th week, at which time the pylorus, which contains more parietal cells than it does in the adult, also contains a relatively larger quantity of intrinsic factor. The significance of the early production of intrinsic factor and the late production of acid by the parietal cells is not known. Chief cells can be identified after weeks 12–13, although they cannot be demonstrated to contain pepsinogen until term. Mucous neck cells actively produce mucus from week 16. Gastrin-producing cells have been demonstrated in the antrum between 19 and 20 weeks and gastrin levels have been measured in cord blood and in the plasma at term. Cord serum contains gastrin levels 2–3 times higher than those in maternal serum.

Muscularis

The stomach muscularis externa develops its circular layer at 8–9 weeks, when neural plexuses are developing in the body and fundus. The longitudinal muscle develops slightly later. The pyloric musculature is thicker than the rest of the stomach: in general, the thickness of the total musculature of the stomach at term is reduced compared to the adult.

Serosa

The serosa of the stomach is derived from the splanchnopleuric coelomic epithelium. No part of this serosa undergoes absorption. The original left side of the gastric serosa faces the greater sac, the right side faces the lesser sac.

Stomach at birth

The stomach exhibits fetal characteristics until just after birth when the initiation of pulmonary ventilation, the reflexes of coughing and swallowing, and crying, cause the ingestion of large amounts of air and liquid. Once postnatal swallowing has started the stomach distends to four or five times its contracted state, and shifts its position in relation to the state of expansion and contraction of the other abdominal viscera, and to the position of the body. In the neonate, the anterior surface of the stomach is generally covered by the left lobe of the liver, which extends nearly as far as the spleen (see Fig.

14.4). Only a small portion of the greater curvature of the stomach is visible anteriorly. The capacity of the stomach is 30–35 ml in the full-term neonate, rising to 75 ml in the second week and 100 ml by the fourth week (adult capacity is on average 1000 ml). The mucosa and submucosa are relatively thicker than in the adult, however, the muscularis is only moderately developed and peristalsis is not coordinated. At birth gastric acid secretion is low, which means that gastric pH is high for the first 12 postnatal hours. It falls rapidly with the onset of gastric acid secretion, usually after the first feed. Acid secretion usually remains low for the first 10 days postnatally. Gastric emptying and transit times are delayed in the neonate.

DUODENUM

The duodenum develops from the caudal part of the foregut and the cranial part of the midgut. A ventral mesoduodenum, which is continuous cranially with the ventral mesogastrium, is attached only to the foregut portion. Posteriorly the duodenum has a thick dorsal mesoduodenum which is continuous with the dorsal mesogastrium cranially and the dorsal mesentery of the midgut caudally. Anteriorly the extreme caudal edge of the ventral mesentery of the foregut extends onto the short initial segment of the duodenum. The liver arises as a diverticulum from the ventral surface of the duodenum at the foregut–midgut junction, i.e. where the midgut is continuous with the yolk sac wall (the cranial intestinal portal). The ventral pancreatic bud also arises from this diverticulum. The dorsal pancreatic bud evaginates posteriorly into the dorsal mesoduodenum slightly more cranially than the hepatic diverticulum. The rotation, differential growth, and cavitations related to the developing stomach and omenta cause corresponding movements in the duodenum, which forms a loop directed to the right, with its original right side now adjacent to the posterior abdominal wall (see Fig. 73.6). This shift is compounded by the migration of the bile duct and ventral pancreatic duct around the duodenal wall. Their origin shifts until it reaches the medial wall of the second part of the fully formed duodenum: the bile duct passes posteriorly to the duodenum and travels in the free edge of the ventral duodenum and ventral mesogastrium. Local adherence and subsequent absorption of part of the duodenal serosa and the parietal peritoneum results in almost the whole of the duodenum, other than a short initial segment, becoming retroperitoneal (sessile).

Duodenal atresia is a developmental defect found in 1 in 5000 live births (Whittle 1999). It may be associated with an annular pancreas which may compress the duodenum externally (20% of duodenal atresia), or with abnormalities of the bile duct. In 40–60% of cases the atresia is complete and pancreatic tissue fills the lumen. The condition can be diagnosed on ultrasound examination, which reveals a typical double bubble appearance caused by fluid enlarging the stomach and the proximal duodenum.

Polyhydramnios is invariably present and often the indication for the scan. Duodenal atresia commonly occurs with other developmental defects, e.g. cardiac and skeletal anomalies and in Down’s syndrome.

DORSAL AND VENTRAL MESENTERIES OF THE FOREGUT

The epithelium of the stomach and duodenum does not rotate relative to its investing mesenchyme. The rotation includes the coelomic epithelial walls of the pericardioperitoneal canals, which are on each side of the stomach and duodenum and form its serosa, and the elongating dorsal mesogastrium or the much shorter dorsal mesoduodenum. A ventral mesogastrium can be seen when the distance between the stomach and liver increases. Whereas the dorsal mesogastrium takes origin from the posterior body wall in the midline, its connection to the greater curvature of the stomach, which lengthens as the stomach grows, becomes directed to the left as the stomach undergoes its first rotation. With the second rotation a portion of the dorsal mesogastrium now faces caudally (see Fig. 73.6). The ventral mesogastrium remains as a double layer of coelomic epithelium which encloses mesenchyme and forms the lesser omentum (see Fig. 73.7).

Movement of the stomach is associated with an extensive lengthening of the dorsal mesogastrium, which becomes the greater omentum, and which now, from its posterior origin, droops caudally over the small intestine, then folds back anteriorly and ascends to the greater curvature of the stomach. The greater omentum is therefore composed of a fold containing, technically, four layers of peritoneum. The dorsal mesoduodenum, or suspensory ligament of the duodenum, is a much thicker structure, and it fixes the position of the duodenum when the rest of the midgut and its dorsal mesentery elongate and pass into the umbilical cord. For a more detailed account of this process see page 1216.

SPECIAL GLANDS OF THE POSTPHARYNGEAL FOREGUT

Pancreas

The pancreas develops from two evaginations of the foregut which fuse to form a single organ. A dorsal pancreatic bud can be seen in stage 13 embryos as a thickening of the endodermal tube which proliferates into the dorsal mesogastrium (Figs 73.3 and 73.4). A ventral pancreatic bud evaginates in close proximity to the liver primordium but cannot be clearly identified until stage 14, when it appears as an evagination of the bile duct itself. At stage 16 (5 weeks) differential growth of the wall of the duodenum results in movement of the ventral pancreatic bud and the bile duct to the right side and ultimately to a dorsal position. It is not clear whether there is a corresponding shift of mesenchyme during this rotation. However, the ventral pancreatic bud and the bile duct rotate from a position within the ventral mesogastrium (ventral mesoduodenum) to one in the dorsal mesogastrium (dorsal mesoduodenum) which is destined to become fixed onto the posterior abdominal wall. By stage 17 the ventral and dorsal pancreatic buds have fused, although the origin of the ventral bud from the bile duct is still obvious. Three-dimensional reconstruction of the ventral and dorsal pancreatic buds have confirmed that the dorsal pancreatic bud forms the anterior part of the head, the body and the tail of the pancreas and the ventral pancreatic bud forms the posterior part of the head and the posterior part of the uncinate process. The ventral pancreatic bud does not form all of the uncinate process (Collins 2002).

Fig. 73.4 Development of the pancreas in a human embryo. **A**, An early stage, 7.5 mm embryo; lateral view. **B**, A later stage, 14.5 mm embryo; ventral view.

The developing pancreatic ducts usually fuse in such a way that most of the dorsal duct drains into the proximal part of the ventral duct (Figs 73.3 and 73.4). The proximal portion of the dorsal duct usually persists as an accessory duct. The fusion of the ducts takes place late in development or in the postnatal period: 85% of infants have patent accessory ducts as compared to 40% of adults. Fusion may not occur in 10% of individuals, in which case separate drainage into the duodenum is maintained, so-called pancreatic divisum. Failure of the ventral pancreatic diverticulum to migrate will result in an annular pancreas which may constrict the duodenum locally.

The ventral pancreas does not always extend anterior to the superior mesenteric vein but remains related to its right lateral surface. Initially the body of the pancreas extends into the dorsal mesoduodenum and then cranially into the dorsal mesogastrium. As the stomach rotates, this portion of the dorsal mesogastrium is directed to the left forming the posterior wall of the lesser sac. The posterior layer of this portion of dorsal mesogastrium fuses with the parietal layer of the coelom wall (peritoneum) and the pancreas becomes mainly retroperitoneal (see Fig. 73.7C). The region of fusion of the dorsal mesogastrium does not extend so far left as to include the tail of the pancreas which passes into the lienorenal (splenorenal) ligament. The anterior border of the pancreas later provides the main line of attachment for the posterior leaves of the greater omentum.

Cellular development of the pancreas

The early specification of pancreatic endoderm involves the proximity of the notochord to the dorsal endoderm, which locally represses the expression of Shh transcription factor. Endoderm caudal to the pancreatic region does not respond to notochordal signals. The ventral pancreatic endoderm does not seem to undergo the same induction. Pancreatic mesenchyme is derived from two regions. The mesenchyme which surrounds the dorsal pancreatic bud proliferates from the splanchnopleuric coelomic epithelium of the medial walls of the pericardioperitoneal canals, whereas the ventral pancreatic bud is invested by septum transversum mesenchyme and by mesenchyme derived from the lower ventral walls of the pericardioperitoneal canals.

The primitive endodermal ductal epithelium provides the stem cell population for all the secretory cells of the pancreas. Initially these endocrine cells are located in the duct walls or in buds developing from them, and later they accumulate in pancreatic islets. The remaining primitive duct cells will differentiate into definitive ductal cells. In the fetus they develop microvilli and cilia but lack the lateral interdigitations seen in the adult. Branches of the main duct become interlobular ductules which terminate as blind ending acini or as tubular, acinar elements.

The ductal branching pattern and acinar structure of the pancreas is determined by the pancreatic mesenchyme. This mesenchyme gives rise to connective tissue between the ducts which, in the fetus, appears to be important in stimulating pancreatic proliferation and maintaining the relative proportions of acinar, α and β cells during development. It also provides cell lines for smooth muscle within the pancreas. Angiogenic mesenchyme invades the developing gland to produce blood and lymphatic vessels.

The process of islet differentiation is divided into two phases (Collins 2002). Phase I, characterized by proliferation of polyhormonal cells, occurs from weeks 9–15. Phase II, characterized by differentiation of monohormonal cells, is seen from week 16 onwards. The β cells, producing insulin and amylin, differentiate first, followed by α-cells which produce glucagon. The δ cells which produce somatostatin are seen after 30 weeks. The dorsal bud gives rise mostly to α cells, and the ventral bud to most of the pancreatic polypeptide producing cells. The β cells develop from the duct epithelium throughout development and into the neonatal period. Later, in weeks 10–15, some of the primitive ducts differentiate into acinar cells in which zymogen granules or acinar cell markers can be detected at 12–16 weeks.

The pancreas in the neonate has all of the normal subdivisions of the adult. The head is proportionately large in the newborn and there is a smooth continuation between the body and the tail. The inferior border of the head of the pancreas is found at the level of the second lumbar vertebra. The body and tail pass cranially and to the left, and the tail is in contact with the spleen (see Fig. 14.4).

Liver

The liver is one of the most precocious embryonic organs and is the main centre for haemopoiesis in the fetus. It develops from an endodermal evagination of the foregut and from septum transversum mesenchyme, which is derived from the proliferating coelomic epithelium in the protocardiac region. The development of the liver is intimately related to the development of the heart. The vitelline veins, succeeded by the umbilical veins passing to the sinus venosus are disrupted by the enlarging septum transversum to form a hepatic plexus, the forerunner of the hepatic sinusoids. (See Collins, 2002 for a detailed account of hepatic development.)

Early liver development

As the head fold and early intraembryonic coelom form, the ventral parietal wall of the pericardial cavity gives rise to populations of cells termed precardiac or cardiac mesenchyme. Hepatic endoderm is induced to proliferate by this mesenchyme, although all portions of the early heart tube, truncus arteriosus, atria, ventricle, both endocardium and myocardium, have hepatic induction potency which is tissue-specific, but not species-specific. As the heart and foregut become separated by the accumulation of the cardiac mesenchyme, the mesenchyme itself is renamed septum transversum. It is seen as a ventral mass, caudal to the heart, which passes dorsally on each side of the developing gut to join the mesenchyme proliferating from the walls of the pericardioperitoneal canals. The majority of the cells within the septum transversum are destined to become hepatic mesenchyme.

In the stage 11 embryo the location of the hepatic endoderm has been identified at the superior boundary of the rostral intestinal portal. By stage 12, the hepatic endodermal primordium is directed ventrally and begins to proliferate as a diverticulum. There are two parts: a caudal part, which will produce the cystic duct and gallbladder, and a cranial part which forms the liver biliary system (Figs 73.3, 73.5A). The cells start to express liver-specific molecular markers and glycogen storage.

Around the cranial portion of the hepatic diverticulum the basal lamina is progressively disrupted and individual epithelial cells migrate into the surrounding septum transversum mesenchyme. The previously smooth contour of the diverticulum merges into columnar extensions of endoderm, the epithelial trabeculae, which stimulate the hepatic mesenchymal cells to form blood islands and endothelium. The advance of the endodermal epithelial cells promotes the conversion of progressively more hepatic mesenchyme into endothelium and blood cells, and only a little remains to form the scanty liver capsule and interlobular connective tissue. This invasion by the hepatic epithelium is completed in stage 13, when it approaches the caudal surface of the pericardial cavity, and is separated from it only by a thin lamina of mesenchyme which will give rise to part of the diaphragm.

During this early phase of development the liver is far more highly vascularized than the rest of the gut. The hepatic capillary plexus is connected bilaterally with the right and left vitelline veins. Dorsolaterally they empty by multiple channels into enlarged hepatocardiac channels, which lead to the right and left horns of the sinus venosus (see Fig. 73.9); usually the channel on the right side is most developed. Both left and right channels bulge into the pericardioperitoneal canals, forming sites for the exchange of fluid from the coelom into the vascular channels. The growth of the hepatic tissue in these regions is sometimes referred to as the left and right horns of the liver.

Fig. 73.9 Development of the vitelline, umbilical and terminal cardinal vein complexes: the early symmetric condition. **A**, Early symmetrical arrangement of cardinal and umbilical veins entering the sinus venosus, and blood from the yolk sac passing via vitelline veins through anastomoses forming in the septum transversum mesenchyme (green). **B**, The developing duodenum is surrounded by transverse duodenal intervitelline anastomoses. Changes in the developing gut and umbilical veins cause shifts in the routes taken by venous blood flowing to the sinus venosus.

The liver remains proportionately large during its development and constitutes a sizeable organ dorsal to the heart at stage 14 then more caudally placed by stage 16. By this stage hepatic ducts can be seen separating the hepatic epithelium from the extrahepatic biliary system, but even at stage 17 the ducts do not penetrate far into the liver.

Maturation of the liver

At 3 months' gestation, the liver almost fills the abdominal cavity and its left lobe is nearly as large as its right. When the haematopoietic activity of the liver is assumed by the spleen and bone marrow, the left lobe undergoes some degeneration and becomes smaller than the right. The liver remains relatively larger than in the adult throughout the remainder of gestation. In the neonate it constitutes 4% of the body weight, compared to 2.5–3.5% in adults. It is in contact with the greater part of the diaphragm and extends below the costal margin anteriorly, and in some cases to within 1 cm of the iliac crest posteriorly. The left lobe covers much of the anterior surface of the stomach and constitutes nearly one-third of the liver (see Fig. 14.4). Although its haemopoietic functions cease before birth its enzymatic and synthetic functions are not completely mature at birth.

Development of intrahepatic biliary ducts

The development of the intrahepatic biliary ducts follows the branching pattern of the portal vein radicles (Collins 2002). The cranial hepatic diverticulum gives rise to the liver hepatocytes, the intrahepatic large bile ducts (right and left hepatic ducts, segmental ducts, area ducts and their first branches) and the small bile ducts (septal bile ducts, interlobular ducts and bile ductules). The portal and hepatic veins arise together from the vitelline veins. Early in development the accumulation of mesenchyme around these veins is similar, whereas later mesenchyme increases around the portal veins. This is a prerequisite for bile duct development. Primitive hepatocytes surround the portal vein branches and associated mesenchyme and form a sleeve of cells termed the ductal plate. Portions of the ductal plate divide to produce lines of epithelial cells which migrate close to a portal vein branch where they differentiate into bile ducts. As the bile ducts develop, angiogenic mesenchymal cells form blood vessels which connect to the hepatic artery from 10 weeks. Thus the portal triads are patterned by the portal vein radicles which initially induce bile duct formation and then artery formation. The development of the biliary system extends from the hilum to the periphery. Abnormalities of the biliary tree are associated with abnormalities of the branching pattern of the portal vein. The developing bile ducts remain patent throughout development; the solid stage of ductal development previously promulgated has been refuted. Atresia of the extrahepatic bile ducts has been noted, often in association with extrahepatic atresia. The cause of this condition is not clear; inflammatory process may be involved, although some cases have features of ductal plate malformation (Howard 2002).

Development of extrahepatic biliary ducts

The caudal part of the hepatic endodermal diverticulum forms the extrahepatic biliary system, the common hepatic duct, gallbladder, cystic duct and common bile duct.

The bile duct, which originated from the ventral wall of the foregut (now duodenum), migrates with the ventral pancreatic bud first to the right and then dorsomedially into the dorsal mesoduodenum. The right and left hepatic ducts arise from the cranial end of the common hepatic duct from 12 weeks’ gestation.

Atresia of the extrahepatic bile ducts in neonates occurs alone or in conjunction with a range of other anomalies, including situs inversus, malrotation, polysplenia and cardiac defects. In such cases the intrahepatic bile ducts have a mature tubular shape but also show features of ductal plate malformation.

In the neonate the gallbladder has a smaller peritoneal surface than in the adult, and its fundus often does not extend to the liver margin. It is generally embedded in the liver and in some cases may be covered by bands of liver. After the second year the gallbladder assumes the relative size it has in the adult.

MIDGUT

The midgut forms the third and fourth parts of the duodenum, jejunum, ileum and two-thirds of the way along the transverse colon: its development produces most of the small and a portion of the large intestine. In embryos of stages 10 and 11 it extends from the cranial to the caudal intestinal portals and communicates directly with the yolk sac over its entire length. Although it has a dorsal wall, at these stages the lateral walls have not yet formed. By stage 12 the connection with the yolk sac has narrowed such that the midgut has ventral walls cranially and caudally. This connection is reduced to a yolk stalk containing the vitellointestinal duct during stage 13, at which time the yolk sac appears as a sphere in front of the embryo. Posterior to the midgut the splanchnopleuric coelomic epithelia converge forming the dorsal mesentery. Ventrolaterally the intraembryonic coelom is in wide communication with the extraembryonic coelom. At stage 14 the midgut has increased in length more than the axial length of the embryonic body and, with elongation of the dorsal mesentery, it bulges ventrally, deviating from the median plane. For all these stages see Figure 73.3.

PRIMARY INTESTINAL (OR MIDGUT) LOOP

The midgut loop can first be seen at stage 15 when a bulge, the caecal bud, can be discerned on the lower limb of the loop, caudal to the yolk stalk (which arises from the apex or summit of the loop) (Fig. 73.3). Later, the original proximal limb of the loop moves to the right and the distal limb to the left (Fig. 73.3C). The longest portion of the dorsal mesentery is at the level of the yolk stalk: there is less relative lengthening near the caudal end of the duodenum or the cranial half of the colon. The midgut extends into the umbilical coelom having already rotated through an angle of 90° (anticlockwise viewed from the ventral aspect). This relative position is approximately maintained so long as the protrusion persists, during which time the proximal limb which forms the small intestine elongates greatly. It becomes coiled, and its adjacent mesentery adopts a pleated appearance. The origin of the root of the mesentery is initially both median and vertical, while at its intestinal attachment it is elongated like a ruffle and folded along a horizontal zone. The mesenteric sheet and its contained vessels has spiralled through 90°. The distal, colic, part of the loop elongates less rapidly and has no tendency to become coiled. By the time the fetus has attained a length of 40 mm (10 weeks), the peritoneal cavity has enlarged and the relative size of the liver and mesonephros is much less. The re-entry of the gut occurs rapidly and in a particular sequence during which it continues the process of rotation. The proximal loop returns first, with the jejunum mainly on the left and the ileum mainly on the right of the subhepatic abdominal cavity. As they re-enter the abdominal cavity the coils of jejunum and ileum slide inwards over the right aspect of the descending mesocolon, and so displace the descending colon to the left. The transverse colon passes superiorly to the origin of the root of the mesentery (Fig. 73.6). The caecum is the last to re-enter and at first lies on coils of ileum on the right. Later development of the colon leads to its elongation and to the establishment of the hepatic and splenic flexures. A timetable for intestinal rotation in staged human embryos is given by Kim et al (2003).

Anomalies of midgut rotation

If the midgut loop fails to return to the abdominal cavity at the appropriate time a range of ventral defects can result. Failure of obliteration of the vitello-intestinal duct connecting the midgut to the yolk sac results in Meckel’s diverticulum. This may present as a short segment of vitelline duct attached to the original ventral side of the ileum; it may remain attached to the umbilicus as a fistula; or it may remain as a ligamentous attachment to the umbilicus.

An umbilical hernia occurs when loops of gut protrude into a widened umbilical cord at term. The degree of protuberance may increase when the infant cries, which raises the intra-abdominal pressure: these hernias usually resolve without treatment. Exomphalos is a ventral wall defect with midline herniation of the intra-abdominal contents into the base of the umbilical cord. Herniated viscera are covered by the peritoneum internally and amnion externally. The omphalocele so formed ranges in size from a large umbilical hernia to a very large mass containing most of the visceral organs. Even after the exomphalos has been repaired these babies will still have a deficient anterior abdominal wall.

Gastroschisis is a para-umbilical defect of the anterior abdominal wall associated with evisceration of the abdominal organs. The organs are not enclosed in membranes, thus gastroschisis can be detected by prenatal ultrasonography and differentiated from exomphalos. Gastro-schisis is thought to result from periumbilical ischaemia caused by vascular compromise of either the umbilical vein or arteries. The incidence of this condition appears to be increasing, especially in babies born to young women less than 20 years old (Whittle 1999).

Congenital volvulus arises if the midgut loop does not rotate appropriately. A number of types of this condition are identified. Left-sided colon occurs if the midgut loop has not rotated at all; mixed rotation results in the caecum lying inferior to the pylorus; failure of attachment of the peritoneum appropriately may result in the small intestine being attached at only two points on the posterior abdominal wall. All of these arrangements lead to a risk of volvulus, which may result in necrosis of the gut.

The position and configuration of the duodenal loop are of particular importance in children. The normal duodenal loop has a U-shaped configuration. The suspensory ligament of the duodenum (ligament of Treitz) is usually found to the left of the body of the first or second lumbar vertebral body after normal gut rotation: any other position of this ligament may indicate some degree of gut malrotation. On barium studies the duodenojejunal flexure should thus lie to the left of the upper lumbar spine at the level of the pylorus.

If the caecum has remained in the right upper quadrant it may become fixed in that position by peritoneal attachments passing to the right, the so called Ladd's bands. These may compress the underlying duodenum and give rise to duodenal stenosis. The high positioning of the caecum close to the duodenal jejunal flexure, in some cases in the midline, is associated with later development of volvulus.

The identification of intestinal malrotation can be made by X-ray investigation. However, ultrasonography has the advantage of showing the position of the superior mesenteric vein and artery. The vein should lie to the right of the artery. Most cases of volvulus will show inversion of this normal relationship, but malrotation can occur with apparently normally related vessels, particularly in malrotation with bowel obstruction due to Ladd's bands and not volvulus.

UMBILICAL CORD

During the period when the midgut loop protrudes into the umbilical coelom, the edges of the ventral body wall are becoming relatively closer, forming a more discrete root for the umbilical cord. Somatic mesenchyme, which will form the ventral body wall musculature, migrates into the somatopleuric mesenchyme and passes ventrally toward the midline. The umbilical cord (see p. 181) forms all of the ventral body wall between the pericardial bulge and the developing external genitalia. It encloses a portion of the extraembryonic coelom, the umbilical coelom, into which midgut loop protrudes. When the midgut loop is abruptly returned to the abdominal cavity the more recognizable umbilical cord forms. The vitellointestinal duct and vessels involute. The cranial end of the allantois becomes thinned and its lumen partially obliterated, and it forms the urachus. The mesenchymal core of the umbilical cord is derived by coalescence from somatopleuric amniotic mesenchyme, splanchnopleuric vitellointestinal (yolk sac) mesenchyme, and splanchnopleuric allantoic (connecting stalk) mesenchyme. These various layers become fused and are gradually transformed into the viscid, mucoid connective tissue (Wharton’s jelly) which characterizes the more mature cord. The changes in the circulatory system result in a large cranially oriented left umbilical vein (the right umbilical vein regresses), and two spirally disposed umbilical arteries (see p. 181).

MATURATION OF THE SMALL INTESTINE

Mucosa

The exact timing of the cellular morphogenesis of the gut is difficult to establish, especially as it undergoes a proximodistal gradient in maturation. Developmental differences between parts of the small intestine or colon have not yet been correlated with age. The endodermal cells of the small intestine proliferate and form a layer some three to four cells thick with mitotic figures throughout. From 7 weeks, blunt projections of the endoderm have begun to form in the duodenum and proximal jejunum; these are the developing villi which increase in length until in the duodenum the lumen becomes difficult to discern. The concept of occlusion of the lumen and recanalization which is described in many accounts of development does not match the cytodifferentiation which occurs in the gut epithelia. Thus it is no longer thought that there is secondary recanalization of the gut lumen. By 9 weeks the duodenum, jejunum and proximal ileum have villi and the remaining distal portion of ileum develops villi by 11 weeks. The villi are covered by a simple epithelium. Primitive crypts, epithelial downgrowths into the mesenchyme between the villi, appear between 10 and 12 weeks similarly along a craniocaudal progression. Brunner’s glands are present in the duodenum from 15 weeks and the muscularis mucosa can be seen in the small intestine from 18 weeks.

Whereas mitotic figures are initially seen throughout the endodermal layer of the small intestine prior to villus formation, by 10–12 weeks they are limited to the intervillous regions and the developing crypts. It is believed that an ‘adult’ turnover of cells may exist when rounded-up cells can be observed at the villus tips, in position for exfoliation. The absorptive enterocytes have microvilli at their apical borders before 9 weeks. An apical tubular system appears at this time composed of deep invaginations of the apical plasma membrane and membrane-bound vesicles and tubules; many lysosomal elements (meconium corpuscles) appear in the apical cytoplasm. These latter features are more developed in the ileum than jejunum, are most prominent at 16 weeks, and diminish by 21 weeks. There are abundant deposits of glycogen in the fetal epithelial cells, and it has been suggested that prior to the appearance of hepatic glycogen the intestinal epithelium serves as a major glycogen store. Goblet cells are present in small numbers by 8 weeks, Paneth's cells differentiate at the base of the crypts in weeks 11 and 12, and enteroendocrine cells appear between weeks 9 and 11. M cells (membrane or microfold cells) are present from 14 weeks.

Meconium can be detected in the lumen of the intestine by the 16th week. It is derived from swallowed amniotic fluid, which contains vernix and cellular debris, salivary, biliary, pancreatic and intestinal secretions, and sloughed enterocytes. As the mixture passes along the gut, water and solutes are removed and cellular debris and proteins concentrated. Meconium contains enzymes from the pancreas and proximal intestine in higher concentrations in preterm than full-term babies.

Muscularis layer

The muscularis layer is derived from the splanchnopleuric mesenchyme as it is in other parts of the gut. Longitudinal muscle can be seen from 12 weeks. At 26–30 weeks the gut shows contractions without regular periodicity; from 30–33 weeks repetitive groups of regular contractions have been seen in preterm neonates.

Serosa

The small intestine possesses only a dorsal mesentery. The movement of the root of this dorsal mesentery, and the massive lengthening of its enteric border in order to match the longitudinal growth of the gut tube, reflect the spiralizing of the midgut loop in the umbilical coelom. The specific regions of adherence of the serosa and parietal peritoneum of the small intestine in the peritoneal cavity are given on page 1216.

Small intestine at birth

In the neonate the small intestine forms an oval-shaped mass with its greater diameter transversely orientated in the abdomen, rather than vertically as in the adult. The mass of the small intestine inferior to the umbilicus is compressed by the urinary bladder, which is anterior at this point. The small intestine is 300–350 cm long at birth and its width when empty is 1–1.5 cm. The ratio between the length of the small and large intestine at birth is similar to the adult ratio. The mucosa and submucosa are fairly well developed and villi are present throughout the small intestine, however, some epithelial differentiation is incomplete. The muscularis is very thin, particularly the longitudinal layer, and there is little elastic tissue in the wall. There are few or no circular folds in the small intestine, and the jejunum and ileum have little fat in their mesentery.

PRIMITIVE HINDGUT

Just as the foregut has an extensive, ventral endodermal diverticulum which contributes to a system separate from the gut, so too the hindgut has a ventral diverticulum, the allantois, destined for a different system. However, unlike the respiratory diverticulum of the foregut, the allantois is formed very early in development, prior even to formation of the embryonic endoderm and tail folding. With the reorganization of the caudal region of the embryo at stage 10, part of the allantois is drawn into the body cavity. The early embryonic hindgut thus consists of a dorsal tubular region extending from the caudal intestinal portal to the cloacal membrane, and a ventral blind-ending allantois extending from the cloacal region into the connecting stalk. The slightly dilated cavity, lined by endoderm, that cranially receives the enteric hindgut proper and the root of the allantoenteric diverticulum is termed the endodermal cloaca. It is closed ventrally by the cloacal membrane (endoderm opposed to proctodeal ectoderm), and it also has, transiently, a small recess of endoderm in the root of the tail, the postanal gut. As elsewhere, the hindgut, allantois and endodermal cloaca are encased in splanchnopleuric mesenchyme. Proliferation of the mesenchyme and endoderm in the angle of the junction of hindgut and allantois produces a urorectal septum (see Fig. 78.4B). Continued proliferation of the urorectal septum and elongation of the endodermal structures thrusts the endodermal epithelium towards the cloacal membrane with which it fuses centrally, separating the presumptive rectum and upper anal canal (dorsally) from the presumptive urinary bladder and urogenital sinus (ventrally) (see Fig. 78.4C). The cloacal membrane is thus divided into anal (dorsal) and urogenital (ventral) membranes. The nodal centre of division is the site of the future perineal body, the functional centre of the perineum. Details of the development of the allantoic hindgut are given on page 1322.

ENTERIC HINDGUT

The development of the large intestine, whether derived from mid- or hindgut, seems to be similar. The proximal end of the colon can be first identified at stage 15 when an enlargement of a local portion of gut on the caudal limb of the midgut loop defines the developing caecum. An evagination of the distal portion of the caecum forms the vermiform appendix at stage 17 (Fig. 73.3). Apart from the embryonic studies of Streeter (1942) there is little information about the development of the large intestine in humans. The early endodermal lining of the colon appears stratified, and mitoses occur throughout the layers. A series of longitudinal folds arise initially at the rectum and caecum and later in the regions of colon between these two points. The folds segment into villi with new villi forming between. The developing mucosa invaginates into the underlying mesenchyme between the villi to form glands which increase in number by splitting longitudinally from the base upwards. The villi gradually diminish in size and are absent by the time of birth.

MATURATION OF THE LARGE INTESTINE

The similarity of development of the small and large intestines is further mirrored in their cytological differentiation. Fetal gut from 11 weeks shows dipeptidase activity in the colon as well as in the small intestine. Throughout preterm development meconium corpuscles are seen in the colon and in the small intestine: they are believed to be the phago-cytosed remains of neighbouring cells which have died as a result of programmed cell death.

There is little direct evidence of colonic function in the human fetus and neonate. However, the specific results of mammalian studies are being correlated to human studies where possible. A number of distinct and important differences between the function of adult and fetal colon have been reported.

Mucosa

The absorption of glucose and amino acids does not take place through the colonic mucosa in adult life, but there is evidence of direct absorption of these nutrients during development. At birth the normal cycle of bile acids is not mature. In the adult, bile is secreted by the liver, stored in the gallbladder and then secreted into the intestine, where it is absorbed by the jejunum and ileum. In the fetus and neonate, the transport of bile acids by an active process from the ileum does not occur, and so bile salts pass on into the colon. In the adult the presence of bile salts in the colon stimulates the secretion of water and electrolytes which results in diarrhoeal syndrome; however, the fetal and neonatal colon seems protected from this effect. The colon is not considered a site of significant nutrient absorption in the adult, and yet neonates are unable to assimilate the full lactose load of a normal breast feed from the small intestine and a large proportion of it may be absorbed from the colon. Thus it appears that the colon fulfills a slightly different role in the preterm and neonatal period, conserving nutrient absorption and minimizing fluid loss until the neonate has adjusted to extrauterine life, oral feeding, and the establishment of the symbiotic bacterial flora.

Muscularis

The muscularis is present and functioning by the eighth week, when peristaltic waves have been observed. The specific orientation of the longitudinal muscle layer into taeniae coli occurs in the 11th to 12th weeks when haustra appear. The enteric nerves are present in Meissner’s and Auerbach’s plexuses at 8 and 12 weeks respectively: there is a craniocaudal migration of neurones into the gut wall. A normal distribution of ganglion cells has been noted in preterm babies of 24 weeks, although there is a region devoid of ganglia just above the anal valves. Abnormal migration of neural crest cells to the gut may give rise to Hirschsprung’s disease (see below). Puborectalis appears in 20–30 mm embryos, following opening of the anal membrane.

Serosa

The development of the serosa of the intestine is considered with the development of the peritoneal cavity (see below).

Colon at birth

In the neonate the colon is typically 66 cm long and averages 1 cm in width. The caecum is relatively smaller than in the adult; it tapers into the vermiform appendix. The ascending colon is shorter in the neonate, reflecting the shorter lumbar region. The transverse colon is relatively long, whereas the descending colon is short, but twice the length of the ascending colon (see Fig. 14.4), The sigmoid colon may be as long as the transverse colon; it often touches the inferior part of the anterior body wall on the left and, in about 50% of neonates, part of the sigmoid colon lies in the right iliac fossa. The muscularis, including the taeniae coli, is poorly developed in the colon as it is in the small intestine. Appendices, epiploicae and haustra are not present, which gives a smooth external appearance to the colon. Haustra appear within the first 6 months. The rectum is relatively long; its junction with the anal canal forms at nearly a right angle.

ANAL CANAL

Mesenchymal proliferation occurs around the rim of the ectodermal aspect of the anal membrane which thus comes to lie at the bottom of a depression, the proctodeum (see Figs 78.4, 78.7E). With the absorption and disappearance of the anal membrane the anorectum communicates with the exterior. The lower part of the anal canal is formed from the proctodeal ectoderm and underlying mesenchyme, but its upper part is lined by endoderm. The line of union corresponds with the edges of the anal valves in the adult. The dual origin of the anal canal is reflected in its innervation: the endodermal portion is innervated by autonomic nerves, and the ectodermal proctodeum is innervated by spinal nerves.

In the fourth and fifth weeks a small part of the hindgut, the postanal gut, projects caudally beyond the anal membrane (Fig. 73.3B); it usually disappears before the end of the fifth week.

Imperforate anus is a term used to describe many different anorectal malformations. The most common is anal agenesis, which is found in almost 50% of all cases of imperforate anus. The condition is usually associated with a fistula, which opens into the vulva (females) or into the urethra (males). It is more rare for the anal membrane to fail to perforate. The condition cannot reliably be diagnosed prenatally by ultrasound diagnosis, and it may be confused with Hirschsprung’s disease (see below) and colonic atresia. The prognosis is good for low lesions of the anal canal. The principal concern in all cases is the degree of bowel control, urinary control and in some cases sexual function, which is compromised by the condition. Anorectal malformations may be indicators of other abnormalities, for example those forming the ‘VATER’ syndrome (Vertebral, Anal, Tracheo-Oesophageal and Renal abnormalities).

ENTERIC NERVOUS SYSTEM

Enteric neurones are derived from trunk neural crest cells at somite levels 1–7 and from 28 onwards (see Fig. 24.19 and p. 374). After neurulation the crest cells begin their ventral migration and invade the gut via the dorsal mesentery (see Fig. 24.11). Glial cells associated with the gut have been identified as arising from similar levels. The local splanchnopleuric mesenchyme patterns the crest cells such that those which enter the gut layers attain an enteric fate, whereas those that remain outside the gut become committed as parasympathetic postganglionic neurones. The enteric neurones also migrate to the glands of the gut, e.g. the pancreas.

Hirschsprung’s disease

Hirschsprung’s disease is usually characterized by an aganglionic portion of gut which does not display peristalsis, and a dilated segment of colon proximal to this site. Histologically there is either an absence or a reduction in the number of ganglia and postganglionic neurones in the myenteric plexus; postganglionic innervation of the muscle layers is also often defective. It is believed that the condition is caused by a failure of neural crest cells to colonize the gut wall appropriately. An overabundance of basal laminal components, perhaps at the mesothelial/mesenchyme interface, may prevent the early migrating neural crest cells from penetrating the gut wall; their new position outside the gut does not confer on them the environmental stimuli for enteric nerve differentiation and so non-enteric development occurs in local ganglia adjacent to the gut (Gershon 1987). A variable length of large intestine may be affected: the lower and midrectum are the most common sites, but in severe cases the rectum, sigmoid, descending and even proximal colon can be aganglionic. The chronic dilatation of the colon or rectum proximal to the affected segment gives rise to the common name, megacolon. It occurs as a consequence of functional obstruction due to the failure of peristalsis within the affected segment, and the dilated colon is structurally normal. Occasionally aganglionosis affects only a very short length of rectum proximal to the anorectal junction and the degree of functional obstruction is minimal: in these cases of ‘ultra-short segment Hirschsprung’s disease’, clinical abnormalities arise later in life. Infants with Hirschsprung’s disease show delay in the passage of meconium, constipation, vomiting and abdominal distension.

GUT-ASSOCIATED LYMPHOID TISSUE

Individual lymphocytes appear in the lamina propria of the gut from approximately week 12 of development, and lymphoid aggregates, Peyer's patches, have been noted between 15 and 20 weeks: it is not clear whether these cells migrate in from distant sources or differentiate from the investing mesenchyme. The endodermal epithelium overlying the lymphoid aggregates is often distorted into a dome shape. The cells within the dome are a mixed population of enterocytes, endocrine cells, goblet cells and M cells. M cells are specialized to provide a mechanism for the transport of micro-organisms and intact macromolecules across the epithelium to the intraepithelial space and lamina propria. They have been observed in the fetus by 17 weeks; it is believed that they are formed by a specialized epithelial/mesenchymal interaction of the endoderm and underlying lymphoid type mesenchyme.

There are similarly specialized epithelial cells between the enterocytes. Intraepithelial leukocytes typically account for 15% of the epithelial cells of the gut in the adult. They have been observed at 11 weeks, with a distribution of 2–3 intraepithelial leukocytes/100 gut epithelial cells. Both T and B lymphocytes have been described in the developing gut wall. For an account of the development of the immune cells of the gut consult Butzner & Befus (1989). The neonatal gut becomes colonized by a range of bacterial flora, some of which exist in a symbiotic relationship with their host, some of which may be considered pathogenic.

FUNCTIONAL MATURITY OF THE GUT AT BIRTH

After birth the first passage of stool of the newborn is termed meconium. This is a dark, sticky, viscid substance formed from the passage of amniotic fluid, sloughed cells, digestive enzymes and bile salts along the fetal gut. Meconium becomes increasingly solid as gestation advances but does not usually pass out of the fetal body while *in utero*. Fetal distress produced by anoxia may induce the premature defecation of meconium into the amniotic fluid, with the risk of its inhalation. At birth the colon contains 60–200 g of meconium. The majority of neonates defecate within the first 24 hours after birth. Delayed passage of stool beyond this time is associated with Hirschsprung’s disease (see above) or imperforate anus. The normal passage of meconium continues for the first 2 or 3 days after birth, and is followed by a transition to faecal stools by day 7.

PERITONEAL CAVITY

The early development of the intraembryonic coelom which gives rise to the peritoneal cavity is described on pages 189 and 199. Figure 12.2 shows a scheme of the shape of the early peritoneal cavity and indicates the mesenchymal populations derived from its epithelial walls. Initially the peritoneal cavity associated with the lower end of the foregut has separate right and left components, the pleuroperioneal canals (Fig. 73.1). At the level of the midgut, the pleuroperitoneal canals join a confluent cavity surrounding the developing gut, which transitorily is in communication with the extraembryonic coelom.

The description of the development of the peritoneal cavity which follows pertains to changes which occur as a consequence of the differential growth of the gut.

PERITONEUM

Peritoneum develops from a specific portion of the intraembryonic coelomic walls (pp. 189, 199). Initially the intraembryonic coelomic epithelium is a pseudostratified germinal layer from which cellular progeny with different fates arise in specific sites and at specific developmental times. The portion which will give rise to the peritoneum is derived from the lower portion of the pericardioperitoneal canals and the somatopleure and splanchnopleure associated with the lower foregut, midgut and upper portions of the hind gut (see Figs 12.2, 73.1).

The proliferative splanchnopleuric epithelium produces cell populations for the mucosa and muscularis of the gut and also the lamina propria and epithelium of the visceral peritoneum (the serosa of the gut wall). The somatopleuric epithelium gives rise to the lamina propria and epithelium of the parietal peritoneum. The visceral and parietal peritoneal layers constitute a mesothelium, which denotes their origin from the intraembryonic mesoderm of the coelomic wall.

As the gut grows, splanchnic mesenchyme accumulates around the endodermal epithelium and the whole unit generally moves ventrally. There is a concomitant enlargement of the caudal ends of the developing pericardioperitoneal (pleuroperitoneal) canals and developing peritoneal cavity. The medial walls of the intraembryonic coelom move closer and there is a relative decrease in the mesenchyme between them. The regions where the medial portions of the intraembryonic coelom come together are termed mesenteries. They are composed of two layers of peritoneum with intervening mesenchyme and contain the neurovascular structures which pass to and from the gut. At the caudal ends of the pleuroperitoneal canals the gut has both ventral and dorsal mesenteries, whereas caudal to this there is only a dorsal mesentery (Figs 73.6, 73.7).

The mesenteries attached to the gut lengthen to permit large movements or rotations of the gut tube. Later, when part or the whole of the mesentery lies against the parietal peritoneum, their apposed surfaces fuse and are absorbed, i.e. they become sessile. Only those viscera developed in direct apposition to one of the primary coelomic regions, or a secondary extension of the latter, retain a partial or almost complete visceral serous cover. Thus the original line of reflexion of mesenteries becomes altered, or in some cases the organ may become retroperitoneal. These mechanisms are significant throughout the subdiaphragmatic gut, but are predominant in the small and large intestine. All serous membranes may vary their thickness, lines of reflexion, disposition, 'space' enclosed and their channels of communication, by a process of areal and thickness growth on one aspect combined with cavitation (leading to expanding embryonic recess formation) on the other (Figs 73.6, 73.7).

Although all of the gut tube and its derived glands are associated with mesenteries formed as described above, the nomenclature for some portions of the gut and glands is different. Thus the mesenteries of the stomach are called omenta and the reflections of peritoneum around the liver, which develop from a confluence of splanchnopleuric, somatopleuric and septum transversum-derived portions, are called ligaments.

The movements of the developing viscera within the peritoneal cavity occur with associated movements of the mesothelia which surround them. The descriptions of peritoneal cavity development which follow are thus describing a sequence of changes which affect a complex space and its boundaries.

Mesenteries of the developing gut

The cervicothoracic oesophagus develops between the pericardioperitoneal canals (Fig. 73.1). It is encased in prevertebral, retrotracheal and retrocardiac mesenchyme. As the pericardioperitoneal canals expand with the developing lung buds, and the diaphragm forms immediately below them, the oesophagus at this level has no true dorsal or ventral mesentery. At superior and intermediate thoracic levels parts of the lateral aspects of the oesophagus are closely related to the secondary, mediastinal, parietal pleura. In the lower thorax the oesophagus inclines ventrally anterior to the descending thoracic aorta. The dorsocaudally sloping midline diaphragm between oesophageal and aortic orifices may be homologized with part of a dorsal meso-oesophagus, and is used in that context in descriptions of diaphragmatic development (see p. 1013). A ventral midline diaphragmatic strip may also be considered to be a derivative of a ventral meso-oesophagus, however, this region is more usually thought of as septum transversum.

The alimentary tube, from the diaphragm to the start of the rectum, initially possesses a sagittal dorsal mesentery. Its line of continuity with the dorsal parietal peritoneum (i.e. its ‘root’ or ‘line of reflexion’) is initially also midline.

The abdominal foregut, from the diaphragm to the future hepatopancreatic duodenal papilla, also has a ventral mesentery. This extends from the ventrolateral margins of the abdominal oesophagus and as yet ‘unrotated’ primitive stomach and proximal duodenum, cranially to the future diaphragm and anteriorly to the ventral abdominal wall (to the level of the cranial rim of the umbilicus). Caudally, between umbilicus and duodenum, it presents a crescentic free border.

The midgut and hindgut have no ventral mesentery; thus the pleural and supra-umbilical peritoneal cavities are initially, and transiently, bilaterally symmetrical above the umbilicus. Below the umbilicus, the peritoneal cavity is freely continuous across the midline ventral to the gut (Fig. 73.5A).

Foregut mesenteries

The ventral and dorsal foregut mesenteries are relatively large compared with the slender endodermal tubes they encase; they are composed of mesenchyme sandwiched between two layers of splanchnopleuric coelomic epithelium. A complex series of recesses develop in the splanchnopleuric mesenchyme and become confluent. As a result of foregut rotation, differential growth of stomach, liver, pancreas and spleen, and completion of the diaphragm, the territories of the greater sac and lesser sac (omental bursa) are delimited, and the mesenteric complexes of these organs (omenta and ‘ligaments’) are defined (Figs 73.6, 73.7).

Consequences of rotation of the stomach

A number of processes occur concurrently which conceptually can be visualized as the movement of the right pleuroperitoneal canal to a position posterior to the stomach such that its communication with the remainder of the peritoneal cavity is reduced. These processes include the differential growth of the walls of the stomach, the formation and specific local extension of the omenta (dorsal and ventral mesogastria), the growth of the liver and particularly of the vessels and ducts which enter and leave the liver. These developments permit stomach expansion both anteriorly and posteriorly when food is ingested and free movement of peristalsis. The right pleuroperitoneal canal forms a discrete region of the peritoneal cavity, the lesser sac, and the remaining left pleuroperitoneal canal and the remainder of the peritoneal cavity form the greater sac. The entrance to the original right pleuroperitoneal canal (lesser sac) becomes reduced in size. It is called the epiploic foramen, foramen of Winslow, or the aditus of the omental bursa (bursa omentalis) (Figs 73.6, 73.7).

Early stages of lesser sac development

The lesser sac is first indicated by the appearance of multiple clefts in the para-oesophageal mesenchyme on both left and right aspects of the oesophagus. Although they may become confluent, the left clefts are transitory and soon atrophy. The right clefts merge to form the right pneumatoenteric recess that extends from the oesophageal end of the lesser curvature of the stomach as far as the caudal aspect of the right lung bud. At its gastric end it communicates with the general peritoneal cavity and lies ventrolateral to the gut; more rostrally it lies directly lateral to the oesophagus. It is not, as commonly stated, a simple progressive excavation of the right side of the dorsal mesogastrium. The right pneumatoenteric recess undergoes further extension, subdivision and modification (Fig. 73.7 A(i), B(i)). From its caudal end a second process of cleft and cavity formation occurs which produces the hepatoenteric recess. This thins and expands the splanchnopleure between the liver and the stomach and proximal duodenum, and reaches the diaphragm (Fig. 73.7A(i), C(i)). The resulting, structurally bilaminar, mesenteric sheet is the lesser omentum. It is derived, cranially to caudally, from the small meso-oesophagus; the much larger ventral mesogastrium and the most caudal free border, is from the ventral mesoduodenum. As differential growth of the duodenum occurs, the biliary duct is repositioned and most of the duodenum becomes sessile. The duodenal attachment of the free border and a continuous neighbouring strip of the lesser omentum become confined to the upper border of a short segment of its superior part. The contrasting growth and positioning of its attached viscera cause the free border to change gradually from the horizontal to the vertical. It carries the bile duct, portal vein and hepatic artery, and its hepatic end is reflected around the porta hepatis. An alternative name for this part of the lesser omentum is the hepatoduodenal ligament: it forms the anterior wall of the epiploic foramen. The floor of the foramen is the initial segment of the superior part of the duodenum, its posterior wall is the peritoneum covering the immediately subhepatic part of the inferior vena cava, and its roof the peritonealized caudate process of the liver. The major part of the lesser omentum from the lesser gastric curvature passes in an approximately coronal plane to reach the floor of the increasingly deep groove for the ductus venosus on the hepatic dorsum: this part is sometimes called the hepatogastric ligament.

Ligaments of the liver

The liver is precociously large during development because of its early role in haematopoiesis. Thus the liver mass projects into the abdominal cavity with equal growth on the two sides of the peritoneal cavity. The ligaments associated with the liver develop from the ventral mesogastrium – which passes from the foregut to the ventral abdominal wall down to the cranial rim of the intestinal portal – and from the reflections of peritoneum from the liver to the diaphragm.

The medial portions of the germinative coelomic epithelial walls, containing splanchnopleuric mesenchyme, septum transversum mesenchyme and developing liver, constitute the early ventral mesogastrium (Fig. 73.5A). The mesenchyme between these layers is continuous superiorly with the septum transversum mesenchyme of the diaphragm. The coelomic epithelial layers of the ventral mesogastrium almost touch anterior and posterior to the liver, and are separated by a slender lamina of mesenchyme. They form the falciform ligament and the lesser omentum respectively, and where they are in contact with the liver directly they form visceral peritoneum (Fig. 73.7D).

When the diaphragm is formed above the liver, local cavities coalesce and open into the general coelomic cavity as extensions of the greater (and lesser) sacs. In this way almost all the ventrosuperior, visceral and some of the posterior aspects of the liver become peritonealized. The process of extending the greater sac continues over the right lobe and stops when the future superior and inferior layers of the coronary ligament and the right triangular ligament are defined. Those, plus a medial boundary provided by an extension of the lesser sac, enclose the ‘bare area’ of the liver where loose areolar tissue of septum transversum origin persists. Later in development, when the haematopoietic function of the liver declines, the left lobe becomes relatively smaller than the right, which presumably accounts for the smaller size of the left triangular ligament.

Where the superior layers of the coronary and left triangular ligaments meet they continue as a (bilaminar) ventral mesentery attached to the ventrosuperior aspects of the liver. Its somewhat arched umbilicohepatic free caudal border carries the left umbilical vein. As the ventral body wall develops this falciform ligament, which initially attaches to the early cranial intestinal portal, is drawn to the diminishing cranial rim of the umbilicus. It may be considered the final ventral part of the ventral mesogastrium, although its free border has a ventral mesoduodenal origin. Its passage to the ventral body wall becomes increasingly oblique, curved and falciform (sickle-shaped) as the umbilicus becomes more defined.

In the early embryo the connection between one pericardioperitoneal canal and the other was directly across the ventral surface of the cranial midgut, immediately caudal to the developing primitive ventral mesogastrium. By stage 14 the passage from one side of the falciform ligament to the other necessitates passing below the greatly enlarged liver, or the curved lower edge of the falciform ligament, or the lesser omentum. The position of the falciform ligament is of clinical interest in the neonate in diagnosing pneumoperitoneum because it is silhouetted by air on abdominal X-rays.

Caval fold

The caval fold is a linear eminence, with divergent cranial and caudal ends, which passes from the upper abdominal to the lower thoracic region and protrudes from the dorsal wall of the pleuroperitoneal canal. Cranially it becomes continuous, lateromedially, with the root of the pulmonary anlage and pleural coelom, the uppermost portion of the septum transversum mesenchyme, and the retrocardiac mediastinal mesenchyme. Caudally it forms an arch with dorsal and ventral horns. The dorsal horn merges with the primitive dorsal mesentery and the mesonephric ridge and associated gonad and suprarenal (adrenal) gland. The ventral horn is confluent with the dorsal surface of the septal mesenchyme.

Thus the caval fold is a zone where intestinal, mesenteric, intermediate, hepatic, pericardial, pulmonary and mediastinal mesenchymes meet and blend. It provides a mesenchymal route for the upper abdominal, transdiaphragmatic and transpericardial parts of the inferior vena cava, and it is also prominent in the development of parts of the liver, lesser sac of peritoneum, and certain mesenteries. The left fold regresses whereas the right fold enlarges rapidly (Fig. 73.7A).

The pneumatoenteric recess continues to expand to the right into the substance of the caval fold. It stops near the left margin of the hepatic part of the inferior vena cava, which remains extraperitoneal and crosses the base of the now roughly triangular bare area of the liver and this new expanded line of reflexion. With closure of the pleuroperitoneal canals the rostral part of the right pneumatoenteric recess is sequestered by the diaphragm but often persists as a small serous sac in the right pulmonary ligament. The remaining caval fold mesenchyme to the left of the inferior vena cava – which forms the right wall of the upper part of the lesser sac – becomes completely invaded by embryonic hepatic tissue and is transformed into the caudate lobe of the liver. This smooth, vertically elongated mass projects into the cavity of the lesser sac: both its posterior, and much of its anterior, surfaces become peritonealized as a result of the increasing depth of the groove for the ductus venosus and the attachment of the lesser omentum to its floor.

Later stages of lesser sac development

The lower (inferior) part of the lesser sac can be first seen in embryos of 8–9 mm CR length and the early pneumatoenteric and hepatoenteric recesses are well established. Progressive differential gastric growth produces an elliptical transverse sectional profile, with a right-sided lesser curvature, which corresponds to the original ventral border of the gastric tube. The lesser omental gastric part of the ventral mesogastrium remains attached to this border. The greater curvature of the stomach is a new, rapidly expanding, region: its convex profile projects mainly to the left, but also cranially and caudally (Fig. 73.7 A(i), B(i), C(i)). The original dorsal border of the gastric tube now traverses the dorsal aspect of the expanding rudiment, curving along a line near the lesser curvature. The primitive dorsal mesogastrium is transiently attached to it, and blends with the thick layer of compound gastric mesenchyme clothing the posterior aspect and greater curvature of the miniature stomach. Because of its thickness, the mesenchyme projects cranially, caudally, and particularly to the left, beyond the ‘new’ greater curvature of the endodermal lining of the stomach.

The processes already described in relation to the ventral mesenteries now supervene. Multiple clefts appear at various loci in the mesenchyme, and there are local mesenchyme to epithelial transitions. The groups of clefts rapidly coalesce to form transiently isolated closed spaces which soon join with each other and with the preformed upper part of the lesser sac; the newly formed epithelia join the coelomic epithelium. In sequence, the initial loci occur in the compound posterior gastric mesenchyme nearer the lesser curvature and along its zone of blending with the primitive dorsal mesogastrium; in the dorsal mesoduodenum; and independently in the caudal rim, where greater curvature mesenchyme and dorsal mesogastrium blend. As these cavities become confluent and their ‘reniform’ expansion follows, matches and then exceeds that of the gastric greater curvature, there are several major sequelae. The primitive dorsal mesogastrium increases in area by intrinsic growth, and, as cavitation proceeds, by incorporating substantial contributions from the dorsal lamella separated by cleavage of the posterior gastric mesenchyme: it is now called the secondary dorsal mesogastrium (Fig. 73.7A(ii)). The gastric attachment of the secondary dorsal mesogastrium changes progressively. It may be regarded as a set of somewhat spiral lines, longitudinally disposed, that move with time to the left, from near the lesser curvature, towards and finally reaching, the definitive greater curvature. The parietal mesogastrial and (cleaving) mesoduodenal attachment remains in the dorsal midline for a time, but it later undergoes profound changes. With the confluence of the cavities that collectively form the lower part of the lesser sac, its communication with the upper part (which corresponds to the lesser gastric curvature and right and left gastropancreatic folds) becomes better defined. Ventral to the lower part of the cavity, postcleavage splanchnopleure covers the posteroinferior surface of the stomach and a short proximal segment of the duodenum. This ventral wall is continued beyond the greater curvature and duodenum as the splanchnopleuric strip of visceral attachment of the secondary dorsal mesogastrium and mesoduodenum. The radial width of the strip is relatively short cranially (gastric fundus) and gradually increases along the descending left part of the greater curvature. It is longest throughout the remaining perimeter of the greater curvature as far as the duodenum: this prominent part shows continued marginal (caudoventral and lateral) growth with extended internal cavitation (its walls constitute the expanding greater omentum; Fig. 73.6H; see Fig. 3.6E). The margins of the cavity of the inferior part of the lesser sac are limited by the reflexed edges of the ventrally placed strata derived from the secondary dorsal mesogastrium just described. These converge to form the splanchnopleuric dorsal wall, which is initially ‘free’ throughout except at its midline dorsal root. At roughly midgastric levels, the pancreatic rudiment grows obliquely encased in this dorsal wall; its tail ultimately reaches the left limit of the lesser sac at the level of the junction between gastric fundus and body (Fig 73.7C(ii)).

Greater omentum

The greater omentum continues to grow both laterally, and particularly caudoventrally. It covers and is closely applied to the transverse mesocolon, transverse colon and inframesocolic and infracolic coils of small intestine (Fig. 73.6D–G). At this stage the quadrilaminar nature of the dependent part of the greater omentum is most easily appreciated. ‘Simple’ mesenteries are bilaminar: they possess two mesothelial surfaces derived from splanchnopleuric coelomic epithelium, which enclose a connective tissue core derived from splanchnopleuric mesenchyme. In the greater omentum, the gastric serosa covering its posteroinferior surface (single mesothelium) and the anterosuperior serosa (single mesothelium) converge to meet at the greater curvature and initial segment of the duodenum. The resulting bilaminar mesentery continues caudoventrally as the ‘descending’ stratum of the omentum. This, on reaching the omental margins, is reflexed and now passes craniodorsally to its parietal root as the ‘ascending’ posterior bilaminar stratum. The two bilaminar strata are initially in fairly close contact caudally, but separated by a fine, fluid-containing, cleft-like extension of the lower part of the lesser sac. The posterior mesothelium of the posterior stratum makes equally close contact with the anterosuperior surface of the transverse colon, starting at the taenia omentalis, and with its transverse mesocolon.

Maturation of the lesser sac

At this stage, and subsequently, it is convenient to designate the lower part of the lesser sac as consisting of three subregions: retrogastric, perigastric and greater omental (Fig. 73.7C(ii)). The names are self-explanatory but their confines are all modified by various factors. Two phenomena are particularly prominent, namely, gastric ‘descent’ relative to the liver, and fusion of peritoneal layers with altered lines of reflexion, adhesion of surfaces and loss of parts of cavities.

After the third month, hepatic growth, particularly of the left lobe, diminishes and the whole organ recedes into the upper abdomen. Meanwhile the stomach elongates and some descent occurs, despite its relatively fixed cranial and caudal ends. This produces the angular flexure of the stomach which persists postnatally. The concavity of the lesser curvature is now directed more precisely to the right, the lesser omentum is more exactly coronal and its free border vertical. Ventral to the liver the free border of the falciform ligament passes steeply craniodorsally from umbilicus to liver (see disposition in neonate in Figs 14.4 and 14.5). The mesenchymal dorsal wall of the lower part of the lesser sac, which is crossed obliquely by the growing pancreas, has hitherto remained free and retained its original dorsal midline root. Substantial areas now fuse with adjacent peritonealized surfaces of retroperitoneal viscera, the parietes, or another mesenteric sheet or fold. Where sheets fuse there is a variable loss of apposed mesothelia and some continuity of their mesenchymal cores, but they remain surgically separable and no vascular anastomosis develops across the interzone. Above the pancreas the posterior secondary dorsomesogastrial wall of the sac becomes closely applied to the peritoneum covering the posterior abdominal wall and its sessile organs, the diaphragm, much of the left suprarenal gland, the ventromedial part of the upper pole of the left kidney, the initial part of the abdominal aorta, the coeliac trunk and its branches, and other vessels, nerves, and lymphatics (see Fig. 14.4). Their peritoneal surfaces fuse. However, albeit with some tissue loss, a single mesothelium remains covering these structures, intercalated as a new secondary dorsal wall for this part of the lesser sac.

The pancreas grows from the duodenal loop, penetrating the substance of the dorsal mesoduodenum and secondary dorsal mesogastrium; their mesenchymes and mesothelia initially clothe its whole surface, except where peritoneal lines of reflexion exist. Its posterior peritoneum becomes closely applied to that covering all the posterior abdominal wall structures it crosses (the inferior vena cava, abdominal aorta, splenic vein, superior mesenteric vessels, inferior mesenteric vein, portal vein, left renal vessels, the caudal pole of the left suprarenal, a broad ventral band on the left kidney and various muscles (see Figs 14.4, 14.5). The intervening peritoneal mesothelia fuse and atrophy, and the mesenchymal cores form fascial sheaths and septa. The pancreas is now sessile. The peritoneum covering the upper left part of its head, neck and the anterosuperior part of its body forms the central part of the dorsal wall of the lesser sac. The pancreatic tail remains peritonealized by a persisting part of the secondary dorsal mesogastrium as it curves from the ventral aspect of the left kidney towards the hilum of the spleen. The infracolic parts of the pancreas are covered with greater sac peritoneum. In the greater omental subregion of the lower part of the lesser sac two contrasting forms of mesenteric adhesion occur. The posterior ‘returning’ bilaminar stratum of the omentum undergoes partial fusion with the peritoneum of the transverse colon at the taenia omentalis and with its mesocolon. The layers remain surgically separable; no anastomosis occurs between omental and colic vessels.

The original dorsal midline attachment to the parietes of the foregut dorsal mesentery is profoundly altered during the development of the lesser sac and its associated viscera. However, despite the extensive areas of fusion, virtually the whole of the gastric greater curvature (other than a small suboesophageal area) and its topographical continuation (the inferior border of the first 2–3 cm of the duodenum), retain true mesenteric derivatives of the secondary dorsal mesogastrium and its continuation, the dorsal mesoduodenum. Although regional names are used to assist identification and description, it must be emphasized that they are all merely subregions of one continuous sheet.

The upper (oesophagophrenic) part of the lesser omentum arches across the diaphragm. As this bilaminar mesentery approaches the oesophageal hiatus its laminae diverge, skirting the margins of the hiatus. They then descend for a limited distance and with variable inclination, to enclose reciprocally shaped areas on the dorsum of the gastric fundus and diaphragm. The area may be roughly triangular to quadrangular; it contains areolar tissue and constitutes the bare area of the stomach or, when large, the left extraperitoneal space. Its right lower angle is the base of the left gastropancreatic fold, and its left lower angle reconstitutes the bilaminar mesentery. The root of the latter arches downwards and to the left across the diaphragm and suprarenal gland and gives the gastrophrenic ligament to the gastric fundus. It continues to arch across the ventral surface of the upper part of the left kidney, and its layers part to receive the pancreatic tail: they initially extend to the hilum of the spleen as the lienorenal (splenorenal) ligament (see Figs 73.6C, 73.7D),. The left half of this bilaminar ‘ligament’ provides an almost complete peritoneal tunic for the spleen. It then reunites with its fellow at the opposite rim of the splenic hilum, and continues to the next part of the gastric greater curvature as the gastrosplenic ligament. The remaining part (perhaps two-thirds) of the gastric greater curvature and its short duodenal extension provide attachment for the anterior, ‘descending’, bilaminar stratum of the greater omentum. Its returning, posterior, bilaminar stratum continues to its parietal root (which extends from the inferior limit assigned to the splenorenal ligament), and curves caudally and to the right along the anterior border of the body of the pancreas, immediately cranial to the line of attachment of the transverse mesocolon. Crossing the neck of the pancreas, the same curve is followed for a few centimetres on to its head; the omental root then sharply recurves cranially and to the left, to reach the inferior border of the duodenum. Thus it reaches that part of the lesser sac provided by cleavage of the dorsal mesoduodenum from the greater sac. It enters the epiploic foramen, traverses the epiploic canal between the caudate hepatic process and proximal duodenum, then crosses the right gastropancreatic fold, and descends behind the proximal duodenum to enter the right marginal strip enclosed by the greater omentum. The definitive origins of the peritoneum from the posterior abdominal wall are shown in the adult in Figures 64.1, 69.4 and 64.5B.

Peritoneum associated with the mid- and hindgut

It is convenient to consider the mesenteries of the small and large intestine after rotation and the principal growth patterns have been achieved and the developing pancreas is becoming retroperitoneal.

Small intestine

Most of the duodenal loop encircles the head of the pancreas and is retroperitoneal. The peritoneum principally covers its ventral and convex aspects. Areas not covered are a short initial segment of the superior (first) part, which is more completely peritonealized because it gives attachment to the right margins of the greater and lesser omenta; the sites where the transverse colon is closely apposed to the descending (second) part, or where the latter is crossed by the root of the transverse mesocolon; and the sites where the mesentery crosses the transverse (third) part, and descends across the ascending (fourth) part from its upper extremity at the duodenojejunal flexure. These regions are illustrated in the adult in Figure 64.1. In addition, one or more of up to six different duodenal recesses may develop. Their variations in shape and size, their intestinal, mesenteric and vascular relations, and, when adequately recorded, the frequencies and disposition of their orifices, are given on page 1108–1109.

From a mesenteric standpoint, the succeeding small intestine, from the duodenojejunal flexure to the ileocaecal junction, undergoes less modification of its embryonic form than other gut regions. Its early dorsal mesentery is a continuous, single (but structurally bilaminar) sheet, with a midline parietal attachment (line of reflexion, or ‘root’). The attachment of the root becomes an oblique narrow band from the left aspect of the second lumbar vertebra to the cranial aspect of the right sacroiliac joint (Fig. 73.6H; see Fig. 64.1).

Ascending colon

The caecum and vermiform appendix arise as a diverticulum from the antimesenteric border of the caudal limb of the midgut loop, consequently the caecum does not possess a primitive mesocaecum. These regions of the gut undergo long periods of growth, often asymmetrical, and their final positions, dimensions and general topography show considerable variation. The vermiform appendix is almost wholly clothed with visceral peritoneum, derived from the diverging layers of its rather diminutive mesoappendix. The latter should perhaps be regarded as a direct derivative of the primitive dorsal mesentery, and perhaps a similar status for the vascular fold of the caecum should be considered.

The colonic gut retains its primitive dorsal mesentery, the meso-colon, until the differential growth, rotation and circumabdominal displacement of this part of the gut tube nears completion. Its original root is still vertical in the dorsal midline, although the mesocolon diverges from it widely as an incomplete, flattened pyramid, to reach its colonic border at the future taenia mesocolica. During the fourth and fifth months substantial areas of the primitive mesocolon adhere to, then fuse with, the parietal peritoneum. In this way, some colonic segments become sessile while others have a shorter mesocolon with an often profoundly altered parietal line of attachment. The mesocolon of the transverse and sigmoid segments normally persists, while the ascending colon, right (hepatic) flexure and descending colon become sessile: the ascending or descending, or both, colonic segments may also retain a mesocolon which varies from a localized ‘fold’ to a complete mesocolon. When sessile, the ventral, medial and lateral aspects of the ascending or descending colon are clothed with peritoneum, and the protrusion of the viscus produces medial and lateral peritoneal paracolic gutters on each side. This form of apposition to underlying structures (zygosis) proceeds from the ascending colon to include the right colic (hepatic) flexure, and thence continues anteroinferiorly to the left, so involving the right-sided initial segment of the transverse colon.

Transverse colon

The right extremity of the transverse colon is sessile, and is separated by fibroareolar tissue from the anterior aspect of the descending (second) part of the duodenum and the corresponding aspect of most of the head of the pancreas. The remainder of the transverse colon, up to and including the left (splenic) colic flexure, is almost completely peritonealized by the diverging layers of the transverse mesocolon. The root of the latter reaches the neck and whole extent of the anterior border of the body of the pancreas. The long axis of the definitive pancreas lies obliquely. The splenic colonic flexure is considerably more rostral than the hepatic flexure and consequently the root of the mesocolon curves obliquely upwards as it crosses the upper abdomen from right to left. As it expands, the posteroinferior wall of the greater omental part of the lesser sac gradually covers, and becomes closely applied to, the transverse mesocolon and its contained colon, finally projecting beyond the latter. Craniocaudal adherence now occurs between the omental wall and the pericolonic and mesocolonic layers.

Descending colon

The left colic flexure receives much of its peritoneal covering from the left extremity of the transverse mesocolon. It is also often connected to the parietal peritoneum of the diaphragm over the 10th and 11th ribs by a phrenicocolic ligament. The latter sometimes blends with a presplenic fold that radiates from the gastrosplenic ligament. The descending colon becomes sessile. The process of fusion and obliteration of both ascending and descending mesocolons starts laterally and progresses medially.

Sigmoid colon

The sigmoid colon is most variable in its length and disposition. It retains its dorsal mesocolon, but the initial midline dorsal attachment of its root is considerably modified in its definitive state.

Rectum

The rectum continues from the ventral aspect of the third sacral vertebra to its anorectal (perineal) flexure anteroinferior to the tip of the coccyx: the distance changes with age. All aspects of the rectum are encased by mesenchyme, and the early dorsally placed mass is named, by some authorities, the dorsal mesorectum. However, the latter does not form a true mesentery: with progressive skeletal development it is reduced to a woven fibroareolar sheet which displays patterned variations in thickness and fibre orientation. The sheet is closely applied to the ventral concavity of the sacrum and coccyx, and encloses numerous fibromuscular and neurovascular elements. The rectum therefore becomes sessile, and visceral peritoneum is restricted to its lateral and ventral surfaces (see Fig. 78.4).

With the disappearance of the postanal gut by the end of the fifth week, the ventrolateral peritoneum reaches the superior surface of the pelvic floor musculature: this condition persists until late in the fourth month. In the male the ventral rectal peritoneum is reflected over the posterior surface of the prostate, bladder trigone and associated structures. In the female the ventral peritoneum initially receives a reflection which covers almost the whole posterior aspect of the vagina, and is continued over the uterus. Subsequently, the closely apposed walls of these deep peritoneal pouches fuse over much of their caudal extent, their mesothelia are lost, and the viscera are separated by an intervening, bilaminar (surgically separable), fibrous stratum. In the male this becomes the rectovesical fascia and posterior wall of the prostatic sheath (see Fig. 78.10). In the female it becomes the rectovaginal septum between the lower part of the vagina and the rectum (see Fig. 78.9). The proximal third of the rectum is covered by peritoneum ventrolaterally: the lateral extensions of this tunic are triangular and deep proximally, but taper to an acute angle by the middle third of the rectum. The middle third of the rectum is covered by peritoneum only on its ventral surface, where it forms the posterior wall of the shallower rectovesical or rectovagino-uterine pouch. The remaining rectum and anal canal are extraperitoneal.

NEONATAL PERITONEAL CAVITY

The fully formed peritoneal cavity, although complex topographically, remains a single cavity with numerous intercommunicating regions, pouches and recesses (see Fig. 14.5). The only small peritoneal sacs to separate completely from the main cavity are the infracardiac bursa (Fig. 73.7(B(i)) and the tunica vaginalis testis (see Fig. 78.17).

In fetal life the greater omental cavity extends to the internal aspect of the lateral and caudal edges of the omentum. Postnatally a slow but progressive fusion of the internal surfaces occurs with obliteration of the most dependent part of the cavity: this proceeds rostrally and, when mature, the cavity does not usually extend appreciably beyond the transverse colon. Transverse mesocolon–greater omentum fusion begins early while the umbilical hernia of the midgut has not returned. It starts between the right margin of the early greater omentum and near the root of the presumptive mesocolon, and later spreads to the left.

In the neonate the peritoneal cavity is ovoid (see Fig. 14.4). It is fairly shallow from anterior to posterior because the bilateral posterior extensions on each side of the vertebral column, which are prominent in the adult, are not present. Two factors lead to the protuberance of the anterior abdominal wall in the neonate and infant. The diaphragm is flatter in the newborn, which produces a caudal displacement of the viscera. The pelvic cavity is very small in the neonate, which means that organs which are normally pelvic in the adult, i.e. urinary bladder, ovaries and uterus, all extend superiorly into the abdomen (see Figs 14.5, 78.9, 78.10). The pelvic cavity is joined to the abdominal cavity at less of an acute angle in the neonate because there is no lumbar vertebral curve and only a slight sacral curve.

The peritoneal attachments are similar to the adult. However, the greater omentum is relatively small: its constituent layers of peritoneum may not be completely fused, and it does not extend much below the level of the umbilicus (see Fig. 14.5). Generally the length of the mesentery of the small intestine and of the transverse and sigmoid mesocolons are longer than in the adult, whereas the area of attachment of the ascending and descending colons is relatively smaller. The peritoneal mesenteries and omenta contain little fat.

SPLEEN

The spleen appears about the sixth week as a localized thickening of the coelomic epithelium of the dorsal mesogastrium near its cranial end (Figs 73.6, 73.7). The proliferating cells invade the underlying angiogenetic mesenchyme, which becomes condensed and vascularized. The process occurs simultaneously in several adjoining areas which soon fuse to form a lobulated spleen of dual origin (from coelomic epithelium and from mesenchyme of the dorsal mesogastrium). The enlarging spleen projects to the left, so that its surfaces are covered by the peritoneum of the mesogastrium on its left aspect, which forms a boundary of the general extrabursal (greater) sac. When fusion occurs between the dorsal wall of the lesser sac and the dorsal parietal peritoneum, it does not extend to the left as far as the spleen, which remains connected to the dorsal abdominal wall by a short lienorenal ligament. Its original connection with the stomach persists as the gastrosplenic ligament. The earlier lobulated character of the spleen disappears, but is indicated by the presence of notches on its upper border in the adult.

The histogenesis of the spleen has attracted relatively little attention. The vascular reticulum is well developed at 8–9 weeks, and contains immature reticulocytes and numerous closely spaced thin-walled vascular loops. Differentiation of blood cells, macrophages, and of arteries, veins, capillaries and sinusoids has occurred by the eleventh to twelfth week. Initially the capsule consists of cuboidal cells bearing cilia and microvilla.

The spleen displays various developmental anomalies, including complete agenesis, multiple spleens or polysplenia, isolated small additional spleniculi and persistent lobulation. Asplenia and polysplenia are associated with other anomalies, especially those involving the cardiac and pulmonary systems. Accessory spleens are very common in neonates, located in the greater omentum. At birth the spleen weighs, on average, 13 g (see Fig. 14.4). It doubles its weight in the first postnatal year and triples it by the end of the third year.

SUPRARENAL GLANDS

The suprarenal (adrenal) cortex is formed during the second month by a proliferation of the coelomic epithelium. Cells pass into the underlying mesenchyme between the root of the dorsal mesogastrium and the mesonephros (see Fig. 24.11). The proliferating tissue, which extends from the level of the sixth to the 12th thoracic segments, is soon dis-organized dorsomedially by invasion of neural crest cells from somite levels 18–24, which form the medulla, and also by the development of venous sinusoids. The latter are joined by capillaries, which arise from adjacent mesonephric arteries and penetrate the cortex in a radial manner. When proliferation of the coelomic epithelium stops, the cortex is enveloped ventrally, and later dorsally, by a mesenchymal capsule which is derived from the mesonephros. The subcapsular nests of cortical cells are the rudiment of the zona glomerulosa: they proliferate cords of cells which pass deeply between the capillaries and sinusoids. The cells in these cords degenerate in an erratic fashion as they pass towards the medulla, becoming granular, eosinophilic and ultimately autolysed. These cords of cells constitute the fetal cortex, which undergoes rapid involution during the first two years after birth. The fascicular and reticular zones of the adult cortex are proliferated from the glomerular zone after birth.

The most common abnormality of suprarenal gland development is congenital hyperplasia, which occurs in 1 : 5000–1 : 15,000 births. This condition is caused by a group of autosomal recessive disorders in which there are deficiencies in enzymes required for the synthesis of cortisol. In 90% of cases the cause is deficiency of the enzyme 21-hydroxylase, producing an accumulation of 17-hydroxyprogesterone, which is converted to androgens. The levels of androgens increase by several hundred times, causing female embryos and fetuses to undergo external genital masculinization ranging from clitoral hypertrophy to formation of a phallus and scrotum: masculinization of the brain has also been suggested. In male embryos the levels do not cause any changes in external genitalia. Signs of androgen excess may appear in childhood with precocious masculinization and accelerated growth (Lewis, Yaron & Evans 1999).

SUPRARENAL GLANDS IN THE NEONATE

The suprarenal glands are relatively very large at birth (see Figs 14.4 and 78.8) and constitute 0.2% of the entire body weight, compared with 0.01% in the adult. The left gland is heavier and larger than the right, as it is in the adult. At term each gland usually weighs 4 g; the average weight of the two glands is 9 g (average in the adult is 7–12 g). The glands involute rapidly in the neonatal period when each gland loses 25% of its mass; the average weight of both glands is 5 g by the end of the second week, and 4 g by 3 months. Birth weight is not regained until puberty. The cortex of the suprarenal gland is thicker than in the adult and the medulla of the gland is small. Early studies on fetal suprarenal glands described extensive degeneration and necrosis of fetal zone cells; however, it is believed that these studies showed disease processes rather than the normal involution of the gland. With normal involution the fetal zone cells of the postnatal gland become smaller and they assume the appearance and organization typical of zona fasciculata.

INFERIOR VENA CAVA, PORTAL CIRCULATION AND UMBILICAL VESSELS

INFERIOR VENA CAVA

The inferior vena cava of the adult is a composite vessel which develops on the posterior abdominal wall dorsal to the developing peritoneal cavity. It forms as a consequence of the temporal remodelling of successive venous complexes (see Fig. 13.4). The precise mode of development of its postrenal segment (caudal to the renal vein) is still somewhat uncertain. Its function is initially carried out by the right and left postcardinal veins (Fig. 73.8; see also Fig. 13.4), which receive the venous drainage of the lower limb buds and pelvis and run in the dorsal part of the mesonephric ridges, receiving tributaries from the body wall (intersegmental veins) and from the derivatives of the mesonephroi.

Left gonadal vein
IVC supracardinal segment
Common iliac veins

Fig. 73.8 The inferior vena cava develops within the posterior abdominal wall. It is a composite vessel formed by temporal remodelling of successive somatic venous anastomoses. (For early venous development see **Fig. 13.4**.)

The early postcardinal veins communicate across the midline via an interpostcardinal anastomosis. This remains as an oblique transverse anastomosis between the iliac veins, and becomes the major part of the definitive left common iliac vein. It diverts an increasing volume of blood into the right longitudinal veins, which accounts for the ultimate disappearance of most of those on the left.

The supracardinal veins receive the larger venous drainage of the growing body wall. The right supracardinal vein persists and forms the greater part of the postrenal segment of the inferior vena cava. The continuity of the vessel is maintained by the persistence of the anastomosis between the right supracardinal and the right subcardinal in the renal collar. The left supracardinal disappears, but some of the renal collar formed by the left supracardinal–subcardinal anastomosis persists in the left renal vein. Both supracardinal veins drain cranially into the subcardinal veins. On the right side, the subcardinal vein comes into intimate relationship with the liver. An extension of the vessel takes place in a cranial direction and meets and establishes continuity with a corresponding new formation that is growing caudally from the right vitelline hepatocardiac (common hepatic) vein. In this way, on the right side a more direct route is established to the heart and the prerenal (cranial) segment of the inferior vena. In summary, the inferior vena cava is formed from below upwards by the confluence of: the common iliac veins, a short segment of the right postcardinal vein, the postcardinal–supracardinal anastomosis, part of the right supracardinal vein, the right supracardinal–subcardinal anastomosis, right subcardinal vein, a new anastomotic channel of double origin (the hepatic segment of the inferior vena cava), and the cardiac termination of the right vitelline hepatocardiac vein (common hepatic vein).

Only the supracardinal part of the inferior vena cava receives intersegmental venous drainage. The postrenal (caudal) segment of the inferior vena cava is on a plane that lies dorsal to the plane of the prerenal (cranial) segment. Thus the right phrenic, suprarenal and renal arteries, which represent persistent mesonephric arteries, pass behind the inferior vena cava, whereas the testicular or ovarian artery, which has a similar developmental origin, passes anterior to it.

In some animals, the right postcardinal vein constitutes a large part of the postrenal segment of the inferior vena cava. In these cases the right ureter, on leaving the kidney, passes medially dorsal to the vessel and then, curving round its medial side, crosses its ventral aspect. Rarely, a similar condition is found in humans, and indicates the persistence of the right postcardinal vein and failure of the right supracardinal to play its normal part in the development of the inferior vena cava.

PORTAL CIRCULATION

The heart first differentiates in splanchnopleure that, after head fold formation, forms the dorsal wall of the primitive pericardial cavity (floor of the rostral foregut) and may therefore be considered a highly specialized vitelline vascular derivative. At the caudal extremity of the splanchnopleuric gut tube (the future lower rectum and upper anal canal) the vitelline venous drainage makes connections with the internal iliac radicles of the postcardinal complex.

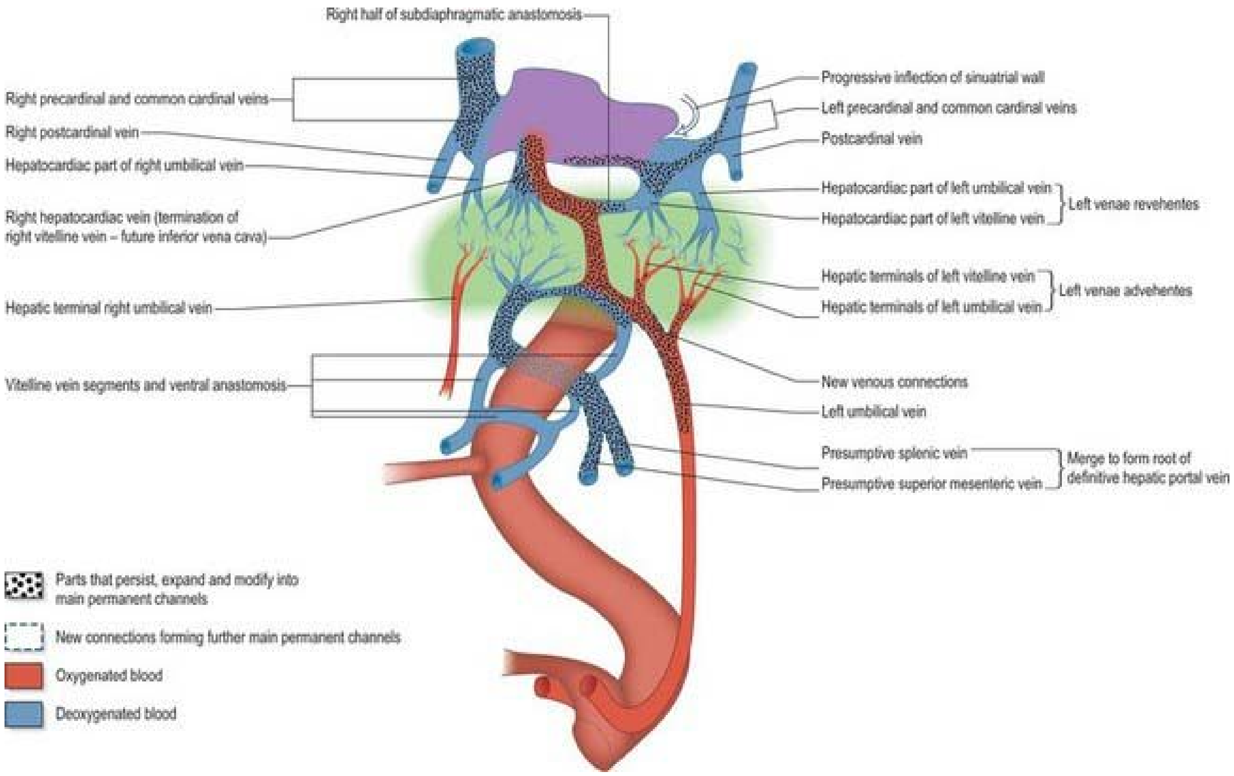
The development of the gut occurs contemporaneously with changes to the early symmetrical embryonic circulation (see Ch. 13). A symmetrical, segmental system of somatic arteries remains and supplies the body wall of the trunk. The underlying arrangement of these vessels is only slightly modified by subsequent development. The main changes to the embryonic arrangement occur with the growth of the foregut, liver and paired viscera, i.e. kidneys and suprarenal glands.

The early development of the ventral splanchnic arteries is outlined in Chapter 13. Three main arterial trunks, the coeliac trunk, superior mesenteric and inferior mesenteric arteries, supply the fore- mid- and hind gut respectively. From the gastric terminal segment of the future oesophagus to the upper rectum, the developing endodermal epithelium is surrounded by splanchnopleuric mesenchyme permeated by a capillary plexus which drains into an anastomosing network of veins. This plexus is particularly dense ventrally associated with the central midgut region where, for a while, it receives a network of small veins from the definitive yolk sac. Later, in normal development, these vessels atrophy as the yolk sac diminishes. More rostrally the splanchnopleuric capillaries associated with the foregut and upper portions of the yolk sac form longitudinal channels anterolateral to the gut and these become increasingly well defined as the embryonic abdominal vitelline veins. Entering the septum transversum, the right and left vitelline veins incline slightly, becoming parallel to the lateral aspects of the gut. They establish connections with capillary plexuses in the septal mesenchyme, then continue, finally curving to enter the medial part of the cardiac sinual horn of their corresponding side. The parts of the gut closely related to the presinual segments of the vitelline veins are the future subdiaphragmatic end of the oesophagus, primitive stomach, the superior (first) and descending (second) regions of the duodenum, and the remainder of the duodenal tube.

The principal ascending vitelline veins flanking the sides of the abdominal part of the foregut receive venules from its splanchnopleuric capillaries, and those of the septal mesenchyme. Within these venular nets, enlarged (but still plexiform) anastomoses connect the two vitelline veins (Fig. 73.9; see Fig. 13.1C). A subdiaphragmatic intervitelline anastomosis develops in the rostral septal mesenchyme, lying a little caudal to the cardiac sinuatrial chamber, connecting the veins near their sinual terminations. (The channel is sometimes termed suprahepatic because of the position of the hepatic primordium; with expansion of the latter it becomes partly intrahepatic.) The presumptive duodenum is crossed by three transverse duodenal intervitelline anastomoses. Their relation to the gut tube alternates so that the most cranial, the subhepatic, is ventral, the intermediate is dorsal and the caudal is ventral (Fig. 73.9B). It has become customary to describe the paraduodenal vitelline veins and their associated anastomoses as forming a figure 8. At this early stage when left and right embryonic veins are still symmetric, the cranial duodenal anastomosis becomes connected with the subdiaphragmatic anastomosis by a median longitudinal channel, the primitive median ductus venosus, which is dorsal to the expanding hepatic primordium, but ventral to the gut. The further development of the vitelline veins and anastomoses is, as indicated, closely interlocked, with rapid hepatic expansion and gut changes, and umbilical vein disposition and modification is closely involved.

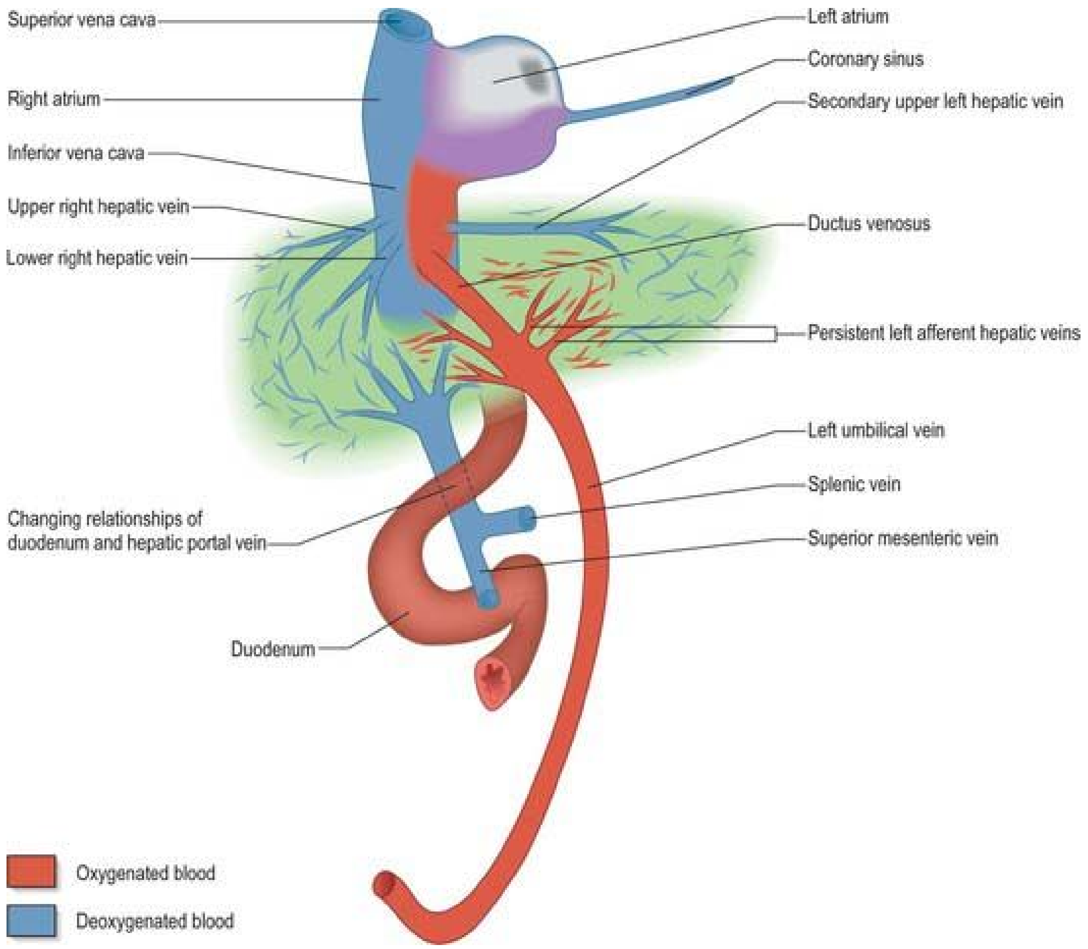
CHANGES IN THE VITELLO-UMBILICAL VEINS

Progressive changes in the vitello-umbilical veins are rapid, profound and closely linked with regional modifications in shape and position of the gut, expansion and invasion of venous channels by hepatic tissue, asymmetry of the heart and cardiac venous return. The principal events are summarized in Figs 73.9, 73.10 and 73.11.



Right half of subdiaphragmatic anastomosis
Right precardinal and common cardinal veins
Right postcardinal vein
Hepatocardiac part of right umbilical vein
Right hepatocardiac vein (termination of right vitelline vein – future inferior vena cava)
Hepatic terminal right umbilical vein
Vitelline vein segments and ventral anastomosis
Progressive inflection of sinuatrial wall
Left precardinal and common cardinal veins
Postcardinal vein
Hepatocardiac part of left umbilical vein
Hepatocardiac part of left vitelline vein
Left venae revehentes
Hepatic terminals of left vitelline vein
Hepatic terminals of left umbilical vein
Left venae advehentes
New venous connections
Left umbilical vein
Presumptive splenic vein
Presumptive superior mesenteric vein
Merge to form root of definitive hepatic portal vein
Parts that persist, expand and modify into main permanent channels
New connections forming further main permanent channels
Oxygenated blood
Deoxygenated blood

Fig. 73.10 Development of the vitelline, umbilical and terminal cardinal vein complexes: a mid-stage of asymmetry has been reached between the early symmetric condition (see **Fig. 73.9**) and the definitive late prenatal state. The extent of the liver within the septum transversum mesenchyme is shown in green.



Superior vena cava
Right atrium
Inferior vena cava
Upper right hepatic vein
Lower right hepatic vein
Changing relationships of duodenum and hepatic portal vein
Duodenum
Left atrium

Secondary upper left hepatic vein
Ductus venosus
Persistent left afferent hepatic veins
Left umbilical vein
Splenic vein
Superior mesenteric vein
Oxygenated blood
Deoxygenated blood

Fig. 73.11 The condition of some main upper abdominal and intrathoracic right atrial terminal veins in the later prenatal months. The rotation of the stomach and movement of the duodenum produce relative changes in the final arrangement of duodenal intervitelline anastomoses which form the hepatic portal vein.

From the cranial portion of the early hepatic evagination of the foregut, interconnected sheets and ‘cords’ of endodermal cells, the presumptive hepatocytes, penetrate the septum transversum mesenchyme. Hepatic mesenchyme is composed of a mixed population of cells with endothelial/angiogenic and connective tissue lineages. Capillary plexuses develop within this mesenchyme and, possibly under the influence of the endodermal hepatic sheets, the plexuses become more profuse by further addition of angioblastic septal mesenchyme, which also forms masses of perivascular intrahepatic haemopoietic tissue. These processes extend along the plexiform connections of the vitelline, and later the umbilical, veins until their intrahepatic (trans-septal) zones themselves become largely plexiform. Initially capillary in nature, they transform into a mass of rather wider, irregular, sinusoidal vessels with a discontinuous endothelium containing many phagocytic cells. The lengths of vitelline veins involved in these processes are the intermediate parts of the segments extending from the subhepatic (cranioventral duodenal) to the suprahepatic (subdiaphragmatic) transverse intervitelline anastomoses, and the corresponding lengths of the umbilical veins. Thus at this early stage the liver sinusoids are perfused by mixed blood reaching them through a series of branching vessels collectively called the venae advehentes, or afferent hepatic veins: they are, deoxygenated from the gut splanchnopleure via vitelline vein hepatic terminals and oxygenated from the placenta via hepatic terminals of the umbilical veins (Fig. 73.10). Blood leaves the liver through four venae revehentes (efferent hepatic veins); two on each side reach and open into their respective cardiac sinual horns. This full complement of four hepatocardiac veins is only transient, and becomes reduced to one dominant, rapidly enlarging channel. The originally bilaterally symmetric cardinal vein complexes, both rostral and caudal, develop transverse or oblique anastomoses so that the cardiac venous return is ultimately restricted to the definitive right atrium.

These cardiac and concomitant hepatoenteric changes are accompanied by events in supra-, intra- and subhepatic parts of the vitello-umbilical veins. Some vessels enlarge, persisting as definitive vessels to maturity and, in places, they are joined later by other channels that become defined in already established capillary plexuses. Other vessels retrogress, either disappearing completely or remaining as vestigial tags and, occasionally, vessels of fine calibre. Some vessels of crucial importance in the circulatory patterns of embryonic and fetal life become obliterated postnatally and transformed to substantial fibrous cords. Both right and left umbilical hepatocardiac and the left vitelline hepatocardiac veins continue, for a time, to discharge blood into their sinual horns; however, they begin to retrogress (Figs 73.9 and 73.10). The right umbilical channel atrophies completely. The left channels also disappear, but their cardiac terminals may, on occasion, be found as conical fibrous tags attached to the inferior wall of the coronary sinus. The right vitelline hepatocardiac vein continues enlarging and ultimately forms the terminal segment of the inferior vena cava. The latter receives the right efferent hepatic veins and new channels draining the territories of the left efferent hepatic veins. These collectively form the upper and lower groups of right and (secondary) left hepatic veins. The terminal caval segment also shows the orifice of the right half of the intervitelline subdiaphragmatic anastomosis, and a large new connection with the right subcardinal vein.

The hepatic terminals of the right and left duodenal parts of the vitelline veins are destined to form the corresponding branches of the hepatic portal vein, the left branch incorporating the cranial ventral intervitelline anastomosis. With rotation of the gut and formation of the duodenal loop, segments of the original vitelline veins and the caudal transverse anastomosis atrophy (indicated in Fig. 73.10 and 73.10), while new splanchnopleuric venous channels, the superior mesenteric and splenic veins, converge and join the left end of the dorsal intermediate anastomosis. The numerous other radicles of the portal vein and its principal branches, including the inferior mesenteric vein, are later formations.

For a period, placental blood returns from the umbilicus via right and left umbilical veins, both discharging through afferent hepatic veins into the hepatic sinusoids, where admixture with vitelline blood occurs. At approximately 7 mm crown–rump length, the right umbilical vein retrogresses completely. The left umbilical vein retains some vessels discharging directly into the sinusoids, but new enlarging connections with the left half of the subhepatic intervitelline anastomosis emerge. The latter is the start of a bypass channel for the majority of the placental blood, which continues through the median ductus venosus and finally the right half of the subdiaphragmatic anastomosis, to reach the termination of the inferior vena cava (Fig. 73.11).

FETAL/NEONATAL UMBILICAL VESSELS

Umbilical vein

The umbilical vein in the neonate is 2–3 cm long and 4–5 mm in diameter when distended. It passes from the umbilicus, within the layers of the falciform ligament, superiorly and to the right, to the porta hepatis. Here it gives off several large intrahepatic branches to the liver and then joins the left branch of the portal vein and the ductus venosus. The umbilical vein is thin walled; it possesses a definite internal lamina of elastic fibres at the umbilical ring, but not in its intra-abdominal course. The tunica media contains smooth muscle fibres, collagen and elastic fibres. When the cord is severed, the umbilical vein contracts, but not so vigorously as the arteries. The rapid decrease in pressure in the umbilical vein after the cord is clamped means that the elastic tissue at the umbilical ring is sufficient to arrest any retrograde flow along the vessel. Before birth there is a subintimal proliferation of connective tissue. After birth, the contraction of the collagen fibres in the tunica media and the increased subintimal connective tissue contribute to the transformation of the vessel into the ligamentum teres. Obliteration occurs from the umbilical ring towards the hepatic end. No thrombi are formed in the obliteration process. For up to 48 hours after birth, the intra-abdominal portion of the umbilical vein can be easily dilated. In most adults the original lumen of the vein persists through the ligamentum teres and can be dilated to 5–6 mm in diameter.

Ductus venosus

The ductus venosus is a direct continuation of the umbilical vein and arises from the left branch of the portal vein, directly opposite the termination of the umbilical vein. It passes for 2–3 cm within the layers of the lesser omentum, in a groove between the left lobe and caudate lobe of the liver, before terminating in either the inferior vena cava, or in the left hepatic vein immediately before it joins the inferior vena cava. The tunica media of the ductus venosus contains circularly arranged smooth muscle fibres, an abundant amount of elastic fibres and some connective tissue.

The ductus venosus is already closed in about one-third of newborn infants. It shuts down by an unknown mechanism. Obliteration begins at the portal vein end in the second postnatal week and progresses to the vena cava; the lumen has been completely obliterated by the second or third month after birth. The fibrous remnant of the ductus venosus is the ligamentum venosum.

Umbilical vein catheterization

The umbilical vein may be catheterized in the neonate to enable exchange and transfusion of blood, for central venous pressure measurement and, usually in an emergency, for vascular access. The catheter is inserted into the cut end of the umbilical vein and is advanced along the length of the vein, through the ductus venosus and into the inferior vena cava, the tip being placed between the ductus venosus and the right atrium. Positioning of the catheter tip is confirmed radiologically and it should be located just above the diaphragm at a point which is level with the ninth or tenth thoracic vertebrae (T9/T10). As with umbilical arterial catheters, estimation of the required catheter length can be determined from standard charts.

Umbilical arteries

The fetal umbilical arteries are in direct continuation with the internal iliac arteries. Their lumen is 2–3 mm in diameter at their origin, when distended. This narrows as they approach the umbilicus, where there is a reciprocal thickening of the tunica media, as a result, in particular, of an increase in the number of longitudinal smooth muscle fibres and elastic fibres. Before birth there is a proliferation of connective tissue within the vessel wall. The umbilical vessels constrict in response to handling, stretching, cooling and altered tensions of oxygen and carbon dioxide. Umbilical vessels are muscular, but devoid of a nerve supply in their extra-abdominal course. After the cord is severed the umbilical arteries contract, preventing significant blood loss; thrombi often form in the distal ends of the arteries. The arteries obliterate from their distal ends until, by the end of the second or third postnatal month, involution has occurred at the level of the superior vesical arteries. The proximal parts of the obliterated vessels remain as the medial umbilical ligaments.

Umbilical arterial catheterization

Insertion of an umbilical catheter is undertaken to provide direct access to the arterial circulation. Arterial blood can be withdrawn repeatedly for measurement of oxygen and carbon dioxide partial pressures, pH, base excess and many other parameters of blood biochemistry and haematology. The indwelling catheter also enables the continuous measurement of arterial blood pressure.

The catheter is inserted directly into either the cut end or the side of one of the two umbilical arteries in the umbilical cord stump that remains attached to the baby after transection of the umbilical cord at the time of delivery. The catheter tip is then advanced along the length of the umbilical artery, through the internal iliac artery, into the common iliac artery and from there into the aorta. In order to keep the catheter patent, a small volume of fluid is continuously infused through it. It is important that the tip of the catheter should be located well away from arteries branching from the aorta, to avoid potentially harmful perfusion of these arteries with the catheter fluid. Thus umbilical arterial catheter tips are placed in the descending aorta either in a 'high' position, above the coeliac artery but well below the ductus arteriosus, or in a 'low' position, below the renal and inferior mesenteric arteries but above the point where the aorta bifurcates into the two common iliac arteries. The length of catheter to be inserted can be estimated from charts relating the required catheter length to external body measurements, or from birth weight. Positioning of the catheter is assessed by means of radiographs of the abdomen or chest: a 'high' catheter tip should be located in the descending aorta somewhere between the levels of the sixth and ninth thoracic vertebrae (T6–9), while a 'low' catheter tip should be at a level between the third and fourth lumbar vertebrae (L3–4). Relevant anatomical reference points are given in Table 73.1.

Table 73.1 Key anatomical reference points for umbilical arterial catheterization

Structure	**Vertebral level**
Ductus arteriosus	T4–5
Coeliac artery	T12
Superior mesenteric artery	T12–L1
Renal artery	L1
Inferior mesenteric artery	L3
Aortic bifurcation	L4–5

CHAPTER 74

Kidney and ureter

KIDNEY

The kidneys excrete the end products of metabolism and excess water. These actions are essential for the control of concentrations of various substances in the body, maintaining electrolyte and water balance approximately constant in the tissue fluids. The kidneys also have endocrine functions, producing and releasing erythropoietin, which affects red blood cell formation; renin, which influences blood pressure; 1,25-di-hydroxycholecalciferol (the metabolically active form of vitamin D), which is involved in the control of calcium absorption and mineral metabolism; and various other soluble factors with metabolic actions.

In the fresh state, the kidneys are reddish-brown. They are situated posteriorly behind the peritoneum on each side of the vertebral column and are surrounded by adipose tissue. Superiorly they are level with the upper border of the 12th thoracic vertebra, inferiorly with the third lumbar vertebra. The right is usually slightly inferior to the left, reflecting its relationship to the liver. The left is a little longer and narrower than the right and lies nearer the median plane (Fig. 74.1). The long axis of each kidney is directed inferolaterally and the transverse axis posteromedially, which means that the anterior and posterior aspects usually described are in fact anterolateral and posteromedial. An appreciation of this orientation is important in percutaneous and endo-urologic renal surgery.

Fig. 74.1 Relationships of the kidneys and ureters in the male retroperitoneum.

(From Sobotta 2006.)

Each kidney is typically 11 cm in length, 6 cm in breadth and 3 cm in anteroposterior dimension. The left kidney may be 1.5 cm longer than the right; it is rare for the right kidney to be more than 1 cm longer than the left. The average weight is 150 g in men and 135 g in women. In thin individuals with a lax abdominal wall the lower pole of the lower right kidney may just be felt in full inspiration by bimanual lumbar examination, but this is unusual.

In the fetus and newborn, the kidney normally has 12 lobules. These are fused in adults to present a smooth surface although traces of lobulation may remain.

Absent and ectopic kidneys

A single absent kidney is seen in 1 in 1200 individuals and results from failure of metanephric blastema to join with a ureteric bud on the affected side. It has no clinical sequelae but may frequently be associated with absence of the ipsilateral vas deferens and/or epididymis and may be associated with other congenital anomalies including imperforate anus, cardiac valvular anomalies and oesophageal atresia. A single kidney often shows compensatory hypertrophy. The life expectancy of individuals with a single kidney is the same as those with two kidneys.

Failure of the kidney to ascend into the renal fossa *in utero* results in renal ectopia. Most commonly the kidney is found in the pelvis: this occurs in 1 in 2500 live births. Kidneys so placed often have associated malrotation anomalies, and may have marked fetal lobulation. Pelvic kidneys frequently become hydronephrotic as a result of an anterior placed ureter and an anomalous arterial supply. An associated pelviureteric junction obstruction is often present.

Very rarely, and despite the normal location of the ureteric orifices within the bladder, the two renal masses may be on the same side. This is termed crossed renal ectopia and usually the two renal masses are fused in such circumstances. A solitary crossed renal ectopia may be associated with skeletal and other genitourinary anomalies. A number of different anatomical patterns can result, all of which are extremely rare (Fig. 74.2).

Horseshoe kidney

Horseshoe kidneys are found in 1 in 400 individuals. A transverse bridge of renal tissue, the isthmus, which usually but not invariably contains functioning renal substance, connects the two renal masses. The isthmus lies between the inferior poles, most commonly anterior to the great vessels. The ureters curve anterior to the isthmus and often have a high insertion into the renal pelvis (Fig. 74.3A,B).

Fig. 74.3 **A**, Horseshoe kidney. Note the ureters pass anterior to the isthmus. Note also the relatively high insertion of the ureters into the renal pelvis. **B**, Late phase post-contrast axial CT scan showing a horseshoe kidney. Both lower poles are directed medially and fused by an isthmus (arrowed). Note that the renal pelves (seen here filled with contrast) are directed anteriorly.

(From Sobotta 2006.)

The blood supply to horseshoe kidneys is variable. One vessel to each moiety is seen in 30% of horseshoe kidneys, but multiple anomalous vessels are common; the isthmus may be supplied by a vessel directly from the aorta or from branches of the inferior mesenteric, common iliac or external iliac arteries. In view of this variable arterial anatomy, angiography or CT scanning with vascular reconstruction is very helpful when planning renal surgery on horseshoe kidneys. Horseshoe kidneys can have an associated congenital pelviureteric junction obstruction in up to 30% of cases. Anomalous vessels crossing the ureter and the abnormal course of the ureter as it passes over renal substance may also cause obstruction. Horseshoe kidneys have an increased incidence of stone disease, probably as a consequence of areas of inefficient drainage.

PERIRENAL FASCIA

The perirenal fascia is a dense, elastic connective tissue sheath which envelops each kidney and suprarenal gland together with a layer of surrounding perirenal fat (Fig. 74.4A,B; see Fig. 62.1). The kidney and its vessels are embedded in perirenal fat, which is thickest at the renal borders and extends into the renal sinus at the hilum.

Fig. 74.4 **A**, Sagittal section through the posterior abdominal wall showing the relations of the renal fascia of the right kidney. **B**, Transverse section, showing the relations of the renal fascia.

The perirenal fascia was originally described as being made up of two separate entities, the posterior fascia of Zuckerkandl and the anterior fascia of Gerota, which fused laterally to form the lateral conal fascia. According to this view, the lateral conal fascia continued anterolaterally behind the colon to blend with the parietal peritoneum. However, work by Mitchell (1950) showed that the perirenal fascia is not made up of distinct fused fasciae, but is in fact a single multilaminated structure which is fused posteromedially with the muscular fasciae of psoas major and quadratus lumborum. It then extends anterolaterally behind the kidney as a bilaminated sheet, which at a variable point divides into a thin anterior lamina, passing around the front of the kidney as the anterior perirenal fascia, and a thicker posterior lamina which continues anterolaterally as the lateral conal fascia, fusing with the parietal peritoneum.

Classically, the anterior perirenal fascia was thought to blend into the dense mass of connective tissue surrounding the great vessels in the root of the mesentery behind the duodenum and pancreas, thereby preventing communication between perirenal spaces across the midline. However inspection of CT images or of anatomical sections of cadavers, following injection of contrast or coloured latex respectively, into the perirenal space, revealed that fluid could extend across the midline at the third to fifth lumbar levels through a narrow channel measuring 2–10 mm in AP dimension. In the midline superiorly, the anterior and posterior renal fasciae fuse and are attached to the crura of their respective hemidiaphragms. Inferiorly the fasciae separate for a variable craniocaudal distance. The posterior perirenal fascia fuses with the muscular fascia of psoas major while the anterior perirenal fascia extends across the midline in front of the great vessels and so communication between the two sides is permitted although very rarely of clinical significance. Below this level the two fasciae once again merge and are attached to the great vessels or iliac vessels. The containment of fluid to one side of the perirenal space that is observed in over two thirds of clinical cases is attributed to the presence of fibrous septae.

Above the suprarenal glands the anterior and posterior perirenal fasciae were previously said to fuse with each other and to the diaphragmatic fascia.

This description of a closed superior cone is not universally accepted. Cadaveric experiments have shown the superior aspect of the perirenal space to be open and in continuity with the bare area of the liver on the right and the subphrenic extraperitoneal space on the left. The posterior fascial layer blends bilaterally with the fascia of psoas major and quadratus lumborum as well as the inferior phrenic fascia. The anterior fascial layer on the right blends with the right inferior coronary ligament at the level of the upper pole of the kidney and bare area of the liver. On the left the anterior layer fuses with the gastrosplenic ligament at the level of the suprarenal gland.

There is some debate concerning the inferior fusion of the perirenal fascia. Many investigators believe that inferiorly the anterior and posterior leaves of the perirenal fascial fuse to produce an inverted cone which is open to the pelvis at its apex. Laterally the anterior and posterior leaves fuse with the iliac fascia, and medially they fuse with the periureteric connective tissue. The inferior apex of the cone is open anatomically towards the iliac fossa but rapidly becomes sealed in inflammatory disease. An alternative view is based on the dissection of recently deceased cadavers after injections of coloured latex into the perirenal space: these have shown that the anterior and posterior perirenal fasciae merge to form a single multilaminar fascia which contains the ureter in the iliac fossa. Anteriorly this common fascia is loosely connected to the parietal peritoneum, and so denies free communication between the perirenal space and the pelvis, and also denies communication between the perirenal and pararenal spaces.

A simple nephrectomy for benign disease removes the kidney from within perirenal fascia; a radical nephrectomy (for cancer) removes the entire contents of the perirenal space including the perirenal fascia, in order to give adequate clearance around the tumour.

RELATIONS

The superior poles of both kidneys are thick and round and each is related to its suprarenal gland (Fig. 74.5A,B). The inferior poles are thinner and extend to within 2.5 cm of the iliac crests. The lateral borders are convex. The medial borders are convex adjacent to the poles, concave between them and slope inferolaterally. In each a deep vertical fissure opens anteromedially as the hilum, which is bounded by anterior and posterior lips and contains the renal vessels and nerves and the renal pelvis. The relative positions of the main hilar structures are the renal vein (anterior), the renal artery (intermediate) and the pelvis of the kidney (posterior). Usually an arterial branch from the main renal artery runs over the superior margin of the renal pelvis to enter the hilum on the posterior aspect of the pelvis, and a renal venous tributary often leaves the hilum in the same plane. Above the hilum the medial border is related to the suprarenal gland and below to the origin of the ureter.

(From Sobotta 2006.)

The convex anterior surface of the kidney actually faces anterolaterally and its relations differ on the right and left. Likewise the posterior surface of the kidneys in reality faces posteromedially. Its relations are similar on both sides of the body (Fig. 74.6A–D).

A small area of the superior pole is in contact with the right suprarenal gland, which may overlap the upper part of the medial border of the superior pole. A large area below this is immediately related the right lobe of the liver separated by a layer of peritoneum. A narrow medial area is directly related to the retroperitoneal descending part of the duodenum. Inferiorly the anterior surface is directly in contact laterally with the retroperitoneal right colic flexure and medially with part of the intraperitoneal small intestine.

A small medial area of the superior pole is related to the left suprarenal gland. The lateral half of the anterior surface is related to the spleen from which it is separated by a layer of peritoneum. A central quadrilateral area lies in direct contact with the retroperitoneal pancreas and the splenic vessels. Above this a small variable triangular region, between the suprarenal and splenic areas, is in contact with the stomach separated by a layer of peritoneum. Below the pancreatic and splenic areas, a narrow lateral strip which extends to the lateral border of the kidney is directly related to the retroperitoneal left colic flexure and the beginning of the descending colon. An extensive medial area is related to intraperitoneal loops of jejunum. The gastric area is covered with the peritoneum of the lesser sac (omental bursa) and the splenic and jejunal areas are covered by the peritoneum of the greater sac. Behind the peritoneum covering the jejunal area, branches of the left colic vessels are related to the kidney (Fig. 74.7A,B).

(From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)

The posteromedial surface of the kidneys is embedded in fat and devoid of peritoneum. The right and left kidneys are related to similar structures. Superiorly are the diaphragm and the medial and lateral arcuate ligaments. More inferiorly, moving in a medial to lateral direction, are psoas major, quadratus lumborum and the aponeurotic tendon of transversus abdominis, the subcostal vessels and the subcostal, iliohypogastric, and ilioinguinal nerves. The upper pole of the right kidney is level with the 12th rib, and that of the left with the 11th and 12th ribs. The diaphragm separates the kidney from the pleura, which descends to form the costodiaphragmatic recess: diaphragmatic muscle is sometimes defective or absent in a triangle immediately above the lateral arcuate ligament, and this allows perirenal adipose tissue to contact the diaphragmatic pleura.

INTERNAL MACROSTRUCTURE

The postnatal kidney has a thin fibrous capsule composed of collagen-rich tissue with some elastic and smooth muscle fibres. In renal disease the capsule may become adherent (Fig. 74.8A,B).

In **B**, the renal pelvis has been opened to reveal the interlobar arteries.

*(**B** from Sobotta 2006.)*

The kidney itself can be divided into an internal medulla and external cortex. The renal medulla consists of pale, striated, conical renal pyramids, their bases peripheral, their apices converging to the renal sinus. At the renal sinus they project into calyces as papillae.

The renal cortex is subcapsular, arching over the bases of the pyramids and extending between them towards the renal sinus as renal columns. Its peripheral regions are termed cortical arches and are traversed by radial, lighter-coloured medullary rays, separated by darker tissue, the convoluted part. The rays taper towards the renal capsule and are peripheral prolongations from the bases of renal pyramids. The cortex is histologically divisible into outer and inner zones. The inner zone is demarcated from the medulla by tangential blood vessels (arcuate arteries and veins), which lie at the junction of the two, however a thin layer of cortical tissue (subcortex) appears on the medullary side of this zone. The cortex close to the medulla is sometimes termed the juxtamedullar cortex.

Renal pelvis and calyces

The hilum of the kidney leads into a central renal sinus, lined by the renal capsule and almost filled by the renal pelvis and vessels, the remaining space being filled by fat. Dissection into this plane can be challenging but is important in surgery on the renal pelvis, particularly open stone surgery. Within the renal sinus, the collecting tubules of the nephrons of the kidney open onto the summits of the renal papillae to drain into minor calyces, which are funnel-shaped expansions of the upper urinary tract. The renal capsule covers the external surface of the kidney and continues through the hilum to line the sinus and fuse with the adventitial coverings of the minor calyces. Each minor calyx surrounds either a single papilla or, more rarely, groups of two or three papillae. The minor calyces unite with their neighbours to form two or possibly three larger chambers, the major calyces. There is wide variation in the arrangement of the calyces. As the posterior aspect of the kidney rotates laterally during its ascent *in utero*, the calyces which were lateral *in utero* become positioned anteriorly, and the medial calyces move more posteriorly. The calyces drain into the infundibula. The renal pelvis is normally formed from the junction of two infundibula, one from the upper and one from the lower pole calyces, but there may be a third, which drains the calyces in the mid-portion of the kidney. The calyces are usually grouped so that three pairs drain into the upper pole infundibulum and four pairs into the lower pole infundibulum. If there is a middle infundibulum, the distribution is normally three pairs at the upper pole, two in the middle, and two at the lower pole. There is considerable variation in the arrangement of the infundibula and in the extent to which the pelvis is intrarenal or extrarenal. The funnel-shaped renal pelvis tapers as it passes inferomedially, traversing the renal hilum to become continuous with the ureter (Fig. 74.8A,B; see Fig. 74.9). It is rarely possible to determine precisely where the renal pelvis ceases and the ureter begins: the region is usually extrahilar and normally lies adjacent to the lower part of the medial border of the kidney. Rarely, the entire renal pelvis has been found to lie inside the sinus of the kidney so that the pelviureteric region occurs either in the vicinity of the renal hilum or completely within the renal sinus.

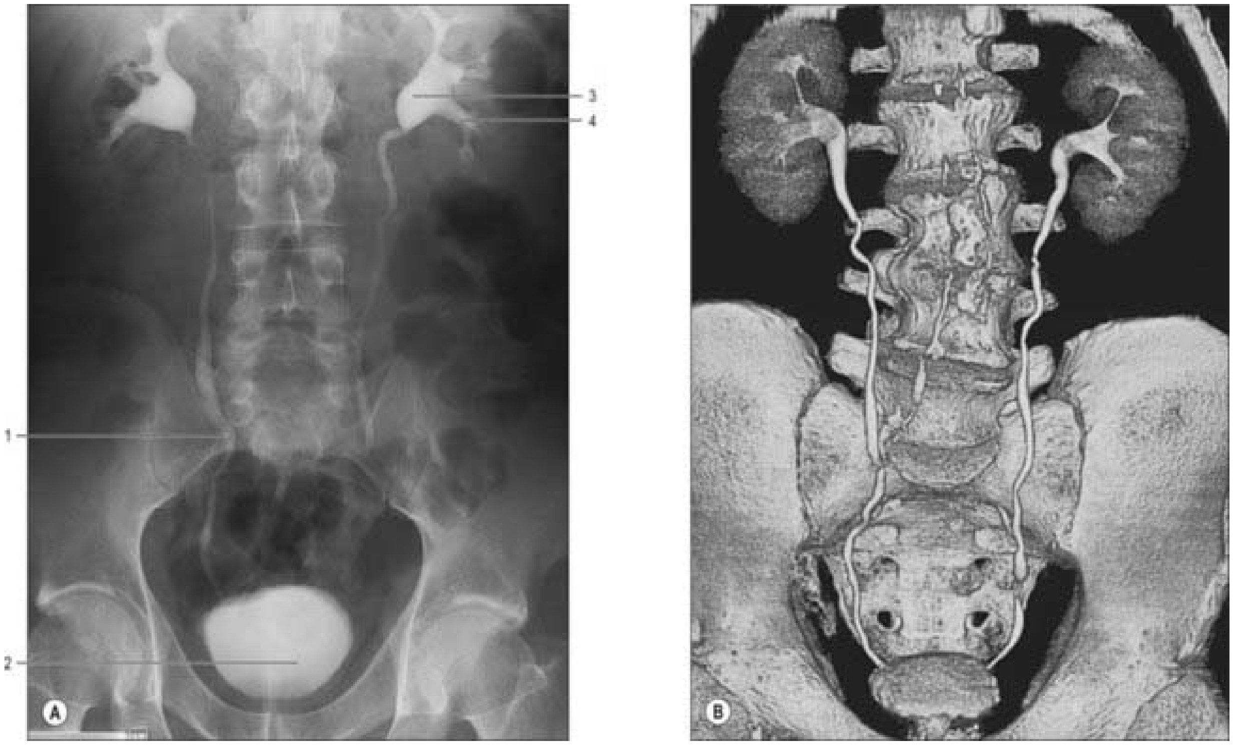

Fig. 74.9 **A**, Conventional intravenous urogram showing the renal calyces, pelves and both ureters. **1**. Ureter. **2**. Bladder. **3**. Renal pelvis. **4**. Calyces. **B**, Multislice CT urogram. 3D-surface shaded reformat showing the kidneys, ureters, bladder and surrounding bony anatomy.

The calyces, renal pelvis and ureter are well-demonstrated radiologically following an intravenous injection of radio-opaque contrast which is excreted in the urine (intravenous urography – IVU) (Fig. 74.9A,B); or after the introduction of radio-opaque contrast into the ureter by catheterization through a cystoscope (ascending or retrograde pyelography. Normal cupping of the minor calyces by projecting renal papillae may be obliterated by conditions that cause hydronephrosis, chronic distension of the ureter and renal pelvis due to upper or lower urinary tract obstruction resulting in elevated intrapelvic pressure. An appreciation of the rotation of the kidneys which results in the posterior calyces lying relatively medially and the anterior calyces lying laterally is essential when interpreting contrast imaging of the collecting system of the kidneys.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Renal arteries

The paired renal arteries take about 20% of the cardiac output to supply organs that represent less than one-hundredth of total body weight. They branch laterally from the aorta just below the origin of the superior mesenteric artery (see Fig. 62.8; Fig. 74.10A). Both cross the corresponding crus of the diaphragm at right angles to the aorta. The right renal artery is longer and often higher, passing posterior to the inferior vena cava, right renal vein, head of the pancreas, and descending part of the duodenum. The left renal artery is a little lower and passes behind the left renal vein, the body of the pancreas, and splenic vein. It may be crossed anteriorly by the inferior mesenteric vein.

Fig. 74.10 **A**, Axial multislice CT renal angiogram. **B**, Variations in the number and patterns of branching of the renal artery (percentages are approximate).

*(**B** from Sobotta 2006.)*

A single renal artery to each kidney is present in approximately 70% of individuals (Fig. 74.11). The arteries vary in their level of origin and in their calibre, obliquity and precise relations (Fig. 74.10B). In its extrarenal course each renal artery gives off one or more inferior suprarenal arteries, a branch to the ureter and branches which supply perinephric tissue, the renal capsule, and the pelvis. Near the renal hilum, each artery divides into an anterior and a posterior division, and these divide into segmental arteries supplying the renal vascular segments. Accessory renal arteries are common (30% of individuals), and usually arise from the aorta above or below (most commonly below) the main renal artery and follow it to the renal hilum. They are regarded as persistent embryonic lateral splanchnic arteries. Accessory vessels to the inferior pole cross anterior to the ureter and may, by obstructing the ureter, cause hydronephrosis. Rarely, accessory renal arteries arise from the coeliac or superior mesenteric arteries near the aortic bifurcation or from the common iliac arteries.

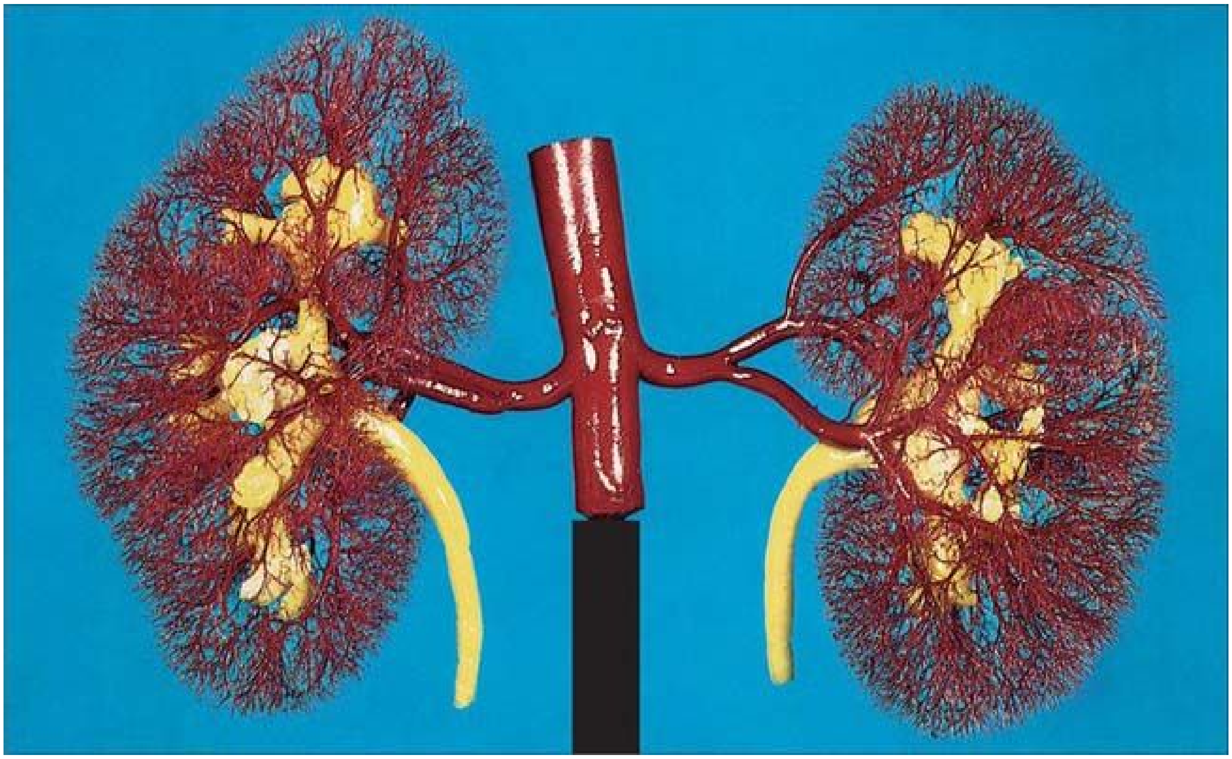

Fig. 74.11 Resin corrosion cast of human kidneys. Ureters, pelves and calyces are yellow; aorta, renal arteries and their branches are red.

(Prepared by the late DH Tompsett of the Royal College of Surgeons of England. By permission of the Museums of The Royal College of Surgeons.)

The subdivisions of the renal arteries are described sequentially as segmental, lobar, interlobar, arcuate and interlobular arteries and afferent and efferent glomerular arterioles (see Fig. 74.14).

Segmental arteries

Renal vascular segmentation was originally recognized by John Hunter in 1794, but the first detailed account of the primary pattern was produced in the 1950s from casts and radiographs of injected kidneys. Five arterial segments have been identified (Fig. 74.12). The apical segment occupies the anteromedial region of the superior pole. The superior (anterior) segment includes the rest of the superior pole and the central anterosuperior region. The inferior segment encompasses the whole lower pole. The middle (anterior) segment lies between the anterior and inferior segments. The posterior segment includes the whole posterior region between the apical and inferior segments. This is the pattern most commonly seen, and although there can be considerable variation it is the pattern that clinicians most frequently encounter when performing partial nephrectomy. Whatever pattern is present, it must be emphasized that vascular segments are supplied by virtual end arteries. In contrast, larger intrarenal veins have no segmental organization and anastomose freely.

Brödel (1911) described a relatively avascular longitudinal zone (the ‘bloodless’ line of Brödel) along the convex renal border, which was proposed as the most suitable site for surgical incision. However, many vessels cross this zone, and it is far from ‘bloodless’: planned radial or intersegmental incisions are preferable. Knowledge of the vascular anatomy of the kidney is important when undertaking partial nephrectomy for renal cell cancers. In this surgery the branches of the renal artery are defined so that the surgeon may safely excise the renal substance containing the tumour while not compromising the vascular supply to the remaining renal tissue.

Lobar, interlobar, arcuate and interlobular arteries

The initial branches of segmental arteries are lobar, usually one to each renal pyramid. Before reaching the pyramid they subdivide into two or three interlobar arteries, extending towards the cortex around each pyramid. At the junction of the cortex and medulla, interlobar arteries dichotomize into arcuate arteries which diverge at right angles. As they arch between cortex and medulla, each divides further, ultimately supplying interlobular arteries which diverge radially into the cortex. The terminations of adjacent arcuate arteries do not anastomose but end in the cortex as additional interlobular arteries. Though most interlobular arteries come from arcuate branches, some arise directly from arcuate or even terminal interlobar arteries (see Fig. 74.14). Interlobular arteries ascend towards the superficial cortex or may branch occasionally en route. Some are more tortuous and recurve towards the medulla at least once before proceeding towards the renal surface. Others traverse the surface as perforating arteries to anastomose with the capsular plexus (which is also supplied from the inferior suprarenal, renal and gonadal arteries).

Afferent and efferent glomerular arterioles

Afferent glomerular arterioles are mainly the lateral rami of interlobular arteries. A few arise from arcuate and interlobar arteries when they vary their direction and angle of origin: deeper ones incline obliquely back towards the medulla, the intermediate pass horizontally, and the more superficial approach the renal surface obliquely before ending in a glomerulus (see Fig. 74.14). Efferent glomerular arterioles from most glomeruli (except at juxtamedullary and, sometimes, at intermediate cortical levels) soon divide to form a dense peritubular capillary plexus around the proximal and distal convoluted tubules: there are thus two sets of capillaries, glomerular and peritubular, in series in the main renal cortical circulation, linked by efferent glomerular arterioles. The vascular supply of the renal medulla is largely from efferent arterioles of juxtamedullary glomeruli, supplemented by some from more superficial glomeruli, and ‘aglomerular’ arterioles (probably from degenerated glomeruli). Efferent glomerular arterioles passing into the medulla are relatively long, wide vessels, and contribute side branches to neighbouring capillary plexuses before entering the medulla, where each divides into 12–25 descending vasa recta. As their name suggests, these run straight to varying depths in the renal medulla, contributing side branches to a radially elongated capillary plexus (see Fig. 74.14) applied to the descending and ascending limbs of renal loops and to collecting ducts. The venous ends of capillaries converge to the ascending vasa recta, which drain into arcuate or interlobular veins. An essential feature of the vasa recta (particularly in the outer medulla) is that both ascending and descending vessels are grouped into vascular bundles, within which the external aspects of both types are closely apposed, bringing them close to the limbs of renal loops and collecting ducts. As these bundles converge centrally into the renal medulla they contain fewer vessels: some terminate at successive levels in neighbouring capillary plexuses. This proximity of descending and ascending vessels with each other and adjacent ducts provides the structural basis for the countercurrent exchange and multiplier phenomena (see countercurrent exchange mechanism later in chapter (see Fig. 74.17)). These complex renal vascular patterns show regional specializations which are closely adapted to the spatial organization and functions of renal corpuscles, tubules and ducts (see below).

Renal veins

Fine radicles from the venous ends of the peritubular plexuses converge to join interlobular veins, one with each interlobular artery. Many interlobular veins begin beneath the fibrous renal capsule by the convergence of several stellate veins, which drain the most superficial zone of the renal cortex and so are named from their surface appearance. Interlobular veins pass to the corticomedullary junction and also receive some ascending vasa recta before ending in arcuate veins (which accompany arcuate arteries), and anastomose with neighbouring veins. Arcuate veins drain into interlobar veins, which anastomose and form the renal vein.

The large renal veins lie anterior to the renal arteries and open into the inferior vena cava almost at right angles. The left is three times longer than the right (7.5 cm and 2.5 cm respectively) and for this reason, the left kidney is the preferred side for live donor nephrectomy. The left renal vein runs from its origin in the renal hilum, posterior to the splenic vein and the body of pancreas, and then across the anterior aspect of the aorta, just below the origin of the superior mesenteric artery. The left gonadal vein enters it from below and the left suprarenal vein, usually receiving one of the left inferior phrenic veins, enters it above but nearer the midline. The left renal vein enters the inferior vena cava a little superior and to the right. The right renal vein is behind the descending duodenum and sometimes the lateral part of the head of the pancreas. It can be extremely short (<1 cm) such that safe nephrectomy may require excision of a cuff of the inferior vena cava (Fig. 74.13).

Fig. 74.13 CT renal venogram. Acquired from a multislice CT examination and reconstructed as a 3D surface shaded reformat.

The left renal vein may be double, one vein passing posterior, the other anterior, to the aorta before joining the inferior vena cava. This is sometimes referred to as persistence of the ‘renal collar’. The anterior vein may be absent so that there is a single retroaortic left renal vein. The left renal vein may be ligated during surgery for aortic aneurysm because it has such a close relationship with the aorta: this seldom results in any harm to the kidney, provided that the ligature is placed to the right of the draining gonadal and suprarenal veins, since these usually provide adequate collateral venous drainage. The right renal vein has no significant collateral drainage and cannot be ligated with impunity.

Lymphatic drainage

Renal lymphatic vessels begin in three plexuses, around the renal tubules, under the renal capsule, and in the perirenal fat (the latter two connect freely). Collecting vessels from the intrarenal plexus form four or five trunks which follow the renal vein to end in the lateral aortic nodes; the subcapsular collecting vessels join them as they leave the hilum. The perirenal plexus drains directly into the same nodes.

INNERVATION

Rami from the coeliac ganglion and plexus, aorticorenal ganglion, lowest thoracic splanchnic nerve, first lumbar splanchnic nerve and aortic plexus form a dense plexus of autonomic nerves around the renal artery.

Small ganglia occur in the renal plexus, the largest usually behind the origin of the renal artery. The plexus continues into the kidney around the arterial branches and supplies the vessels and renal glomeruli, and especially the cortical tubules. Axons from plexuses around the arcuate arteries innervate juxtamedullary efferent arterioles and vasa recta, which control the blood flow between the cortex and medulla without affecting the glomerular circulation. Axons from the renal plexus contribute to the ureteric and gonadal plexuses.

MICROSTRUCTURE

The kidney is composed of many tortuous, closely packed uriniferous tubules, bounded by a delicate connective tissue in which run blood vessels, lymphatics and nerves. Each tubule consists of two embryologically distinct parts, the nephron, which produces urine, and the collecting duct, which completes the concentration of urine and through which urine passes out into the calyces of the kidney, the renal pelvis, the ureter and urinary bladder (see p. 1305).

Nephron

The nephron consists of a renal corpuscle, concerned with filtration from the plasma, and a renal tubule, concerned with selective resorption from the filtrate to form the urine (Fig. 74.14). Collecting ducts carry fluid from several renal tubules to a terminal papillary duct, opening into a minor calyx at the apex of a renal papilla. Papillary surfaces show numerous minute orifices of these ducts and pressure on a fresh kidney expresses urine from them.

Renal corpuscle

Renal corpuscles are small rounded structures averaging 0.2 mm in diameter, visible in the renal cortex deep to a narrow peripheral cortical zone (Fig. 74.15A,B). Each has a central glomerulus of vessels and a glomerular (Bowman's) capsule, from which the renal tubule originates.

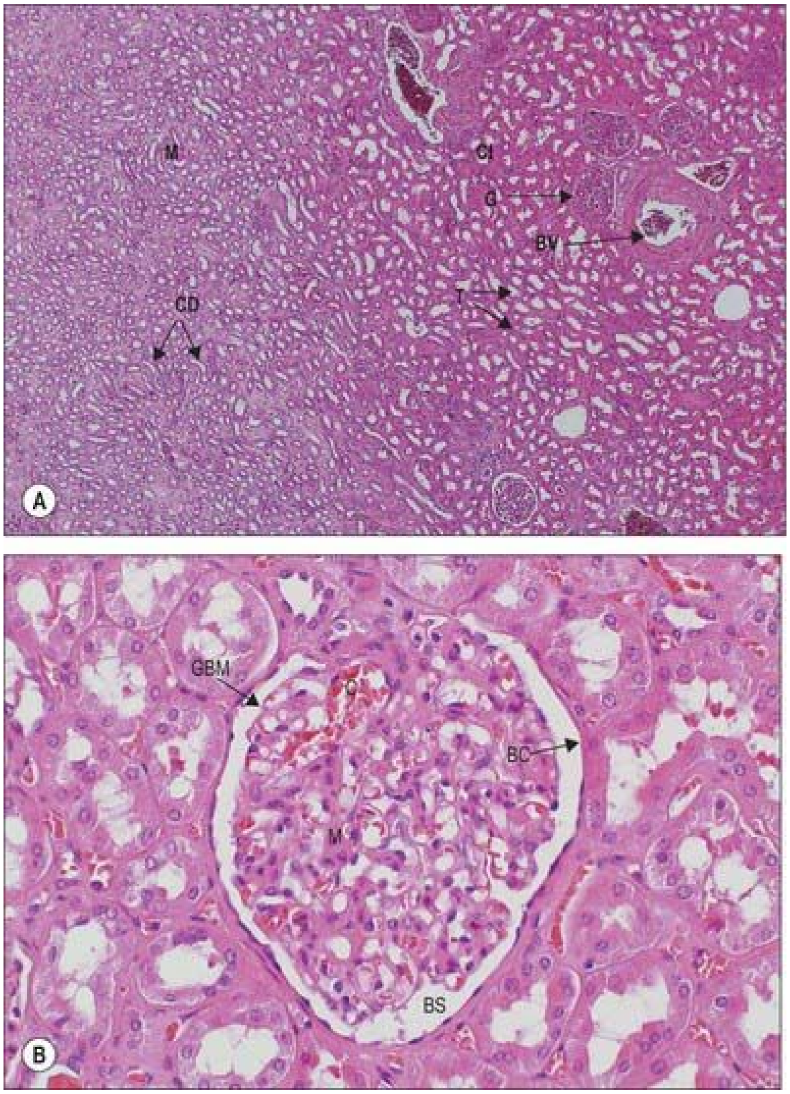

Fig. 74.15 **A**, Low power view of the kidney showing renal cortex (Ct) comprising glomeruli (G), proximal and distal convoluted tubules (T) and blood vessels (BV). The medulla (M) contains loops of Henle and collecting ducts (CD) (× 20, H&E stain). **B**, A glomerulus with a network of capillaries (C) set within a small amount of connective tissue, the mesangium (M). The glomerular basement membrane (GBM) of the capillaries is continuous with the Bowman's capsule (BC) of the glomerulus, and is separated from it by Bowman's space (BS) (× 200, H&E stain).

There are about one million renal corpuscles in each kidney, their number (which may be determined in part by intra-uterine factors) decreases with age; this process is accelerated by raised blood pressure. After birth new nephrons cannot be developed – a lost nephron can never be replaced. The decrease in corpuscular numbers with age is reflected in a corresponding reduction in the rate of glomerular filtration from the fourth decade onwards.

Glomerulus

A glomerulus is a collection of convoluted capillary blood vessels, united by a delicate mesangial matrix and supplied by an afferent arteriole which enters the capsule opposite the urinary pole, where the filtrate enters the tubule. (The term glomerulus is used most frequently to describe the entire renal corpuscle.) An efferent arteriole emerges from the same point, the vascular pole of the corpuscle. Glomeruli are simple in form until late prenatal life; some remain so for about 6 months after birth, the majority maturing by 6 years and all by 12 years (see p. 1305).

Bowman’s capsule

Bowman’s capsule is the blind expanded end of a renal tubule, and is deeply invaginated by the glomerulus. It is lined by a simple squamous epithelium on its outer (parietal) wall; its glomerular, juxtacapillary (visceral) wall is composed of specialized epithelial podocytes. Between the two walls of the capsule is a flattened urinary (Bowman’s) space, continuous with the proximal convoluted tubule (Fig. 74.15B; see Fig. 74.17).

Podocytes are stellate cells. Their major (primary) foot processes curve around the capillary loops and branch to form secondary processes which are applied closely to the basal lamina; secondary or tertiary processes give rise to terminal pedicels (Fig. 74.16A). Pedicels of one cell alternate with those of an adjacent cell and interdigitate tightly with each other, separated by narrow (25 nm) gaps, the filtration slits (Fig. 74.16B). The latter are covered by a dense, membranous slit diaphragm, through which filtrate must pass to enter the urinary space. The differentiation of the adult podocyte phenotype is associated with the presence of several specific proteins, including nephrin, podocin, synaptopodin and GLEPP-1. Mutations in these proteins can cause important functional problems, e.g. the classical Finnish form of congenital nephritic syndrome is caused by a mutation of NHPS1 coding for nephrin. The luminal membrane and the slit diaphragm are covered by a dense surface coat rich in sialoglycoproteins, which gives this surface a very high negative charge and is one of the key characteristics of the perm-selectivity barrier. Differentiated podocytes cannot replicate.

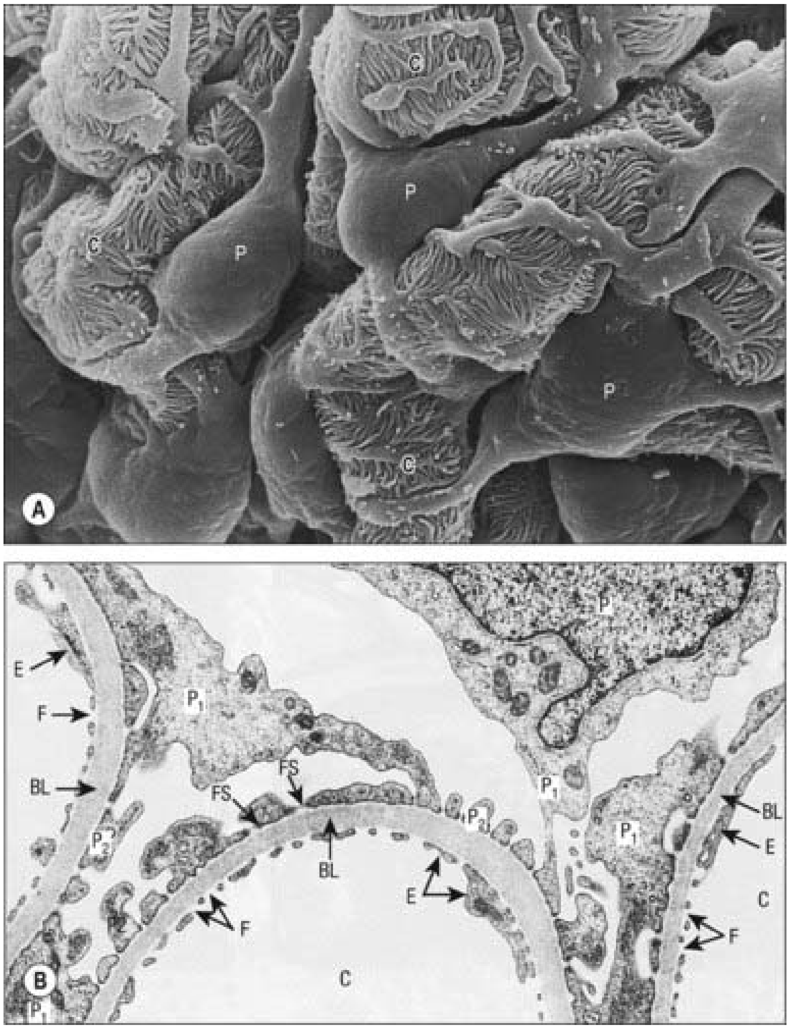

Fig. 74.16 **A**, Podocytes forming the visceral layer of Bowman's capsule in the renal corpuscle. Their cell bodies (P) send out primary processes which branch several times and end in fine pedicels which wrap tightly around the glomerular capillaries (C), and interdigitate with similar pedicels from a neighbouring podocyte. **B**, The glomerular filtration apparatus is

formed by the endothelial cells of fenestrated capillaries, the filtration slits between podocyte pedicels and their thick shared basal lamina. BL, basal lamina; C, capillary loops; E, endothelial cell cytoplasm; F, fenestrations; FS, filtration slits; P, podocyte, P_1 and P_2, primary and secondary foot processes which rest on the glomerular basal laminae.

The glomerular endothelium is finely fenestrated. The principal barrier to the passage of fluid from capillary lumen to urinary space is the glomerular basal lamina, the fused endothelial and podocyte basal laminae. This is usually 0.33 μm thick in man, and acts as a selective filter, allowing the passage from blood, under pressure, of water and various small molecules and ions in the circulation. Haemoglobin may cross the filter, but larger molecules and those of similar size with a negative charge, are largely retained. Most protein that does enter the filtrate is selectively resorbed and degraded by cells of the proximal convoluted tubule.

The glomerular basement membrane (GBM) serves as the skeleton of the glomerular tuft. Its outer aspect is completely covered by podocytes, and the interior is filled by capillaries and a delicate mesangial matrix (mesangium). The major components of the GBM are laminin and type IV collagen (both of which are expressed as unique isoforms) and heparin sulphate proteoglycans.

Irregular mesangial cells, with phagocytic and contractile properties, lie within and secrete the glomerular mesangium, a specialized connective tissue which binds the loop of glomerular capillaries and fills the spaces between endothelial surfaces that are not invested by podocytes (Fig. 74.15B; see Fig. 74.17). Mesangial cells are related to vascular pericytes and are concerned with the turnover of glomerular basement membrane. They clear the glomerular filter of immune complexes and cellular debris, and their contractile properties help to regulate blood flow. Similar cells, the extraglomerular mesangial (lacis) cells, lie outside the glomerulus at the vascular pole and form part of the juxtaglomerular apparatus.

Renal tubule

A renal or uriniferous tubule consists of a glomerular capsule that leads into a proximal convoluted tubule connected to the capsule by a short neck and continuing into a sinuous or coiled convoluted part (Fig. 74.17). This straightens as it approaches the medulla, and becomes the descending thick limb of the loop of Henle and then the ascending limb by an abrupt U-turn. The limbs of the loop of Henle are narrower and thin-walled within the deeper medullary tissue where they become the descending and ascending thin segments. The ascending thick limb continues into the distal tubule. The tubule wall shows a focal thickening, the macula densa, where it comes close to the vascular pole of its parent glomerulus at the start of the convoluted part of the distal tubule. The nephron finally straightens once more as the connecting tubule, which ends by joining a collecting duct.

Collecting ducts originate in the cortical medullary rays and join others at intervals. They finally open into wider papillary ducts which open on to a papilla, their numerous orifices forming a perforated area cribrosa on the surface at its tip (Fig. 74.14).

Renal tubules are lined throughout by a single-layered epithelium (Figs 74.17, 74.18). The type of epithelial cell varies according to the functional roles of the different regions, e.g. active transport and passive diffusion of various ions and water into and out of the tubules; reabsorption of organic components such as glucose and amino acids; uptake of any proteins which leak through the glomerular filter.

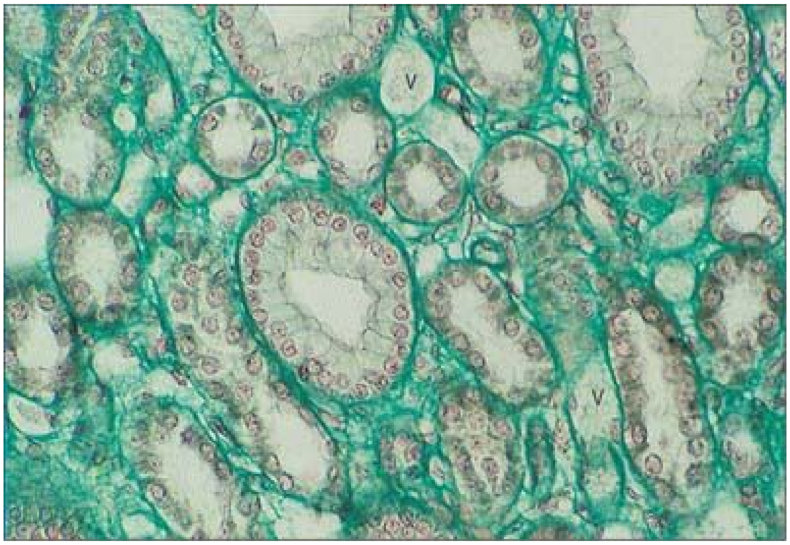

Fig. 74.18 Part of the renal medulla in cross-section. Note large collecting ducts and small thin segments of the loop of Henle, interspersed with vasa recta (V) (trichrome stained).

The proximal convoluted tubule is lined by cuboidal or low columnar epithelium and has a brush border of tall microvilli on its luminal surface. The shape of the cells depends on tubular fluid pressure, which in life distends the lumen and flattens the cells (they become taller when glomerular blood pressure falls postmortem or at biopsy). The cytoplasm of proximal tubular cells is strongly eosinophilic and the nuclei are euchromatic and central. The basal cytoplasm is rich in mitochondria, orientated perpendicularly, and the basal plasma membrane is highly infolded. The lateral surfaces of adjacent epithelial cells interdigitate, increasing the complexity of the basolateral plasma membrane. The microvilli on the luminal surfaces significantly increase the area of plasma membrane in contact with tubular fluid and the extratubular space, facilitating the transport of ions and small molecules against steep concentration gradients. The abundant mitochondria supply the energy, as ATP, needed for this process. Sodium/potassium adenosine triphosphatase (Na/K ATPase) is located in apical and basal membranes, and the cytoplasm contains numerous other enzymes concerned with ion transport. Water and other solutes pass between cells (paracellular transport) passively along osmotic and electrochemical gradients, probably through leaky apical tight junctions. Pinocytotic vesicles are found near the apical surface, and represent the means by which small proteins and peptides from the filtrate are internalized and degraded by associated lysosomes. Peroxisomes and lipid droplets abound in the cytoplasm.

The loop of Henle consists of a thin segment (30 μm in diameter), lined by low cuboidal to squamous cells, and a thick segment (60 μm in diameter) composed of cuboidal cells like those in the distal convoluted tubule. The thin segment forms most of the loop in juxtamedullary nephrons which reach deep into the medulla. Few organelles appear in cells lining the thin segment, indicating that these cells play a passive, rather than an active, role in ion transport. The thick segment is composed of cuboidal epithelium with many mitochondria, deep basolateral folds and short apical microvilli, indicating a more active metabolic role. The thick limb of the loop of Henle is the source of Tamm–Horsfall protein in normal urine.

Cells of the distal tubule are cuboidal and resemble those in the proximal tubule. They have few microvilli, and so the tubular lumen has a more distinct outline. The basolateral folds containing mitochondria are deep, almost reaching the luminal aspect (Fig. 74.17). Enzymes concerned in active transport of sodium, potassium and other ions are abundant. At the junction of the straight and convoluted regions the distal tubule comes close to the vascular pole of its parent renal corpuscle. Here, tubular cells form the macula densa, a sensory structure which is concerned with the regulation of blood flow and thus filtration rate. Cells in the terminal part of the distal tubule have fewer basal folds and mitochondria and constitute a connecting duct formed from metanephric mesenchyme during embryogenesis. Collecting ducts are lined by simple cuboidal or columnar epithelium. This increases in height from the cortex, where the ducts receive the contents of distal tubules, to the wide papillary ducts which discharge at the area cribrosa. The pale-staining principal cells have relatively few organelles or lateral interdigitations and only occasional microvilli. A second cell type, intercalated or dark cells (also present in smaller numbers in the distal convoluted tubule), have longer microvilli and more mitochondria and secrete H^+ into the filtrate; they function in the maintenance of acid–base homeostasis.

Renal vessels

Renal, interlobar and arcuate arteries are typical large muscular arteries and the interlobular vessels resemble small muscular arteries. Afferent glomerular vessels have a typical arteriolar structure with a muscular coat two to three cells thick: this coat and the connective tissue components of the wall diminish near a glomerulus until a point 30–50 μm proximal to it where arteriolar cells begin to show modifications typical of the juxtaglomerular apparatus. The efferent arterioles from most cortical glomeruli have thicker walls and a narrower calibre than corresponding afferents. Although the afferent arteriole is generally considered to be solely responsible for tubuloglomerular feedback, the peritubular and medullary capillaries possess a well-defined basal lamina and their endothelial cells have typically fenestrated cytoplasm, as do the ascending vasa recta, whereas the descending vasa recta have a thicker, continuous endothelium.

Other renal cells

Other cells essential to renal structure and function lie between the renal tubules and blood vessels. Connective tissue is inconspicuous in the cortex but prominent in the medulla, particularly in the papillae. Medullary interstitial cells, which may be modified fibroblasts, form vertical stacks of tangentially orientated cells between the more distal collecting ducts, like the rungs of a ladder. These cells secrete prostaglandins and may contribute, with cortical tubular cells, to the renal source of erythropoietin.

Calyces and pelvis

The wall of the proximal part of the urinary tract is composed of three layers, an outer connective tissue adventitia, an intermediate layer of smooth muscle and an inner mucosa. The mucosal lining of the renal calyces and pelvis is identical in structure to that of the ureter (see below). The adventitia consists of loose fibroelastic connective tissue which merges with retroperitoneal areolar tissue. Proximally the coat fuses with the fibrous capsule of the kidney lining the renal sinus.

The smooth muscle of the renal calyces and pelvis is composed of two distinct types of smooth muscle cell. One type of muscle cell is identical to that described for the ureter and can be traced proximally through the pelviureteric region and renal pelvis as far as the minor calyces. The other type of cell forms the muscle coat of each minor calyx and continues into the major calyces and pelvis where it forms a distinct inner layer. The cells also form a thin sheet of muscle which covers each minor calyx and extends across the renal parenchyma between the attachments of neighbouring minor calyces, thereby linking each minor calyx to its neighbours. This discrete inner layer of atypical smooth muscle ceases in the pelviureteric region so that the proximal ureter lacks such an inner layer. Pacemaker cells that initiate renal pelvic and ureteric peristalsis are sited within the calyces. These allow coordinated peristalsis of the ureter six times a minute.

PRODUCTION OF URINE

Glomerular filtration

Glomerular filtration (see Figs 74.14, 74.17) is the passage of water containing dissolved small molecules from the blood plasma to the urinary space in the glomerular capsule. Larger molecules, e.g. plasma proteins above 70 kilodaltons and those with a net negative charge, polysaccharides lipids and cells, are largely retained in blood by the selective permeability of the glomerular basal lamina.

Filtration occurs along a steep pressure gradient between the large glomerular capillaries and the urinary space, the principal structure separating the two being the glomerular basal lamina (Fig. 74.16B). This gradient far exceeds the colloid osmotic pressure of blood which opposes the outward flow of filtrate. In the peripheral renal cortex the arteriolar pressure gradient is enhanced because afferent glomerular arterioles are wider than efferent glomerular arterioles. In all glomeruli the rate of filtration can be altered by changes in the tone of the glomerular arterioles. When first formed, the glomerular filtrate is isotonic with glomerular blood and has an identical concentration of ions and small molecules.

The assessment of glomerular filtration is fundamental to the diagnosis of renal glomerular pathology and the management of drug therapy where clearance depends on the glomerular filtration, and in chronic kidney disease to facilitate timely management decisions. Measurements of glomerular filtration rate (GFR) are based on the renal clearance of a marker in plasma, expressed as the volume of plasma completely cleared of the marker per unit time. Markers used to measure GFR may be endogenous (creatinine, urea) or exogenous (inulin, iothalamate) substances. The ideal marker is endogenous, freely filtered by the glomerulus, neither reabsorbed nor secreted by the renal tubule, and eliminated only by the kidney.

Selective resorption

Selective resorption from the filtrate is an active process and occurs mainly in the proximal convoluted tubules, which resorb glucose, amino acids, phosphate, chloride, sodium, calcium and bicarbonate; they also take up small proteins (e.g. albumin) by endocytosis. Cells of the proximal tubules are permeable to water, which passes out of the tubules passively, so that the filtrate remains locally isotonic with blood. The rest of the tubule reabsorbs most of the water (to a variable extent up to 95%), so that when it reaches the calyces, urine is generally much reduced in volume and hypertonic to blood. The process depends on the establishment of high osmolality in the medullary interstitium, in order to exert sufficient osmotic pressure on water-permeable regions of the tubule, and is achieved by a countercurrent multiplier mechanism (see Figs 74.14, 74.17).

Countercurrent multiplier mechanism

The countercurrent multiplier mechanism is responsible for producing a high osmolality in the extratubular interstitial tissue of the renal medulla. Water passes freely from the tubular lumen into the adjacent medullary interstitium along the descending limb of the loop of Henle. This part of the tubule is less permeable to solutes. In the thick segment of the ascending limb, sodium and chloride ions are actively transported from the tubule lumen to interstitial spaces, while the tubular epithelium remains impermeable to water. It is in this segment of the tubule where furosemide and bumetamide act as diuretics. The increased interstitial osmolality causes water to be withdrawn from the descending part of the loop, thus concentrating the filtrate. Tubular fluid flows in a countercurrent on its descent into and ascent out of the medulla: it is augmented by new isotonic fluid entering the loop and depleted by hypotonic fluid leaving the loop, as solutes are actively resorbed.

In this way the osmotic gradient within the interstitium is multiplied from the corticomedullary boundary to the medullary pyramids, where it reaches an equilibrium of four to five times the osmolality of plasma. Although the tonicity of the tubular fluid changes during its passage through the steep osmotic gradient within the medulla, the osmotic gradient between ascending and descending limbs at each level never exceeds 200 mOsm/kg, a force which can be sustained by the cells of the tubular wall.

Countercurrent exchange mechanism

Rapid removal of ions from the renal medulla by the circulation of blood is minimized by another looped countercurrent system. This is the countercurrent exchange mechanism, in which arterioles entering the medulla pass for long distances parallel to the venules leaving it, before ending in capillary beds around tubules. This close apposition of oppositely flowing blood allows the direct diffusion of ions from outflowing to inflowing blood, so that the vasa recta (Fig. 74.14) conserve the high osmotic pressure in the medulla.

Concentration of urine

Because sodium and chloride ions are selectively resorbed by the cells of the ascending limbs and distal tubules under aldosterone control, the filtrate at the distal end of the convoluted tubules is hypotonic. As it reaches the collecting ducts, fluid descends again through the medulla and thus re-enters a region of high osmotic pressure. The cells lining the collecting ducts are variably permeable to water, under the influence of neurohypophysial ADH. Water follows an osmotic gradient into the adjacent extratubular spaces, so that the tonicity of the filtrate gradually rises along collecting ducts, until at the tip of the renal pyramids it is above that of blood. This complex system is highly flexible and the balance between the rate of filtration and absorption can be varied to meet current physiological demands.

Control of hydrogen and ammonium ion concentrations is essential to the regulation of acids and bases in the blood. Secretion of various ions occurs at several sites. Over 91% of ingested potassium is excreted in urine, largely through secretion by cells of the distal tubule and collecting duct. (For further details of renal physiology, see Madias & Adroque, 2005; Tannen & Hallows, 2005.)

Juxtaglomerular apparatus

The juxtaglomerular apparatus provides a tubuloglomerular feedback system which maintains systemic arterial blood pressure during a reduction in vascular volume and decrease in filtration rate. The elements of a juxtaglomerular apparatus are juxtaglomerular and lacis cells, and the macula densa.

The afferent and efferent arterioles at the vascular pole of a glomerulus and the macula densa of the distal tubule of the same nephron lie in close proximity, enclosing a small cone of tissue populated by extraglomerular mesangial (lacis) cells (Fig. 74.17). The cells of the tunica media of afferent and, to a lesser extent, efferent, arterioles differ from typical smooth muscle cells. These juxtaglomerular cells are large, rounded myoepithelioid cells and their cytoplasm contains many mitochondria and dense, renin-containing vesicles, 10–40 nm in diameter.

Each macula densa of the distal tubule is a cluster of up to 40 tightly packed cells in the tubule wall; the cells have large, oval nuclei and apically concentrated mitochondria. They are osmoreceptors, sensing the NaCl content of the filtrate after its passage through the loop of Henle.

When NaCl concentrations in the filtrate change, tubuloglomerular feedback mechanisms operate to maintain the inverse relationship between salt concentration and glomerular filtration rate. Juxtaglomerular cells release renin, an enzyme which acts on circulating angiotensinogen to activate the cascade whereby angiotensin II increases blood pressure (and therefore filtration rate), stimulates aldosterone and ADH release and increases sodium ion and water resorption, primarily from the distal tubule, to increase plasma volume. Macula densa cells are thought to respond to high salt concentration in the distal tubule by releasing nitric oxide, which inhibits the tubuloglomerular feedback response and reduces filtration rate. The role of macula densa cells in the stimulation of renin release to increase filtration rate is less well understood.

The third element of the juxtaglomerular apparatus is a population of extraglomerular mesangial cells which form a network (or lace, hence their alternative name of lacis cells) of stellate cells connecting the macula densa sensory cells with the juxtaglomerular effector cells. It is likely that extraglomerular mesangial cells transmit the sensory signal, possibly through gap junctions. They may also signal to contractile glomerular mesangial cells and effect vasoconstriction directly within the glomerulus. Adrenergic nerve fibres occur in small numbers among these cells.

URETER

The ureters are two muscular tubes whose peristaltic contractions convey urine from the kidneys to the urinary bladder (Fig. 74.9). Each measures 25–30 cm in length, is thick-walled and narrow, and is continuous superiorly with the funnel-shaped renal pelvis. Each descends slightly medially, anterior to psoas major, and enters the pelvic cavity where it curves initially laterally, then medially, to open into the base of the urinary bladder. The diameter of the ureter is normally 3 mm, but is slightly less at its junction with the renal pelvis, at the brim of the lesser pelvis near the medial border of psoas major, and where it runs within the wall of the urinary bladder, which is its narrowest part. These are the commonest sites for renal stone impaction.

RELATIONS

In the abdomen the ureter descends posterior to the peritoneum on the medial part of psoas major, which separates it from the tips of the lumbar transverse processes. During surgery on intraperitoneal structures, the ureter can be tented up as the peritoneum is drawn anteriorly, resulting in inadvertent ureteric injury. Anterior to psoas major it crosses in front of the genitofemoral nerve and is obliquely crossed by the gonadal vessels (Fig. 74.19). It enters the lesser pelvis anterior to either the end of the common iliac vessels or at the origin of the external iliac vessels (Fig. 74.20).

The inferior vena cava is medial to the right ureter while the left ureter is lateral to the aorta. The inferior mesenteric vein has a long retroperitoneal course lying close to the medial aspect of the left ureter.

At its origin the right ureter is usually overlapped by the descending part of the duodenum. It descends lateral to the inferior vena cava, and is crossed anteriorly by the right colic and ileocolic vessels. Near the superior aperture of the lesser pelvis it passes behind the lower part of the mesentery and terminal ileum. The left ureter is crossed by the gonadal and left colic vessels (see Fig. 74.24). It passes posterior to loops of jejunum and sigmoid colon and its mesentery in the posterior wall of the intersigmoid recess.

In the pelvis the ureter lies in extraperitoneal areolar tissue (see Fig. 75.3). At first it descends posterolaterally on the lateral wall of the lesser pelvis along the anterior border of the greater sciatic notch. Opposite the ischial spine it turns anteromedially into fibrous adipose tissue above levator ani to reach the base of the bladder. On the pelvic side-wall it is anterior to the internal iliac artery and the beginning of its anterior trunk, posterior to which are the internal iliac vein, lumbosacral nerve and sacroiliac joint. Laterally it lies on the fascia of obturator internus. It progressively crosses to become medial to the umbilical, inferior vesical, and middle rectal arteries.

In males, the pelvic ureter hooks under the vas deferens (Fig. 74.21), then passes in front of and slightly above the upper pole of the seminal vesicle to traverse the bladder wall obliquely before opening at the ipsilateral trigonal angle. Its terminal part is surrounded by tributaries of the vesical veins. In females, the pelvic part at first has the same relations as in males, but anterior to the internal iliac artery it is immediately behind the ovary, forming the posterior boundary of the ovarian fossa (see Ch. 77). In the anteromedial part of its course to the bladder it is related to the uterine artery, uterine cervix and vaginal fornices. It is in extraperitoneal connective tissue in the inferomedial part of the broad ligament of the uterus where it may be damaged during hysterectomy. In the broad ligament, the uterine artery is anterosuperior to the ureter for 2.5 cm and then crosses to its medial side to ascend alongside the uterus. The ureter turns forwards slightly above the lateral vaginal fornix and is generally 2 cm lateral to the supravaginal part of the uterine cervix in this location. It then inclines medially to reach the bladder, with a variable relation to the anterior aspect of the vagina. As the uterus is commonly deviated to one side, one ureter, usually the left, may be more extensively apposed to the vagina, and may cross the midline.

(From Sobotta 2006.)

The distal 1–2 cm of each ureter is surrounded by an incomplete collar of non-striated muscle, which forms a sheath (of Waldeyer). The ureters pierce the posterior aspect of the bladder and run obliquely through its wall for a distance of 1.5–2.0 cm before terminating at the ureteric orifices (see Fig. 75.5B). This arrangement is believed to assist in the prevention of reflux of urine into the ureter, since the intramural ureters are thought to be occluded during increases in bladder pressure at the time of micturition. There is no evidence of a classic ureteral sphincter mechanism in man. The longitudinally oriented muscle bundles of the terminal ureter continue into the bladder wall and at the ureteric orifices become continuous with the superficial trigonal muscle. In the distended bladder, in both sexes, the ureteric openings are usually 5 cm apart, and 2.5 cm apart when the bladder is empty.

Duplex ureters

In 1 in 125 individuals, two ureters drain the renal pelvis on one side; this is termed a duplex system (Fig. 74.22). Bilateral duplex ureters occur in approximately 1 in 800 cases. The duplex ureters derive from two ureteric buds arising from the mesonephric duct. They are contained in a single fascial sheath and may fuse at any point along their course or may be separate until they insert through separate ureteric orifices into the bladder. Care must be taken not to compromise the blood supply of the second ureter when excising or reimplanting a single ureter of a duplex.

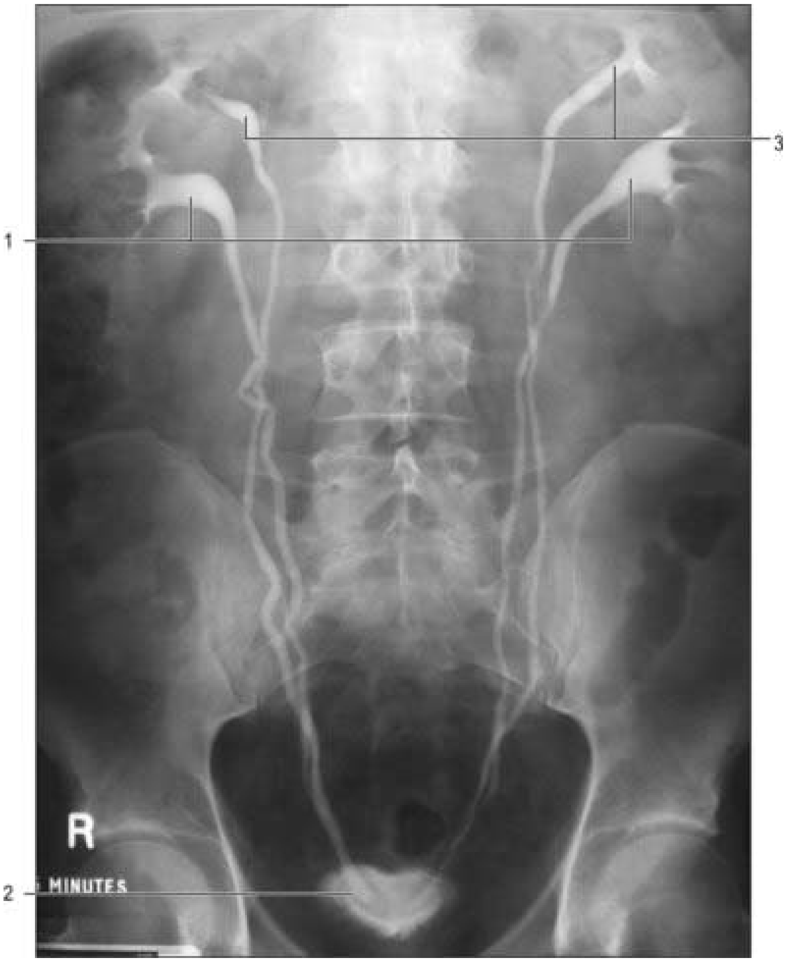

Fig. 74.22 Intravenous urogram showing bilateral duplex ureters and bilateral ureteroceles. Note that the ureters cross during their course. The right ureterocele can be clearly seen producing a halo appearance within the bladder surrounding the lower ureter. **1**. Contrast within lower moiety of

collecting system. **2**. ‘Cobra’s head’ halo around lower ureter showing ureterocele. **3**. Contrast within upper moiety of collecting system.

The ureter from the upper pole of the kidney (the longer ureter) inserts more medially and caudally in the bladder than the ureter from the lower pole (the shorter ureter). This reflects the embryological development of the ureter: the ureteric bud which is initially more proximal on the mesonephric duct has a shorter time to be pulled cranially in the bladder and so it inserts more distally in the mature bladder. The ureter from the lower pole has a shorter intramural course than the longer ureter and is prone to reflux.

Ectopic ureters

Single ureters, and more commonly the longer ureter of a duplex system, can insert more caudally and medially than normal in some individuals. In the male the ureter can insert at the bladder neck or posterior urethra, or rarely into the seminal vesicle, but it always inserts cranial to the external urethral sphincter. In the female, ectopic insertion can be distal to the external urethral sphincter in the urethra, or into the vagina, resulting in persistent childhood incontinence.

Ureteroceles

A ureterocele is a cystic dilatation of the lower end of the ureter: the ureteric orifice is covered by a membrane which expands as it is filled with urine and then deflates as it empties. Ureteroceles can vary in size, and although usually they have no influence on ureteric drainage they can be a cause of obstruction in the ureter and pelvicalyceal system more proximally. They usually do not cause bladder outflow obstruction except for the rare prolapsing ureterocele. Prolapsing ureteroceles, though small, prolapse from their position around the uretero-vesical junction region in to the urethra, causing intermittent bladder outflow obstruction. They are identified antenatally with ultrasound. In adults, ureteroceles tend to be bilateral and small and often found incidentally when the urinary tract is being imaged in the investigation of a coincidental pathology. Radiologically they classically result in a ‘cobra-head’ halo around the ureteric orifice following administration of contrast on intravenous urography (Fig. 74.22).

Retrocaval ureter

A persistence of the posterior cardinal vein, associated with high confluence of the right and left common iliac veins or a double inferior vena cava, may result in a retrocaval (or circumcaval) ureter which passes behind the inferior vena cava, usually at the level of the inferior edge of the third part of the duodenum, before it emerges in front of it to pass from medial to lateral. Retrocaval ureter occurs in 1 in 1500 individuals. Most commonly it has no clinical sequelae although it can result in upper ureteric obstruction (Fig. 74.23).

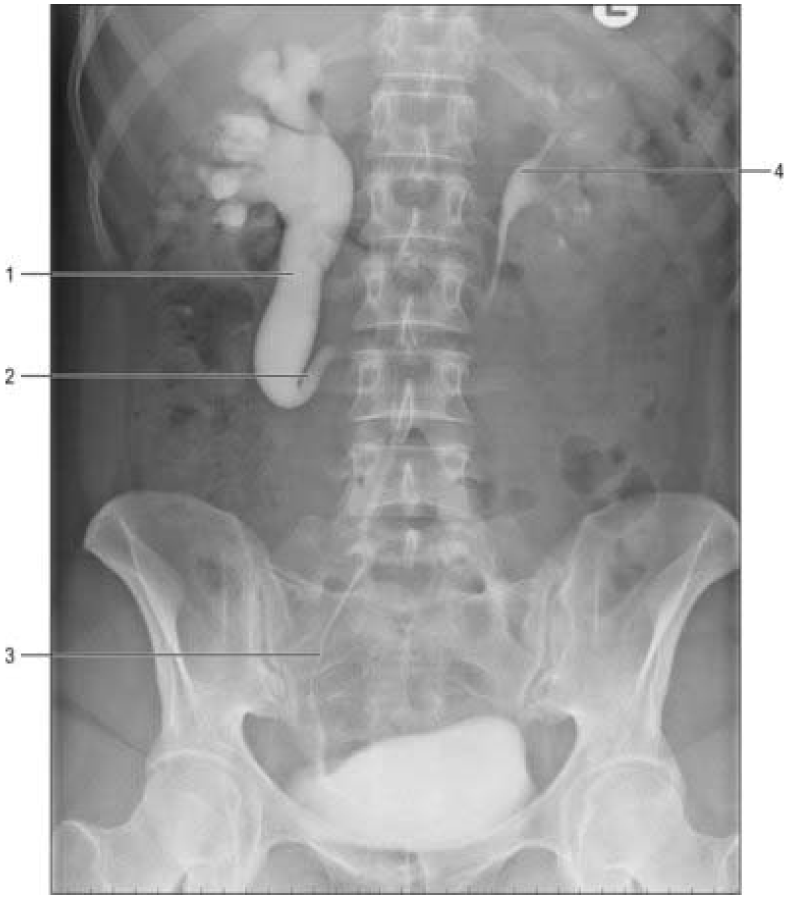

Fig. 74.23 Intravenous urogram showing a classical retrocaval (or circumcaval) ureter. A degree of obstruction has resulted in a markedly

dilated upper ureter. The ureter passes cranially, medially and then caudally, and can be followed into the pelvis. **1**. Contrast within dilated collecting system of right kidney and upper ureter. **2**. Contrast within ureter turning behind inferior vena cava. **3**. Contrast within normal calibre ureter seen below the obstruction. **4**. Contrast within normal collecting system of left kidney and upper ureter.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The ureter is supplied by branches from the renal, gonadal, common iliac, internal iliac, vesical and uterine arteries, and the abdominal aorta (Fig. 74.24). The pattern of distribution is subject to much variation. The abdominal ureter is supplied from vessels originating medial to the ureter, while the pelvic ureter is supplied by vessels lateral to the ureter. There is a good longitudinal anastomosis between these branches on the wall of the ureter, which means that the ureter can be safely transected at any level intraoperatively, and a uretero-ureterostomy performed, without compromising its viability. The branches from the inferior vesical artery are constant in their occurrence and supply the lower part of the ureter as well as a large part of the trigone of the bladder. The branch from the renal artery is also constant and is preserved whenever possible in renal transplantation to ensure good vascularity of the ureter.

Veins

The venous drainage of the ureters generally follows the arterial supply.

Lymphatic drainage

Lymph vessels draining the ureter begin in submucosal, intramuscular and adventitial plexuses which all communicate. Collecting vessels from the upper abdominal ureter may join the renal collecting vessels or pass directly to the lateral aortic nodes near the origin of the gonadal artery, those from the lower abdominal ureter drain to the common iliac nodes, and those from the pelvic ureter drain to common, external or internal iliac nodes.

INNERVATION

The ureter is supplied from the lower three thoracic, first lumbar, and the second to fourth sacral segments of the spinal cord by branches from the renal and aortic plexuses, and the superior and inferior hypogastric plexuses. The ureteric nerves consist of relatively large bundles of axons which form an irregular plexus in the adventitia of the ureter. The plexus receives branches from the renal and aortic plexuses (in its upper part), from the superior hypogastric plexus and hypogastric nerve (in its intermediate part), and from the hypogastric nerve and inferior hypogastric plexus (in its lower part). Numerous small branches penetrate the ureteric muscle coat: some of the adventitial nerves accompany the blood vessels and branch with them as they extend into the muscle layer, others are unrelated to the vascular supply and lie free in the adventitial connective tissue around the circumference of the ureter.

The density of innervation increases gradually from the renal pelvis and upper ureter (where autonomic nerves are sparse) to a maximum density in the juxtavesical segment. At least three different neurotransmitter phenotypes, cholinergic, noradrenergic and peptidergic (substance P), are well known and others have been reported. The functional significance of these different types of autonomic nerve fibres in relation to ureteric smooth muscle activity is not fully understood: although they are thought to influence the inherent motility of the ureter, they are not essential for the initiation and propagation of ureteric contraction waves. A branching plexus of fine cholinergic, noradrenergic and peptidergic axons occurs throughout the lamina propria and extends from the inner aspect of the muscle coat towards the base of the urothelium. Some of these axons form perivascular plexuses, others lie in isolation from the vascular supply and may be sensory in function.

Ureteric peristalsis

Under normal conditions contraction waves originate in the proximal part of the upper urinary tract and are propagated in an anterograde direction towards the bladder. Atypical smooth muscle cells in the wall of the minor calyces act individually or collectively as pacemaker sites. A peristaltic wave begins at one (or possibly more) of these sites. Once initiated, the contraction is propagated through the wall of the adjacent major calyx and activates the smooth muscle of the renal pelvis. Contraction waves are propagated away from the kidney, and so undesirable pressure rises are not directed against the renal parenchyma. Since several potential pacemaker sites exist, the initiation of contraction waves is unimpaired by partial nephrectomy: the minor calyces spared by the resection remain *in situ* to continue their pacemaking function. Pressures within the ureter at the time of peristalsis reach 20–80 cm H_2O.

Experimental evidence indicates that autonomic nerves do not play a major part in the propagation of peristalsis. It seems more likely that they play a modulatory role on the contractile events occurring in the musculature of the upper urinary tract. The most likely mechanism to account for impulse propagation is myogenic conduction mediated by the electrotonic coupling of one muscle cell to its immediate neighbours by means of intercellular ‘gap’ junctions: there are numerous regions of close approach between ureteric smooth muscle cells and also between both types of muscle cell in the renal pelvis and calyces.

Referred pain

Excessive distension of the ureter or spasm of its muscle may be caused by a stone (calculus) and provokes severe pain (ureteric colic, which is commonly, but mistakenly, called renal colic). The pain is spasmodic and agonizing, particularly if the obstruction is gradually forced down the ureter by the muscle spasm. It is referred to cutaneous areas innervated from spinal segments which supply the ureter, mainly T11–L2, and shoots down and forwards from the loin to the groin and scrotum or labium majus; it may extend into the proximal anterior aspect of the thigh by projection to the genitofemoral nerve (L1, 2). The cremaster, which has the same innervation, may reflexly retract the testis.

RENAL AND URETERIC CALCULI

An understanding of intrarenal and ureteric anatomy is essential when managing patients with calculi, particularly now that minimally invasive techniques are widely used to treat this common pathology.

Smaller renal calculi are treated with extracorporeal shock wave lithotripsy. Stones in the lower pole of the kidney clear less well if the angle between the infundibulum of the calyx containing the stone and the ureter is acute, or if there is a particularly long and narrow infundibulum. Percutaneous stone extraction is most frequently achieved by puncturing a posterior calyx with a needle.

Ureteric calculi tend to be arrested in their descent in either the pelviureteric region, or the point where the ureter passes over the pelvic brim as it crosses the common iliac artery, or the vesico-ureteric junction, because these are the three areas where the ureter is narrowest. The vesico-ureteric junction is the narrowest of these areas and can be responsible for arresting the passage of stones of as little as 2–3 mm.

The kidney and upper ureter move with respiration within the perirenal fascia, and this can affect the visualization and tracking of a stone, both at the time of extracorporeal shock wave lithotripsy and at retrograde endoscopy.

MICROSTRUCTURE

Like the calyces and the renal pelvis, the wall of the ureter is composed of an external adventitia, a smooth muscle layer and an inner mucosal layer (Fig. 74.25). The mucosal layer consists of a urothelium and an underlying connective tissue lamina propria.

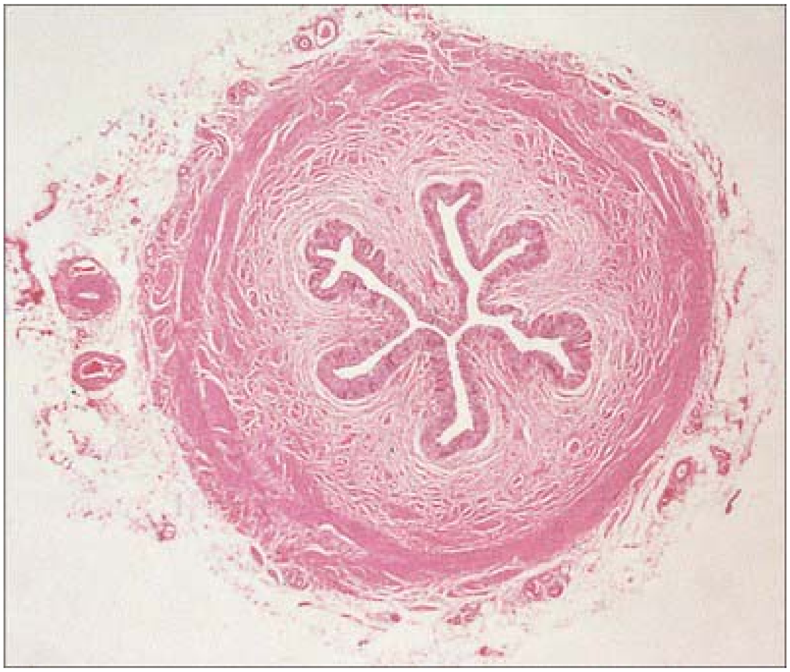

Fig. 74.25 Transverse section of ureter. The walls are muscular and are lined by a specialized urothelium.

(By permission from Stevens A, Lowe JS 1996 Human Histology, 2nd edn. London: Mosby.)

The ureteric adventitial blood vessels and connective tissue fibres are orientated parallel to the long axis of the ureter. Throughout its length, the muscle coat of the ureter is fairly uniform in thickness and in cross-section measures 750–800 µm in width. The muscle bundles which constitute this coat are frequently separated from one another by relatively large amounts of connective tissue. However, branches which interconnect muscle bundles are common and there is frequent interchange of muscle fibres between adjacent bundles. As a consequence of this extensive branching, individual muscle bundles do not spiral around the ureter, but form a complex meshwork of interweaving bundles. Moreover, unlike the gut (see Ch. 66), the muscle bundles are so arranged that morphologically distinct longitudinal and circular layers cannot be clearly distinguished. In the upper part of the ureter, the inner muscle bundles tend to lie longitudinally while those on the outer aspect have a circular or oblique orientation. In the middle and lower parts, there are additional outer longitudinally orientated fibres, and as the ureterovesical junction is approached, the muscle coat consists predominantly of longitudinally orientated muscle bundles.

The mucosa of the ureter consists of an epithelium, the urothelium, on the deep aspect of which is a layer of subepithelial fibroelastic connective tissue lamina propria. The latter varies in thickness from 350–700 µm and is a conduit for small blood vessels and bundles of non-myelinated nerve fibres. Occasional lymphocytes may be present in the lamina propria but their aggregation into definitive lymph nodules is rare. The urothelium is usually extensively folded, which gives the ureteric lumen a stellate outline.

CHAPTER 75

Bladder, prostate and urethra

URINARY BLADDER

The urinary bladder is a reservoir. Its size, shape, position and relations all vary according to its content and the state of neighbouring viscera. When the bladder is empty, it lies entirely in the lesser pelvis, but as it distends it expands anterosuperiorly into the abdominal cavity. An empty bladder is somewhat tetrahedral and has a base (fundus), neck, apex, a superior and two inferolateral surfaces.

RELATIONS

The base of the bladder is triangular and located posteroinferiorly. In females it is closely related to the anterior vaginal wall (Fig. 75.1; see Fig. 77.25B); in males it is related to the rectum although it is separated from it above by the rectovesical pouch, and below by the seminal vesicle and vas deferens on each side and Denonvillier's fascia (Fig. 75.2A,B). The neck, which is most fixed, lies most inferiorly, 3–4 cm behind the lower part of the symphysis pubis and just above the plane of the inferior aperture of the lesser pelvis. The bladder neck is essentially the internal urethral orifice, which lies in a constant position, independent of the varying positions of the bladder and rectum. In males the neck rests on, and is in direct continuity with, the base of the prostate; in females it is related to the pelvic fascia, which surrounds the upper urethra. In both sexes the apex of the bladder faces towards the upper part of the symphysis pubis. The median umbilical ligament (urachus) ascends behind the anterior abdominal wall from the apex to the umbilicus, covered by peritoneum to form the median umbilical fold (see below).

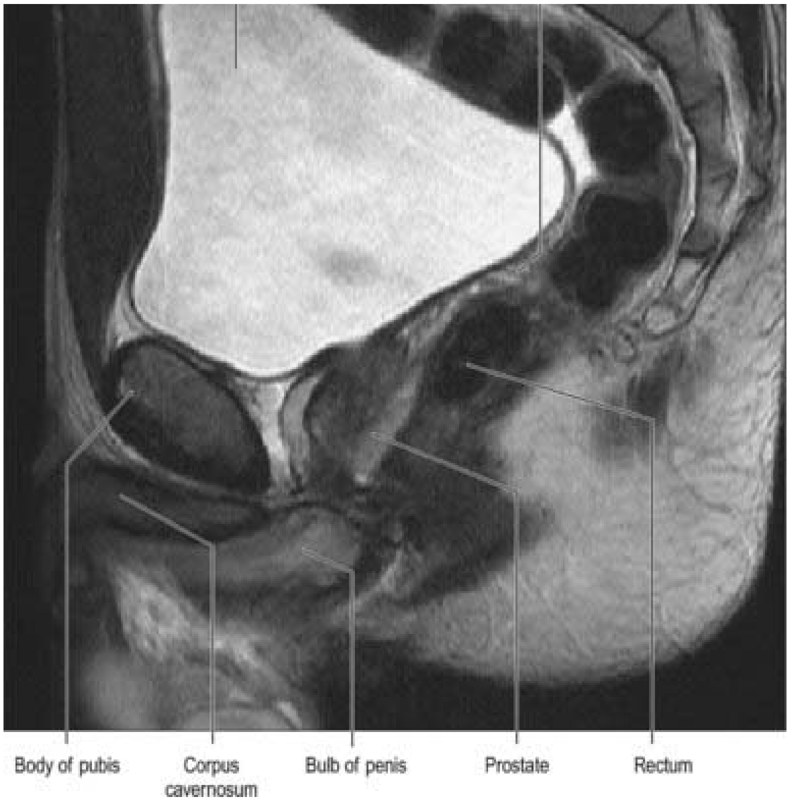

Fig. 75.2 **A**, The relationship of the bladder and prostate, sagittal section, male pelvis. The relationship of the bladder to the peritoneum and anterior abdominal wall on filling allows suprapubic cystotomy without intraperitoneal urinary leak. (**A**, From Sobotta 2006.) **B**, Sagittal T2 MRI of the male pelvis showing the bladder, prostate and relations.

The anterior surface of the bladder is separated from the transversalis fascia by fat in the potential retropubic space (of Retzius). This is more adherent to the bladder than to the anterior surface of the prostate, which aids reliable identification of the region of the bladder neck surgically. In males, each inferolateral surface is related anteriorly to the pubis and puboprostatic ligaments. In females the relations are similar, except that the pubovesical ligaments replace the puboprostatic ligaments. The inferolateral surfaces are not covered by peritoneum. The triangular superior surface is bounded by lateral borders from the apex to the ureteric entrances, and by a posterior border which joins them. In males the superior surface is completely covered by peritoneum, which extends slightly onto the base and continues posteriorly into the rectovesical pouch and anteriorly into the median umbilical fold: it is in contact with the sigmoid colon and the terminal coils of the ileum (Figs 75.1, 75.2 and 75.3; see page 1105). In females the superior surface is largely covered by peritoneum, which is reflected posteriorly onto the uterus at the level of the internal os (the junction of the uterine body and cervix), to form the vesicouterine pouch. The posterior part of the superior surface, devoid of peritoneum, is separated from the supravaginal cervix by fibroareolar tissue.

Fig. 75.3 Internal aspect of anterior abdominal wall and male anterior pelvic viscera.

(From Sobotta 2006.)

These relationships are important in managing bladder trauma. Extraperitoneal injuries can often be managed conservatively because urine is contained, whereas peritoneal injuries usually require surgical repair.

As the bladder fills it becomes ovoid. Anteriorly, it displaces the parietal peritoneum from the suprapubic region of the abdominal wall. Its inferolateral surfaces become anterior and rest against the abdominal wall without intervening peritoneum for a distance above the symphysis pubis which varies with the degree of distension, but is commonly 5–7 cm. The distended bladder may be punctured just above the symphysis pubis without traversing the peritoneum (suprapubic cystostomy): surgical access to the bladder through the anterior abdominal wall is usually by this route. The summit of the full bladder points up and forwards above the attachment of the median umbilical ligament, so that the peritoneum forms a supravesical recess of varying depth between the summit and the anterior abdominal wall: this recess often contains coils of small intestine. At birth, the bladder is relatively higher than in the adult because the true pelvis is shallow, and the internal urethral orifice is level with the upper symphysial border. The bladder is then abdominal rather than pelvic, and extends about two-thirds of the distance towards the umbilicus. Urine samples may therefore be obtained in children by performing suprapubic needle puncture. The bladder progressively descends with growth, and reaches the adult position shortly after puberty. Congenital abnormalities of the bladder are described on page 1312 (see also Fig. 78.11).

LIGAMENTS OF THE BLADDER

The bladder is anchored inferiorly by condensations of pelvic fascia which attach it to the pubis, lateral pelvic side-walls, and rectum.

In both sexes, stout bands of fibromuscular tissue, the pubovesical ligaments, extend from the bladder neck to the inferior aspect of the pubic bones. They are derived from the detrusor muscle, part of the detrusor apron (Fig. 75.4A,B). In the female, they constitute the superior extensions of the pubourethral ligaments. In the male, the detrusor apron is described as an extension of detrusor that extends over the anterior surface of the prostate, and condenses distally and anteriorly to form the puboprostatic ligaments.

into the pubic bone. It condenses to form pubovesical/puboprostatic ligaments (**B**,**C**).

*(**A**,**B** From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)*

The pubovesical ligaments lie on each side of the median plane, leaving a midline hiatus through which numerous small veins pass. A number of other so-called ligaments have been described in relation to the base of the urinary bladder, namely the lateral and posterior vesical ligaments in the male and the cardinal and ureterosacral ligaments in the female. The reflections of the peritoneum from the bladder to the side-walls of the pelvis form the lateral ligaments, and the sacrogenital folds constitute the posterior ligaments. They are all condensations of connective tissue around major neurovascular structures rather than true ‘anatomical’ ligaments, nevertheless they are described as ligaments in routine clinical use.

The apex of the bladder is connected to the umbilicus by the remains of the urachus, which forms the median umbilical ligament (Fig. 75.3). It is composed of longitudinal muscle fibres derived from the detrusor, and becomes more fibrous towards the umbilicus. It usually maintains a lumen lined with epithelium which persists into adult life but is only rarely complicated by a urachal cyst, sinus, fistula or adenocarcinoma. From the superior surface of the bladder the peritoneum is carried off in a series of folds, the ‘false’ ligaments of the bladder. Anteriorly there are three folds, the median umbilical fold over the median umbilical ligament (urachus) and two medial umbilical folds over the obliterated umbilical arteries. The inferior epigastric vessels are lateral to these folds on the anterior abdominal wall.

BLADDER INTERIOR

Vesical mucosa

Almost all of the vesical mucosa (Fig. 75.5A–C) is attached only loosely to subjacent muscle: it folds when the bladder empties, and the folds are stretched flat as it fills. Over the trigone, immediately above and behind the internal urethral orifice, it is adherent to the subjacent muscle layer and is always smooth. The anteroinferior angle of the trigone is formed by the internal urethral orifice, its posterolateral angles by the ureteric orifices. The superior trigonal boundary is a slightly curved interureteric bar, which connects the two ureteric orifices and is produced by the continuation into the vesical wall of the ureteric internal longitudinal muscle. Laterally this ridge extends beyond the ureteric openings as ureteric folds, produced by the terminal parts of the ureters which run obliquely through the bladder wall. At cystoscopy the interureteric crest appears as a pale band and is a guide to the ureteric orifices.

*(**A** from Sobotta 2006.)*

Trigone

The smooth muscle of the trigone consists of two distinct layers, sometimes termed the superficial trigonal muscle and deep trigonal detrusor muscle. The latter is composed of muscle cells, indistinguishable from those of the detrusor, and is simply the posteroinferior portion of the detrusor muscle proper. The superficial trigonal muscle represents a morphologically distinct component of the trigone, which, unlike the detrusor, is composed of relatively small diameter muscle bundles that are continuous proximally with those of the intramural ureters. The superficial trigonal muscle is relatively thin but is generally described as becoming thickened along its superior border to form the interureteric bar. Similar thickenings occur along the lateral edges of the superficial trigone. In both sexes the superficial trigone muscle becomes continuous with the smooth muscle of the proximal urethra, and extends in the male along the urethral crest as far as the openings of the ejaculatory ducts.

Ureteric orifices

The slit-like ureteric orifices are placed at the posterolateral trigonal angles (Fig. 75.5A). In empty bladders they are approximately 2.5 cm apart, and 2.5 cm from the internal urethral orifice: in distension these measurements may be doubled.

Internal urethral orifice

The internal urethral orifice is sited at the trigonal apex, the lowest part of the bladder, and is usually somewhat crescentic in section. There is often an elevation immediately behind it in adult males (particularly past middle age) which is caused by the median prostatic lobe.

BLADDER NECK

The smooth muscle of the bladder neck is histologically, histochemically and pharmacologically distinct from the detrusor muscle proper and so the bladder neck should be considered as a separate functional unit. The arrangement of smooth muscle in this region is quite different in males and females, and therefore will be described separately.

Female

The female bladder neck (Fig. 75.5C) consists of morphologically distinct smooth muscle. The large diameter fasciculi characteristic of the detrusor are replaced in the region of the bladder neck by small diameter fasciculi which extend obliquely or longitudinally into the urethral wall. In the normal female, the bladder neck sits above the pelvic floor supported predominantly by the pubovesical ligaments (Fig. 75.4A), the endopelvic fascia of the pelvic floor and levator ani. These support the urethra at rest; with elevated intra-abdominal pressure the levators contract, increasing urethral closure pressure to maintain continence. This anatomical arrangement commonly alters after parturition and with increasing age, such that the bladder neck lies beneath the pelvic floor, particularly when the intra-abdominal pressure rises, which means that the mechanism described above fails to maintain continence and women may experience stress incontinence as a result of urethral hypermobility.

Male

In the male (Fig. 75.4B), the bladder neck is completely surrounded by a circular collar of smooth muscle, with its own distinct adrenergic innervation, which extends distally to surround the preprostatic portion of the urethra. Distinct from the smooth muscle bundles which run in continuity from the bladder neck down to the prostatic urethra, and from the smooth muscle within the prostate, these smooth muscle bundles surround the bladder neck and preprostatic urethra. The bundles which form this ‘preprostatic sphincter’ are small in size compared with the muscle bundles of the detrusor and are separated by a relatively larger connective tissue component rich in elastic fibres.

The bladder neck is sometimes called the proximal sphincter mechanism, to distinguish it from the distal urinary sphincter mechanism. However, it is not a urinary sphincter and is not responsible for continence. It is a genital sphincter that allows antegrade ejaculation of semen. Unlike the detrusor and the rest of the urethral smooth muscle (common to both sexes), the preprostatic sphincter is richly supplied with sympathetic noradrenergic nerves and is almost totally devoid of parasympathetic cholinergic nerves. Contraction of the preprostatic sphincter serves to prevent the retrograde flow of ejaculate through the proximal urethra into the bladder. It is extensively disrupted in the vast majority of men undergoing bladder neck surgery, e.g. transurethral resection of the prostate, which results in retrograde ejaculation.

Whether this preprostatic sphincter replaces, or is additional to, the bladder neck muscle pattern seen in the female is unclear, but it is probably additional.

Bladder outflow obstruction

In progressive chronic obstruction to micturition, e.g. as a result of prostatic enlargement or urethral stricture, the muscle of the bladder hypertrophies. The muscle fasciculi increase in size and, because they interlace in all directions, a thick-walled ‘trabeculated bladder’ is produced. Mucosa between the fascicles forms ‘diverticula’. When outflow is obstructed, emptying is not complete: some urine remains and may become infected. Back pressure from a chronically distended bladder may gradually dilate the ureters and renal pelves and even the renal collecting tubules, which can result in progressive renal impairment.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The bladder is supplied principally by the superior and inferior vesical arteries (see Fig. 77.3A,B), derived from the anterior trunk of the internal iliac artery, supplemented by the obturator and inferior gluteal arteries. In the female additional branches are derived from the uterine and vaginal arteries.

Superior vesical artery

The superior vesical artery supplies many branches to the fundus of the bladder. The artery to the vas deferens often originates from one of these and accompanies the vas deferens to the testis, where it anastomoses with the testicular artery. Other branches supply the ureter. The beginning of the superior vesical artery is the proximal, patent section of the fetal umbilical artery.

Inferior vesical artery

The inferior vesical artery often arises with the middle rectal artery from the internal iliac artery. It supplies the base of the bladder, prostate, seminal vesicles and lower ureter. Prostatic branches communicate across the midline. The inferior vesical artery may sometimes provide the artery to the vas deferens.

Veins

The veins which drain the bladder (see Fig. 77.3A,B) form a complicated plexus on its inferolateral surfaces and pass backwards in the lateral ligaments of the bladder to end in the internal iliac veins.

Lymphatics

Lymphatics which drain the bladder (see Fig. 77.3A,B) begin in mucosal, intermuscular and serosal plexuses. There are three sets of collecting vessels, most of which end in the external iliac nodes. Vessels from the trigone emerge on the exterior of the bladder to run superolaterally. Vessels from the superior surface of the bladder converge to the posterolateral angle and pass superolaterally to the external iliac nodes (some may go to the internal or common iliac group). Vessels from the inferolateral surface of the bladder ascend to join those from the superior surface or run to the lymph nodes in the obturator fossa. Minute nodules of lymphoid tissue may occur along the vesical lymph vessels.

INNERVATION

The nerves supplying the bladder arise from the pelvic plexuses, which are a mesh of autonomic nerves and ganglia on the lateral aspects of the rectum, internal genitalia and bladder base. They consist of both sympathetic and parasympathetic components, each of which contains both efferent and afferent fibres. The innervation of the bladder has been reviewed in some detail by Mundy (1999).

Efferent fibres

Parasympathetic fibres arise from the second to the fourth sacral segments of the spinal cord and enter the pelvic plexuses on the posterolateral aspects of the rectum as the pelvic splanchnic nerves. The sympathetic fibres are derived from neuronal cell bodies in the lower three thoracic and upper two lumbar segments of the spinal cord and form the coeliac and mesenteric plexuses around the great vessels in the abdomen, from which the hypogastric plexuses descend into the pelvis as fairly discrete nerve bundles within the extraperitoneal connective tissue posterior to the ureter on each side. The anterior part of the pelvic plexus is known as the vesical plexus. Small groups of autonomic neurones occur within the plexus and throughout all regions of the bladder wall. These multipolar intramural neurones are rich in acetylcholinesterase (AChE) and occur in ganglia consisting of up to 20 neuronal cell bodies. The majority of the preganglionic nerve terminals correspond morphologically to presumptive cholinergic fibres. Noradrenergic terminals also relay on cell bodies in the pelvic plexus: it is not known whether similar nerves synapse on intramural bladder ganglia.

The urinary bladder (including the trigonal detrusor muscle) is profusely supplied with nerves which form a dense plexus among the detrusor muscle cells. The majority of these nerves contain AChE and occur in abundance throughout the muscle coat of the bladder. Axonal varicosities adjacent to detrusor muscle cells possess features which are considered to typify cholinergic nerve terminals, and contain clusters of small (50 nm diameter) agranular vesicles, occasional large (80–160 nm diameter) granulated vesicles and small mitochondria. Terminal regions approach to within 20 nm of the surface of the muscle cells and may be partially surrounded by Schwann cell cytoplasm, or more often are naked nerve endings. The human detrusor muscle possesses a sparse supply of sympathetic noradrenergic nerves which generally accompany the vascular supply and only rarely extend among the myocytes. Non-adrenergic, non-cholinergic nerves have been identified, and a number of other neurotransmitters or neuromodulators have been detected in intramural ganglia, including the peptide somatostatin. The superficial trigonal muscle is associated with more noradrenergic (sympathetic) fibres than cholinergic (parasympathetic) nerves, a difference that supports the view that the superficial trigonal muscle should be regarded as ‘ureteric’ rather than ‘vesical’ in origin. However it must be emphasized that the superficial trigonal muscle forms a very minor part of the total muscle mass of the bladder neck and proximal urethra in either sex and is probably of little significance in the physiological mechanisms which control these regions.

The smooth muscle of the bladder neck in males is predominantly orientated obliquely or circularly. It is sparsely supplied with cholinergic (parasympathetic) nerves, but possesses a rich noradrenergic (sympathetic) innervation. A similar distribution of autonomic nerves also occurs in the smooth muscle of the prostate gland, seminal vesicles and vasa deferentia. Stimulation of sympathetic nerves causes contraction of smooth muscle in the wall of the genital tract resulting in seminal emission. Concomitant sympathetic stimulation of the proximal urethral smooth muscle causes sphincteric closure of the preprostatic sphincter, thereby preventing reflux of ejaculate into the bladder. Although this genital function of the bladder neck of the male is well established, it is not known whether the smooth muscle of this region plays an active role in maintaining urinary continence. In contrast, the smooth muscle of the bladder neck of the female receives relatively few noradrenergic nerves but is richly supplied with presumptive cholinergic fibres. The sparse supply of sympathetic nerves presumably relates to the absence of a functioning ‘genital’ portion of the wall of the female urethra.

The lamina propria of the fundus and inferolateral walls of the bladder is virtually devoid of autonomic nerve fibres, apart from some noradrenergic and occasional presumptive cholinergic perivascular nerves. However, the density of nerves unrelated to blood vessels increases closer to the urethral orifice. At the bladder neck and trigone a nerve plexus of cholinesterase positive axons extends throughout the lamina propria independent of blood vessels. Some of the larger diameter axons are myelinated and others lie adjacent to the basal urothelial cells. In the absence of any obvious effector target sites, the subepithelial nerve plexuses of the bladder and the ureter are assumed to subserve a sensory function.

Afferent fibres

Vesical nerves are also concerned with pain and awareness of distension and are stimulated by distension or spasm due to a stone, inflammation or malignant disease: they travel in sympathetic and parasympathetic nerves, but predominantly in the latter. Division of the sympathetic paths (e.g. ‘presacral neurectomy’), or of the superior hypogastric plexus, therefore does not materially relieve vesical pain, whereas considerable relief follows bilateral anterolateral cordotomy. Since nerve fibres mediating awareness of distension travel in the posterior columns (fasciculus gracilis), the patient still retains awareness of the need to micturate after anterolateral cordotomy. The nerve endings detecting noxious stimuli are probably of more than one type: a subepithelial plexus of fibres containing dense vesicles, which are probably afferent endings, has been described.

MICROSTRUCTURE

The bladder consists of four layers: a lining epithelium (urothelium), lamina propria, muscularis propria and serosa.

Lining epithelium or urothelium

Urothelium (transitional epithelium) is 4–7 cells thick; it may appear to be attenuated to 2–3 cells thick when the bladder is fully distended. It contains three distinctive cell layers, a basal layer, an intermediate layer and a superficial (‘umbrella’ cell) layer (see Fig. 75.8). The basal layer consists of small cuboidal cells from which the upper layers arise. The intermediate layers are polygonal and possess the capacity to stretch and flatten. The superficial layer forms a protective, almost impermeable surface for the bladder mucosa and consists of large, sometimes multinucleated, cells displaying degenerative changes in their cytoplasm; these cells are ultimately exfoliated into the urine. The apical surface of the umbrella cell layer is covered by 16 nm protein particles packed hexagonally to form 2D crystals of asymmetric unit membranes, (AUMs), that contribute to the permeability barrier function of the urinary bladder, preventing reabsorption of urine across the urothelium into the bloodstream. Islands or nests of urothelium may become separated from the surface during development and are found embedded in the underlying lamina propria. These are called von Brunn’s nests and may undergo central degeneration to form cysts (cystitis cystica).

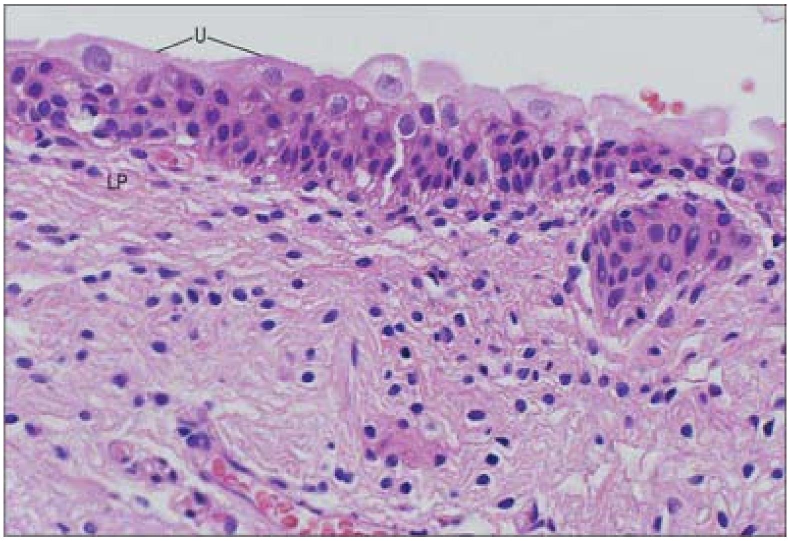

Fig. 75.8 The bladder is lined by urothelium with a surface ‘umbrella cell’ layer (U) and a layer of intermediate cells (3–5 cells thick). The lamina propria (LP) consists of stroma with blood vessels and von Brunn’s nests.

Lamina propria

The lamina propria forms a connective tissue bed supporting the overlying urothelium, from which it is separated by a basement membrane. It is rich in capillaries, lymphatics and nerve-endings. It contains elastic fibres and a thin, poorly defined layer of smooth muscle fibres, muscularis mucosae, that is variably distributed within the bladder. This layer is often very superficial, lying close beneath the urothelium, but is sometimes deeper in the lamina propria where it may be well developed, and must be distinguished from the muscularis propria.

Muscularis propria

The muscularis propria is the detrusor muscle of the bladder wall. It consists of three indistinct layers, an inner and outer longitudinal and an intermediate circular layer. In contrast to the muscularis mucosae, which consists of small wispy fibres, the muscularis propria is made up of larger, poorly defined bundles of smooth muscle that form well-defined inner circular and outer longitudinal layers at the neck of the bladder.

Serosa

The serosa partially covers the bladder. It is lined externally by mesothelium, beneath which there is a variable amount of vascularized adipose tissue that frequently extends into the muscularis propria and occasionally into the lamina propria.

MALE URETHRA

The male urethra (Fig. 75.6A,B) is 18–20 cm long, and extends from the internal orifice in the urinary bladder to the external opening, or meatus, at the end of the penis. It may be considered in two parts. The anterior urethra is approximately 16 cm long and lies within the perineum (proximally) and the penis (distally), surrounded by the corpus spongiosum. The posterior urethra is 4 cm long and lies in the pelvis proximal to the corpus spongiosum, where it is acted upon by the urogenital sphincter mechanisms. Functionally both parts act as a conduit.

*(**A** from Sobotta 2006.)*

The anterior urethra is subdivided into a proximal component, the bulbar urethra, which is surrounded by the bulbospongiosus and is entirely within the perineum, and a pendulous or penile component, which continues on to the tip of the penis. The posterior urethra is divided into preprostatic, prostatic, and membranous segments. In the flaccid penis, the urethra has a double curve. The urethral canal is a mere slit, except during the passage of fluid: in transverse section it is transversely arched in the prostatic part, stellate in the preprostatic and membranous portions, transverse in the bulbar and penile portions, and sagittal at the external orifice.

Posterior part

Preprostatic urethra

The preprostatic urethra (Fig. 75.6B; endoscopic views of bladder neck and urethral crest) is approximately 1 cm in length, and extends from the base of the bladder to the prostate. Small periurethral glands at this site may contribute to benign prostatic hyperplasia (BPH) and symptoms of outflow obstruction in older men.

Prostatic urethra

The prostatic urethra (Fig. 75.7; see Fig. 75.14) is 3–4 cm in length and tunnels through the substance of the prostate, closer to the anterior than the posterior surface of the gland. It is continuous above with the preprostatic part and emerges from the prostate slightly anterior to its apex (the most inferior point of the prostate). Throughout most of its length the posterior wall possesses a midline ridge, the urethral crest, which projects into the lumen causing it to appear crescentic in transverse section. On each side of the crest there is a shallow depression, the prostatic sinus, the floor of which is perforated by the orifices of 15–20 prostatic ducts. An elevation, the verumontanum (seminal colliculus), is seen at about the middle of the length of the urethral crest: it is used as a surgical landmark for the urethral sphincter during trans-urethral resection for benign enlargement of the prostate. At this point the urethra turns anteriorly by 35° and contains the slit-like orifice of the prostatic utricle. On both sides of, or just within, this orifice are the two small openings of the ejaculatory ducts. The prostatic utricle is a cul-de-sac 6 mm long, which runs upwards and backwards in the substance of the prostate behind its median lobe. Its walls are composed of fibrous tissue, muscular fibres and mucous membrane, the latter pitted by the openings of numerous small glands. The prostatic utricle develops from the paramesonephric ducts or urogenital sinus, and is thought to be homologous with the vagina of the female (p. 1338). It is sometimes called the ‘vagina masculina’, but the more usual view is that it is a uterine homologue and hence the term ‘utricle’. The lowermost part of the prostatic urethra is fixed by the puboprostatic ligaments and is therefore immobile.

Membranous urethra

The membranous part of the urethra is the shortest (2–2.5 cm), least dilatable and, with the exception of the external orifice, the narrowest, section of the urethra. It descends with a slight ventral concavity from the prostate to the bulb of the penis, passing through the perineal membrane, 2.5 cm posteroinferior to the pubic symphysis. The wall of the membranous urethra consists of a muscle coat which is separated from the epithelial lining by a narrow layer of fibroelastic connective tissue. The muscle coat contains a relatively thin layer of bundles of smooth muscle, which are continuous proximally with those of the prostatic urethra, and a prominent outer layer of circularly orientated striated muscle fibres, which together form the external urethral sphincter.

Urinary continence at the level of the membranous urethra is mediated by the radial folds of urethral mucosa, the submucosal connective tissue, the intrinsic urethral smooth muscle, the striated muscle fibres and the pubourethral component of levator ani. The muscle coat of the urethra and puborectalis surround the membranous urethra and are attached to the inner surface of the ischiopubic ramus; fibres also reach up to the lowest part of the neck of the bladder and lie on the surface of the prostate. The striated external urethral sphincter has a posterior fibrous defect and is inserted throughout its length into the perineal body. It is related to the dorsal vein complex anteriorly, levator ani laterally and the perineal body and rectourethralis posteriorly, and is suspended from the pubis by fibrous tissue that extends from its anterior and lateral parts to the puboprostatic liagaments posteriorly and to the suspensory ligament of the penis anteriorly. The bulbourethral glands are invested in sphincteric muscle and drain into the membranous urethra during sexual excitement.

Anterior part

The anterior or spongiose part of the urethra lies within the corpus spongiosum penis (p. 1271). In the flaccid penis it is about 15 cm long and extends from the end of the membranous urethra to the external urethral orifice on the glans penis. It starts below the perineal membrane at a point anterior to the lowest level of the symphysis pubis as the bulbar urethra, the widest part of the urethra, surrounded by bulbospongiosus. The bulbourethral glands open into the bulbar urethra approximately 2.5 cm below the perineal membrane. The urethra next curves downwards as the penile urethra. It is a narrow, transverse slit when empty, and has a diameter of approximately 6 mm when passing urine. It is dilated at its termination within the glans penis where it is known as the navicular fossa. The external urethral orifice is the narrowest part of the urethra, and is a sagittal slit, about 6 mm long, bounded on each side by a small labium.

The urethral epithelium, particularly in the bulbar and distal penile segments, presents the orifices of numerous small mucous urethral glands that lie in the submucosa. It also contains a number of small pit-like recesses, or lacunae, of varying sizes whose orifices are directed forwards. One, the lacuna magna, is larger than the rest and is situated in the roof of the navicular fossa.

Traumatic injury to the male urethra

The urethra may be ruptured by a fall-astride (straddle) injury to the bulbar urethra in the perineum, or by an injury related to a pelvic fracture. These injuries usually affect the junction of the membranous with the bulbar segments across the perineal membrane. One of the complications associated with such injuries is extravasation of urine. After an injury to the bulbar urethra, urine usually extravasates between the perineal membrane and the membranous layer of the superficial fascia (clinically known as Colles' fascia). As both of these are attached firmly to the ischiopubic rami, extravasated fluid cannot pass posteriorly because the two layers are continuous around the superficial transverse perineal muscles. Laterally, the spread of urine is blocked by the pubic and ischial rami. Urine cannot enter the lesser pelvis through the perineal membrane if this remains intact, and so it tracks anteriorly into the loose connective tissue of the scrotum and penis and thence to the anterior abdominal wall. If the posterior urethra is injured, urine is extravasated into the pelvic extraperitoneal tissue: if the perineal membrane is also torn then urine may be extravasated into the perineum.

Congenital anomalies of the male urethra

Hypospadias, found in one in 300 boys, most often results in the urethra opening in the distal penis, either on the ventral aspect of the penis or dorsally on to the perineum more proximally. There is also an associated abnormality of the prepuce, which is longer dorsally and lacking ventrally, and often an associated chordee which causes a ventral curvature of the penis. It is important that this anomaly be identified prior to circumcision, because the abnormal foreskin is sometimes used for surgical correction of the deformity.

Posterior urethral valves occur in one in 5000 to 8000 males and are the most common cause of urinary outflow obstruction in male infants. The commonest type (type I) is believed to occur if the Wolffian ducts open too anteriorly onto the primitive prostatic urethra: this abnormal migration of the ducts leaves behind thick vestigial tissue that forms rigid valve cusps extending caudally from the verumontanum.

Very rarely, urethral duplication occurs: the two urethrae almost invariably lie on top of each other rather than side-by-side. One of the urethrae, usually the more dorsal, may be blind ending.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Urethral artery

The urethral artery arises from the internal pudendal artery or common penile artery just below the perineal membrane and travels through the corpus spongiosum, to reach the glans penis. It supplies the urethra and erectile tissue around it. In addition, the urethra is supplied by the dorsal penile artery, via its circumflex branches on each side and retrogradely from the glans, by its terminal branches. The blood supply through the corpus spongiosum is so plentiful that the urethra can be divided without compromising its vascular supply.

Veins

The venous drainage of the anterior urethra is to the dorsal veins of the penis and internal pudendal veins, which drain to the prostatic plexus. The posterior urethra drains into the prostatic and vesical venous plexuses, which drain into the internal iliac veins.

Lymphatic drainage

Vessels from the posterior urethra pass mainly to the internal iliac nodes (see Fig. 77.3A,B); a few may end in the external iliac nodes. Vessels from the membranous urethra accompany the internal pudendal artery. Vessels from the anterior urethra accompany those of the glans penis, ending in the deep inguinal nodes. Some may end in superficial nodes, others may traverse the inguinal canal to end in the external iliac nodes.

INNERVATION

The prostatic plexus supplies the smooth muscle of the prostate and prostatic urethra. On each side it is derived from the pelvic plexus and lies on the posterolateral aspect of the seminal vesicle and prostate. Lesser cavernous nerves pierce the bulb of the corpus spongiosum proximally to supply the penile urethra. The greater cavernous nerves carry the sympathetic supply which causes contraction of the preprostatic sphincter during ejaculation and prevents reflux of ejaculate into the bladder. The parasympathetic preganglionic fibres are axons from neurones in the second to fourth sacral spinal segments. The nerve supply of the external urethral sphincter is controversial. It is generally believed to be supplied by neurones in Onuf’s nucleus and by perineal branches of the pudendal nerve lying on the perineal aspect of the pelvic floor; in both instances the axons arise from neurones in S2, 3 and 4. Fibres from Onuf’s nucleus (somatic) travel with the pelvic plexus on each side until they branch off and run on the pelvic aspect of the pelvic floor to enter the membranous urethra.

MICROSTRUCTURE

The epithelium lining the preprostatic urethra and the proximal part of the prostatic urethra is a typical urothelium (Fig. 75.8). It is continuous with that lining the bladder, and with the epithelium lining the ducts of the prostate and bulbourethral glands, the seminal vesicles, and the vasa deferentia and ejaculatory ducts. These relationships are important in the spread of urinary tract infections.

The epithelium changes below the openings of the ejaculatory ducts to a pseudostratified or stratified columnar type, which lines the membranous urethra and the major part of the penile urethra. Mucus-secreting cells are common throughout this epithelium and frequently occur in small clusters in the penile urethra. Branching tubular paraurethral glands secrete protective mucus onto the urethral epithelial lining and are especially numerous on its dorsal aspect. In older men, many of the deep recesses of the urethral mucosa contain concretions similar to those found within prostatic glands (see Fig. 75.15A). Towards the distal end of the penile urethra the epithelium changes once again, becoming stratified squamous in type with well-defined connective tissue papillae. This epithelium also lines the navicular fossa and becomes keratinized at the external meatus. The epithelial cells lining the navicular fossa are glycogen-rich. This may provide a substrate for commensal lactobacilli which, as in the female vagina provide a defence against pathogenic organisms.

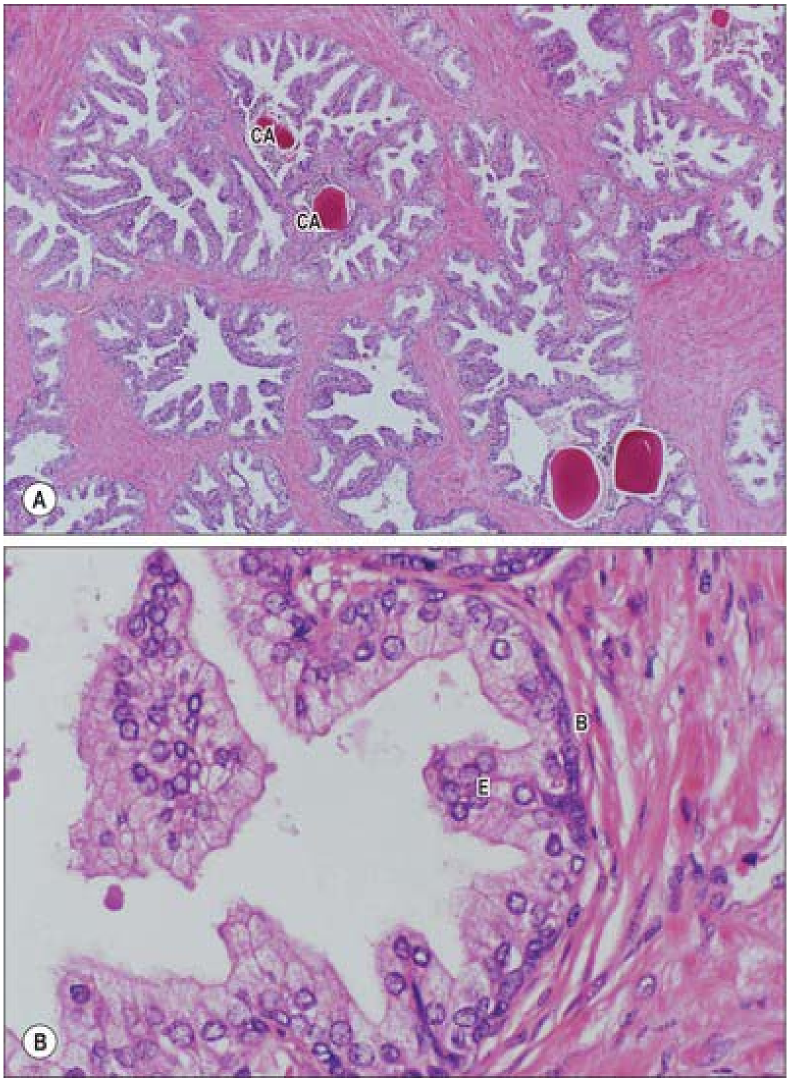

Fig. 75.15 **A**, Prostatic acini show papillary infoldings at the base of the gland (central zone). They are irregularly divided by fibromuscular stroma. Some acini contain eosinophilic (pink) secretions called corpora amylacea (CA) (×10, H&E stain). **B**, Prostatic acini consist of a double layer of epithelial cells (E), which line the lumen, and basal cells (B), which give rise to epithelial cells.

FEMALE URETHRA

The female urethra is approximately 4 cm long and 6 mm in diameter. It begins at the internal urethral orifice of the bladder, approximately opposite the middle of the symphysis pubis, and runs anteroinferiorly behind the symphysis pubis, embedded in the anterior wall of the vagina. It is suspended beneath the pubis by the posterior pubourethral ligaments and anteriorly by the suspensory ligament of the clitoris. It crosses the perineal membrane and normally ends at the external urethral orifice in the vestibule as an anteroposterior slit with rather prominent margins, directly anterior to the opening of the vagina, and 2.5 cm behind the glans clitoris. It sometimes opens into the anterior vaginal wall. Except during the passage of urine, the anterior and posterior walls of the urethra are in apposition and the epithelium is thrown into longitudinal folds, one of which, on the posterior wall of the canal, is termed the urethral crest. Many small mucous urethral glands and minute pit-like recesses or lacunae open into the urethra and may give rise to urethral diverticula. On each side, near the lower end of the urethra, a number of these glands, Skene’s glands, are grouped together and open into the para-urethral duct: each duct runs down in the submucous tissue and ends in a small aperture on the lateral margin of the external urethral orifice.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Urethral artery

The urethra is supplied principally by the vaginal artery, but also receives a supply from the inferior vesical artery.

Veins

The venous plexus around the urethra drains into the vesical venous plexus around the bladder neck, and into the internal pudendal veins. An erectile plexus of veins along the length of the urethra is continuous with the erectile tissue of the vestibular bulb.

Lymphatic drainage

The urethral lymphatics drain into the internal and external iliac nodes.

INNERVATION

Parasympathetic preganglionic fibres arise from neurones in the second to fourth segments of the sacral spinal cord and run in the pelvic splanchnic nerves; they synapse in the vesical plexus in or near the bladder wall. Postganglionic fibres are distributed to the smooth muscle of the urethral wall. Somatic fibres to the striated muscle are also derived from S2 to S4, and run in the pelvic splanchnic nerves but do not synapse in the vesical plexus. Sensory fibres run in the pelvic splanchnic nerves to the second to fourth segments of the sacral spinal cord. Postganglionic sympathetic fibres arise from the plexus around the vaginal arteries.

MICROSTRUCTURE

The mucosa lining the female urethra consists of a stratified epithelium and a supporting lamina propria of loose fibroelastic connective tissue. The latter is bulky and well-vascularized, and contains numerous thin-walled veins. Its abundant elastic fibres are orientated both longitudinally and circularly around the urethra. The lamina propria contains a fine nerve plexus, believed to be derived from sensory branches of the pudendal nerves. The proximal part of the urethra is lined by urothelium, identical in appearance to that of the bladder neck. Distally the epithelium changes into a non-keratinizing stratified squamous type which lines the major portion of the female urethra. This epithelium is keratinized at the external urethral meatus where it becomes continuous with the skin of the vestibule.

The wall of the female urethra consists of an outer muscle coat and an inner mucosa, which lines the lumen and is continuous with that of the bladder. The muscle coat consists of an outer sheath of striated muscle together with an inner coat of smooth muscle fibres. The female external urethral sphincter is anatomically separate from the adjacent periurethral striated muscle of the anterior pelvic floor. The muscle cells forming the external urethral sphincter are all small diameter, slow twitch, fibres.

The smooth muscle coat extends throughout the length of the urethra and consists of slender muscle bundles, the majority of which are orientated obliquely or longitudinally. A few circularly arranged muscle fibres occur in the outer aspect of the non-striated muscle layer and intermingle with the skeletal muscle fibres forming the inner part of the external urethral sphincter. Proximally the urethral smooth muscle extends as far as the bladder neck where it is replaced by fascicles of detrusor smooth muscle. This region in the female lacks a well-defined circular smooth muscle component comparable with the preprostatic sphincter of the male. Distally, urethral smooth muscle bundles terminate in the subcutaneous adipose tissue surrounding the external urethral meatus.

The smooth muscle of the female urethra receives an extensive presumptive cholinergic parasympathetic nerve supply, but contains relatively few noradrenergic nerves. In the absence of an anatomical bladder neck sphincter, competence of the female bladder neck and proximal urethra is unlikely to be totally dependent on smooth muscle activity, and is more probably related to the support provided by the ligamentous structures which surround them. The innervation and longitudinal orientation of most of the muscle fibres suggest that urethral smooth muscle in the female is active during micturition, serving to shorten and widen the urethral lumen.

MICTURITION AND URINARY CONTINENCE

The central integration of the nervous control of the bladder and urethra is essential for normal micturition (Fig. 75.9).

Fig. 75.9 The micturition control centre is in the paramedian pontine reticular formation on each side and consists of a medially placed micturition centre, ‘M’ and a laterally placed storage centre, ‘L’. Neurones project from the ‘M’ centre and the storage centre ‘L’ to parasympathetic neurones in segments 2–4 of the sacral spinal cord, and to Onuf’s nucleus, which is in the same segments, and which innervates the external urethral sphincter. At higher levels, neurones in the right prefrontal and anterior cingulate cortex, right preoptic nucleus and periaqueductal grey matter, are involved in the control of micturition. Vesical afferents from stretch receptors in the detrusor and trigonal mucosa relay the extent of bladder filling to the brain stem and thalamus via spinoreticulothalamic fibres (1). Activity in the sympathetic system which maintains increases in bladder compliance (via β_2 receptors on detrusor fibres) and parasympathetic activity is inhibited (2). Spinoreticular fibres synapsing in the ‘L’ nucleus in the pons activate Onuf’s nucleus to increase the tone of the external sphincter (3). If micturition is deferred, fibres projecting from the inferior frontal gyrus inhibit the right anterior cingulate gyrus, preoptic area and periaqueductal grey matter) (4). Voluntary contraction of the pelvic floor musculature, controlled by the prefrontal cortex driving the perineal ‘area’ of the motor cortex (5) cannot be long sustained once filling is complete.

(By permission from FitzGerald MJT, Folan-Curren J 2001 Clinical Neuroanatomy, 4th edn. London: Saunders.)

Micturition consists of storage and voiding phases. During the storage phase the bladder accommodates an increasing volume of urine without any change in intravesical pressure, partly because of the viscoelastic properties of its walls, and partly because a gating mechanism operates in the spinal cord that reflexly inhibits preganglionic parasympathetic activity. A gating mechanism in the pelvic ganglia prevents the activation of postganglionic parasympathetic neurones until preganglionic activity has reached a threshold level.

Mean bladder capacity in adult males varies around 400 ml, but micturition commonly occurs at smaller volumes. Voluntary control is imposed from the inferior frontal gyrus of the cerebral cortex. Filling to 500 ml may be tolerated; beyond this level, pain caused by tension in the bladder wall leads to the urgent desire to micturate. The pain is referred to the cutaneous areas supplied by T10–L2, S2–4, including the lower anterior abdominal wall, perineum and penis. Threshold afferent stimulation activates the micturition centre in the rostral pons (the M-centre) (Fig. 75.9) which drives preganglionic parasympathetic neurones in the intermediolateral grey column of the second, third and fourth sacral spinal segments via descending spinal pathways. The axons of these neurones run to the inferior hypogastric plexus in the pelvic splanchnic nerves: they synapse on postganglionic neurones in ganglia lying within the plexus and in the wall of the bladder. Postganglionic axons ramify throughout the thickness of the detrusor smooth muscle coat. When stimulated, they release acetylcholine which activates muscarinic receptors in the detrusor layer of the bladder wall and produces the sustained bladder contraction required for micturition. The distal urethral sphincter maintains urethral closure.

Urinary continence in the male

Urinary continence at the level of the membranous urethra is mediated by the radial folds of urethral mucosa, the submucosal connective tissue, the intrinsic urethral smooth muscle, the striated external urethral sphincter and the pubourethral component of levator ani. The external urethral sphincter represents the point of highest intraurethral pressure in the normal, contracted state. The striated muscle component of the external urethral sphincter is devoid of muscle spindles. The striated muscle fibres themselves are unusually small in cross-section (15–20 μm diameter), and are physiologically of the slow twitch type, unlike the pelvic floor musculature, which is a heterogeneous mixture of slow and fast twitch fibres of larger diameter. The slow twitch fibres of the external sphincter are capable of sustained contraction over relatively long periods of time and actively contribute to the tone which closes the urethra and maintains urinary continence. They are innervated by neurones that lie in Onuf’s nucleus in the anterolateral grey matter of the second to fourth sacral spinal segments. Their firing is controlled centrally by a storage centre within the rostral pons (the L-centre) (Fig. 75.9). Just before the onset of voiding, the external urethral sphincter is relaxed by central inhibition of Onuf's nucleus. Relaxation of the urethra is currently believed to be due to the release of nitric oxide from parasympathetic nerves in the bladder neck and urethra.

Urinary continence in the female

The urethral sphincter mechanism consists of the intrinsic striated and smooth muscle of the urethra, the mucosa and submucosal connective tissue, and the puborectalis component of levator ani (which surrounds the urethra at the point of maximum concentration of those muscles). The striated muscle component of the urethral sphincter mechanism surrounds the middle and lower thirds of the urethra in the female. Proximally it forms a complete ring around the urethra, more distally it covers the anterior and lateral aspects of the urethra: it blends above with the smooth muscle of the bladder neck and below with the smooth muscle of the lower urethra and vagina. Contraction of this part of the sphincter compresses the urethra against the relatively fixed anterior vaginal wall. At its most distal point the striated sphincter encompasses the urethra and vagina as the urethrovaginal sphincter. The mucosa and submucosa are oestrogen dependent and atrophy postmenopausally, possibly resulting in stress incontinence.

PROSTATE

The prostate is a pyramidal fibromuscular gland which surrounds the prostatic urethra from the bladder base to the membranous urethra. It has no true fibrous capsule, but is enclosed by visceral fascia containing neurovascular tissue (Fig. 75.10A,B). The fascia is firmly adherent to the gland and is continuous with a median septum and with numerous fibromuscular septa which divide the glandular tissue into indistinct lobules.

Fig. 75.10 **A**, The endopelvic fascia. The fascia covers the pelvic viscera and continues posteriorly over the lateral aspect of the prostate, as the lateral prostatic fascia and on the lateral aspect of the rectum as the lateral rectal fascia. Its relationship with Denonvilliers may be visualized as an ‘H’. The deep dorsal vein and lateral branches run deep to the endopelvic fascia and the lateral prostatic fascia, although communicating with perforators to the pelvic side wall. Denonvilliers is adherent to the prostate in the posterior midline, but like the lateral prostatic fascia is separated from the prostatic tissue by the neurovascular structures and fatty tissues elsewhere. Between Denonvilliers and the rectum is a fatty potential plane, the prerectal space. **B**, The prostatic capsule (PC) is a condensation of connective tissue on the

surface of the gland (green) and encloses the neurovascular bundle (NVB). The prostatic fibromuscular stroma and glands lie beneath the capsule.

The muscular tissue within the prostate is mainly smooth muscle. Anterior to the urethra a layer of smooth muscle merges with the main mass of muscle in the fibromuscular septa; it blends superiorly with vesical smooth muscle. Anterior to the layer of smooth muscle a transversely crescent-shaped mass of skeletal muscle is continuous inferiorly with the external urethral sphincter in the deep perineal pouch. Its fibres pass transversely internal to the capsule, and are attached to it laterally by diffuse collagen bundles; other collagen bundles pass posteromedially, merging with the prostatic fibromuscular septa and the septum of the urethral crest. This muscle, supplied by the pudendal nerve, probably compresses the urethra but it may pull the urethral crest back and the prostatic sinuses forwards, dilating the urethra. Glandular contents may be expelled simultaneously into the urethra when it has expanded in this way, so that it contains 3–5 ml seminal fluid prior to ejaculation.

The prostate lies at a low level in the lesser pelvis, behind the inferior border of the symphysis pubis and pubic arch (Figs 75.2A, 75.11) and anterior to rectourethralis and the rectal ampulla, through which it may be palpated. Being somewhat pyramidal, it presents a base or vesical aspect superiorly, an apex inferiorly, and posterior, anterior and two inferolateral surfaces. The prostatic base measures about 4 cm transversely. The gland is 2 cm in anteroposterior and 3 cm in its vertical diameters, and weighs about 8 g in youth, but almost invariably enlarges with the development of BPH: it usually weighs 40 g, but sometimes as much as 150 g or even more, after the first five decades of life. The small prostate without BPH is described as a croissant shape (short anterior commissure, prominent apical notch and posterior lip of prostatic tissue), and the enlarged gland is more doughnut-shaped. The shape of the prostate affects the relationship of the prostatic apex to the external urethral sphincter. This relationship is important when removing the prostate at radical prostatectomy for cancer, and anastomosing the bladder to the urethra to maintain sphincter integrity. The external urethral sphincter is flush to a large doughnut-type gland so a perpendicular incision will separate the prostate and external urethral sphincter accurately. In a small prostate the external urethral sphincter fills the defect in the anterior aspect of the prostate, so a perpendicular incision at the level of the posterior lip of the croissant shaped gland will excise much external urethral sphincter and leave the patient incontinent.

Fig. 75.11 Sagittal section, male pelvis. The pelvic plexus lies with its midpoint level with the tip of the seminal vesicles. It gives branches to the prostate, bladder urethra, seminal vesicles, rectum and corpora cavernosa via the cavernous nerves. The cavernous nerves are the continuation of the neurovascular bundles, lying posterolateral to the prostate. These bundles may be damaged at radical prostatectomy resulting in impotence.

Superiorly the base is largely contiguous with the neck of the bladder. The apex is inferior, surrounding the junction of the prostatic and membranous parts of the posterior urethra. The apical posterior relation of the prostate and external urethral sphincter is rectourethralis, a Y-shaped muscle that originates from the outer longitudinal coat of the rectum. The upper limbs of the Y extend from the lateral rectal wall to the midline where rectourethralis inserts into the perineal body at the anorectal junction.

The anterior surface lies in the arch of the pubis, separated from it by the dorsal venous complex (Santorini's plexus) and loosely attached adipose tissue. It is transversely narrow and convex, extending from the apex to the base. Near its superior limit it is connected to the pubic bones by the puboprostatic ligaments. The urethra emerges from this surface anterosuperior to the apex of the gland. The anterior part of the prostate is relatively deficient in glandular tissue and is largely composed of fibromuscular tissue. The anterior and lateral aspects of the prostate are covered by a layer of fascia derived from the endopelvic fascia on each side, called the lateral prostatic fascia. This is adherent medially to the prostate, continues posteriorly over the lateral aspect of the prostate, neurovascular bundles and rectum (lateral rectal fascia) and passes distally over the urethra (Fig. 75.10A). The prostatic venous plexus (Fig. 75.11) lies between this extension of the endopelvic fascia and the prostate. Anteroinferiorly the parietal and visceral fasciae of the prostate merge and blend with the puboprostatic ligaments. The anterior surface of the prostate and associated vascular plexus is covered by the detrusor apron.

The inferolateral surfaces are related to the muscles of the pelvic sidewall: the anterior fibres of levator ani embrace the prostate in the pubourethral sling or pubourethralis. These muscles are separated from the prostate by a thin layer of connective tissue.

The posterior surface of the prostate is transversely flat and vertically convex. Near its superior (juxtavesical) border is a depression where it is penetrated by the two ejaculatory ducts. Below this is a shallow, median sulcus, usually considered to mark a partial separation into right and left lateral lobes. It is separated from prerectal fat in the prerectal space (Figs 75.2A, 75.10A), and rectum by Denonvillier's fascia, a condensation of pelvic fascia which develops by obliteration of the rectovesical peritoneal pouch, and by loose yellow fatty areolar tissue. The rectovesical pouch is obliterated from below upwards as fetal life progresses, forming Denonvillier’s fascia: at birth this fascia separates the prostate, the seminal vesicles and the ampullae of the vasa deferentia from the rectum. The superior limit of Denonvillier’s fascia is the peritoneum of the rectovesical pouch. Laterally Denonvillier’s fascia fuses with the lateral pelvic fascia: anterior to Denonvillier’s fascia, the fascia is called the lateral prostatic fascia, and posterior to Denonvillier’s fascia it is called the lateral rectal fascia.

The prostate is traversed by the urethra and ejaculatory ducts, and contains the prostatic utricle. The urethra enters the prostate near its anterior border and usually passes between its anterior and middle thirds. The ejaculatory ducts pass anteroinferiorly through its posterior region to open into the prostatic urethra (p. 1250).

ZONAL ANATOMY OF THE PROSTATE

The prostate gland was initially thought to be divided into five anatomical lobes, but it is now recognized that five lobes can only be distinguished in the fetal gland prior to 20 weeks' gestation. Between then and the onset of BPH, only three lobes are recognizable, two lateral and a median lobe. Clinicians refer to left and right 'lobes' when describing either what can be felt on rectal palpation, or endoscopically visible abnormalities in the diseased state when prostatic anatomy is distorted by BPH.

From an anatomical, and particularly from a morbid anatomical perspective, the glandular tissue may be subdivided into three distinct zones (Figs 75.12-75.14), peripheral (70% by volume), central (25% by volume), and transitional (5% by volume). Non-glandular tissue (fibromuscular stoma) fills up the space between the peripheral zones anterior to the preprostatic urethra. The central zone surrounds the ejaculatory ducts, posterior to the preprostatic urethra, and is more or less conical in shape with its apex at the verumontanum. The transitional zone lies around the distal part of the preprostatic urethra just proximal to the apex of the central zone and the ejaculatory ducts. Its ducts enter the prostatic urethra just below the preprostatic sphincter and just above the ducts of the peripheral zone. The peripheral zone is cup-shaped and encloses the central transitional zone and the preprostatic urethra except anteriorly, where the space is filled by the anterior fibromuscular stroma. Simple mucus-secreting glands lie in the tissue around the preprostatic urethra, above the transitional zone and surrounded by the preprostatic sphincter. These simple glands are similar to those in the female urethra and unlike the glands of the prostate.

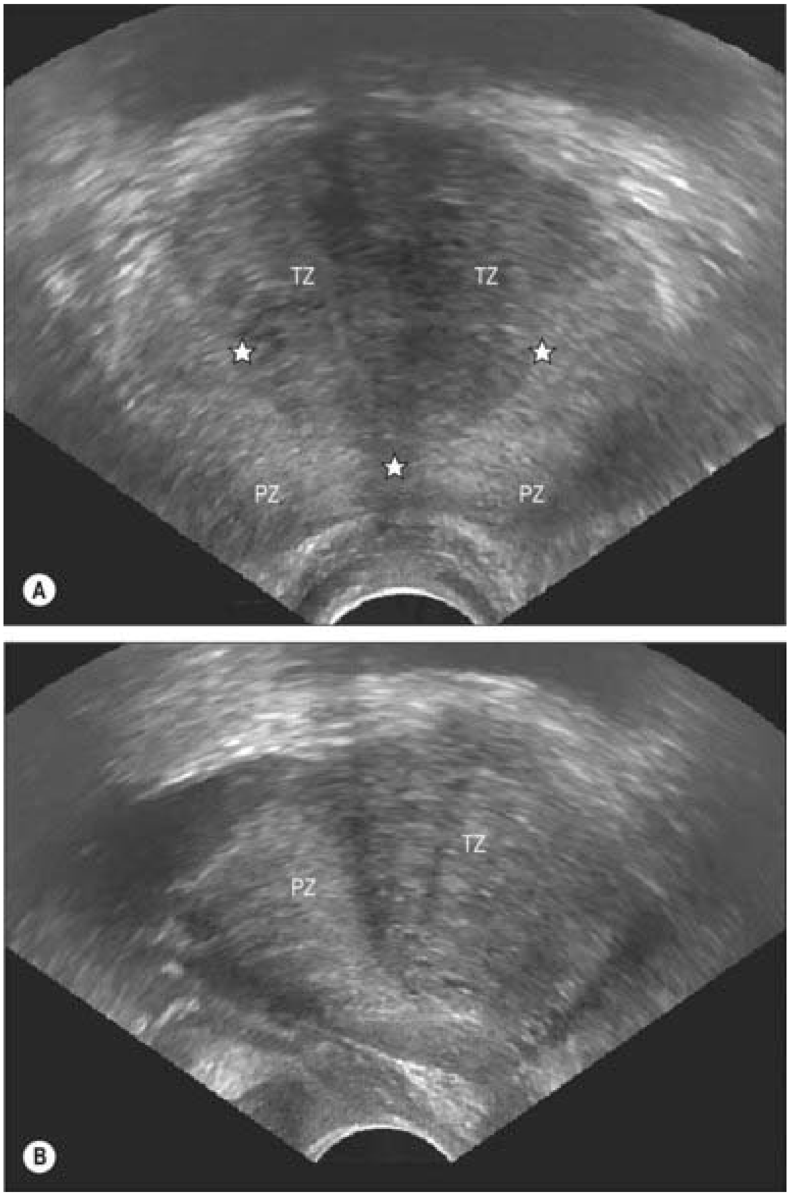

Fig. 75.12 Ultrasound of the prostate. **A**, Axial view showing the hypoechoic transition zone (TZ) and the more echogenic peripheral zone (PZ). Their interface is the surgical capsule (*). **B**, Sagittal view showing the hypoechoic transition zone (TZ) and the more echogenic peripheral zone (PZ).

Fig. 75.13 MRI of the prostate. **A**, T2-weighted MRI scan showing the normal high signal of the peripheral zone and the intermediate signal of the central and transitional zones and the verumontanum in the central gland. **B**, T2-weighted coronal MRI scan of the prostate showing the zonal anatomy.

The zonal anatomy of the prostate is clinically important because most carcinomas arise in the peripheral zone, whereas BPH affects the transitional zone, which may grow to form the bulk of the prostate. BPH begins as micronodules in the transitional zone which grow and coalesce to form macronodules around the inferior margin of the preprostatic urethra, just above the verumontanum. Macronodules in turn compress the surrounding normal tissue of the peripheral zone posteroinferiorly, creating a ‘false capsule’ around the hyperplastic tissue which coincidentally provides a plane of cleavage for its surgical enucleation. As the transitional zone grows, it produces the appearance of ‘lobes’ on either side of the urethra. In due course, these lobes may compress or distort the preprostatic and prostatic parts of the urethra and produce symptoms. The central zone surrounding the ejaculatory ducts is rarely involved in any disease. It shows certain histochemical characteristics which differententiate it from the rest of the prostate: it is thought to be derived from the Wolffian duct system (much like the epididymi, vasa deferentia and seminal vesicles), whereas the rest of the prostate is derived from the urogenital sinus (p. 1323).

On magnetic resonance (MR) imaging the prostate gland has a zonal anatomy on T2-weighted images (Fig. 75.13). The normal peripheral zone has high signal intensity, as does fluid within the seminal vesicles. The central and transitional zones have relatively low signal and are often referred to as the ‘central gland’. The verumontanum may be seen as high signal within the central gland.

The relationship of the zones of the gland normally changes with age. The central zone atrophies, and the transitional zone enlarges secondary to BPH. This often produces a low signal band at the margin of the hypertrophied transitional and compressed peripheral zones, the surgical pseudocapsule, which is well seen on T2-weighted MR images.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The prostate is supplied by branches from the inferior vesical, internal pudendal and middle rectal arteries (Fig. 75.11). They perforate the gland along a posterolateral line from the junction of the prostate with the bladder down to the apex of the gland.

The inferior vesical artery often arises from the internal iliac artery with the middle rectal artery. It gives rise to two groups of branches, the urethral and capsular. The urethral vessels enter at the prostatovesical junction principally posteriorly at the 5 and 7 o'clock positions, but also anteriorly at 1 and 11 o'clock. This bladder neck arterial anatomy is always apparent at transurethral resection of the prostate and open removal of BPH adenomas. The capsular arteries run posterolaterally and inferiorly in the neurovascular bundles, providing perpendicular perforating vessels to the prostate. The most constant in position and prominence is the apical perforator at the prostatourethral junction, an important landmark for this point and for the neurovascular bundle at radical prostatectomy.

Veins

The veins run into a plexus around the anterolateral aspects of the prostate, posterior to the arcuate pubic ligament and the lower part of symphysis pubis, anterior to the bladder and prostate (see Fig. 76.22). The chief tributary is the deep dorsal vein of the penis. The plexus also receives anterior vesical and prostatic rami (which connect with the vesical plexus and internal pudendal vein), and drains into vesical and internal iliac veins.

Lymphatic drainage

Collecting vessels from the vas deferens drain into the external iliac nodes, while those from the seminal vesicle drain to the internal and external iliac nodes. Prostatic vessels end mainly in internal iliac, sacral and obturator nodes. A vessel from the posterior surface accompanies the vesical vessels to the external iliac nodes, and another from the anterior surface reaches the internal iliac group by joining vessels which drain the membranous urethra.

INNERVATION

The prostate receives an abundant nerve supply from the inferior hypogastric (pelvic) plexus (Figs 75.10A, 75.11). The prostatic capsule is covered by numerous nerve fibres and ganglia posterolaterally, forming a crescenteric periprostatic nerve plexus. The greatest density of nerves is found in the preprostatic sphincter; fewer fibres are found in the anterior fibromuscular stroma, and the peripheral zone is the least densely innervated. Nerves containing neuropeptide Y and vasointestinal polypeptide (VIP) are localized in the subepithelial connective tissue, in the smooth muscle layers of the gland, and in the walls of its blood vessels. Neurovascular bundles containing autonomic nerves which supply the prostate, seminal vesicles, prostatic urethra, ejaculatory ducts, corpora cavernosa, corpus spongiosum, membranous and penile urethra and bulbourethral glands are closely applied to, but separable from, the posterolateral margins of the prostate. They are intimately related to the prostatic fascia. These nerves may be damaged during radical prostate surgery for organ-confined prostate cancer, producing impotence (p. 1277), or sacrificed as part of wide local excision of the prostate.

The somatic pudendal nerve (p. 1092) supplies the external urethral sphincter. The branches enter at the 5 and 7 o’clock positions, and must be avoided when placing anastomotic sutures to bring the bladder and urethra together during a radical prostatectomy. Sensory branches pass through the penile hilus in association with the dorsal venous complex and dorsal vein of the penis. They may be damaged during ligation of the dorsal vein during radical prostatectomy, which results in an anaesthetic penis.

MICROSTRUCTURE

The glandular tissue consists of numerous follicles with frequent internal papillae. Follicles open into elongated canals which join to form 12–20 main ducts. The follicles are separated by loose connective tissue, supported by extensions of the fibrous capsule and muscular stroma and enclosed in a delicate capillary plexus. Follicular epithelium is variable but predominantly columnar, and either single-layered or pseudostratified.

Prostatic ducts open mainly into the prostatic sinuses in the floor of the prostatic urethra. They have a bilayered epithelium, the luminal layer is columnar and the basal layer is populated by small cuboidal cells. Small colloid amyloid bodies (corpora amylacea) are frequent in the follicles (Fig. 75.15A,B). Prostatic and seminal vesicular secretions form the bulk of seminal fluid. Prostatic secretions are slightly acid, and contain acid phosphatase, amylase, prostate specific antigen, fibrinolysin and zinc. Numerous neuroendocrine cells, containing neuronespecific enolase, chromogranin and serotonin, are present in the glandular epithelium: their numbers decline after middle age and their function is unknown.

Histological sections just above the level of the verumontanum reveal two concentric, partially circumurethral, zones of glandular tissue. The larger outer zone is the peripheral zone and has long, branched glands, whose ducts open mainly into the prostatic sinuses. The inner zone is the transitional zone and consists of glands whose ducts open on the floor of the prostatic sinuses and colliculus seminalis, and a group of simple mucosal glands which surround the preprostatic urethra. Anteriorly, in the prostatic isthmus, the peripheral zone and submucosal glands are absent.

AGE CHANGES IN THE PROSTATE

At birth, the prostate has a system of ducts embedded in a stroma which forms a large part of the gland. Follicles are represented by small end-buds on the ducts. Before birth, the epithelium of the ducts, seminal colliculus and prostatic utricle display hyperplasia and squamous metaplasia, possibly due to maternal oestrogens in the fetal blood. This subsides after birth and is followed by a period of quiescence lasting for 12–14 years.

At puberty, between the ages of approximately 14 and 18 years, the prostate gland enters a maturation phase, and more than doubles in size during this time. Growth is almost entirely due to follicular development, partly from end-buds on ducts, and partly from modification of the ductal branches. Morphogenesis and differentiation of the epithelial cords starts in an intermediate part of the epithelial anlage and proceeds to the urethral and subcapsular parts of the gland; the latter is reached by the age of 17–18 years. The glandular epithelium is initially multilayered squamous or cuboidal, and is transformed into a pseudostratified epithelium consisting of basal, exocrine secretory (including mucous) and neuroendocrine cells. The mucous cells are temporary, and are lost as the gland matures. The remaining exocrine secretory cells produce a number of products including acid phosphatase, prostate-specific antigen and β-microseminoprotein. Growth of the secretory component is associated with a condensation of the stroma, which diminishes relative to the glandular tissue. These changes are probably a response to the secretion of testosterone by the testis.

During the third decade the glandular epithelium grows by irregular multiplication of the epithelial infoldings into the lumen of the follicles. After the third decade, the size of the prostate remains virtually unaltered until 45–50 years, when the epithelial foldings tend to disappear, follicular outlines become more regular, and amyloid bodies increase in number: all signs of prostatic involution. After 45–50 years the prostate tends to develop BPH: an age-related condition. If a man lives long enough then BPH is inevitable, although not always symptomatic.

CHAPTER 76

Male reproductive system

The male reproductive system consists of the spermatic cord and scrotum, testes and epididymes, vas deferens, prostate, seminal vesicles and penis.

SPERMATIC CORD

As the testis traverses the abdominal wall into the scrotum during early life, it carries its vessels, nerves and vas deferens with it. These meet at the deep inguinal ring to form the spermatic cord, which suspends the testis in the scrotum and extends from the deep inguinal ring to the posterior aspect of the testis (Fig. 76.1). The left cord is a little longer than the right. Between the superficial ring and testis the cord is anterior to the tendon of adductor longus. It is crossed anteriorly by the superficial external pudendal artery and posteriorly by the deep external pudendal artery. The ilioinguinal nerve lies inferior to the cord as it traverses the inguinal canal.

In the canal the cord acquires coverings from the layers of the abdominal wall that extend into the scrotal wall as the internal spermatic, cremasteric and external spermatic fasciae (Fig. 76.2). The internal spermatic fascia is derived from the transversalis fascia and forms a thin, loose layer around the spermatic cord. The cremasteric fascia contains fasciculi of skeletal muscle united by loose connective tissue to form the cremaster muscle which is continuous with internal oblique. The external spermatic fascia descends from the crura of the superficial ring and is a thin fibrous stratum continuous above with the aponeurosis of external oblique. The spermatic cord contains the vas deferens; the testicular artery and veins, cremasteric artery (a branch of the inferior epigastric artery) and artery to the vas deferens (from the superior vesical artery); the genital branch of the genitofemoral nerve and cremasteric nerve and the sympathetic components of the testicular plexus (which are joined by filaments from the pelvic plexus accompanying the artery to the vas deferens); 4–8 lymph vessels draining the testis. All of these structures are conjoined by loose connective tissue (Figs 76.2, 76.3A).

(From Sobotta 2006.)

SCROTUM

The scrotum is a cutaneous fibromuscular sac containing the testes and lower parts of the spermatic cords and hangs below the pubic symphysis between the anteromedial aspects of the thighs. It consists of skin, dartos muscle and external spermatic, cremasteric and internal spermatic fasciae. The internal spermatic fascia is loosely attached to the parietal layer of the tunica vaginalis (Fig. 76.3B). The scrotum is divided into right and left halves by a cutaneous raphe, which continues ventrally to the inferior penile surface and dorsally along the midline of the perineum to the anus. The raphe indicates the bilateral origin of the scrotum from the genital swellings. The left side of the scrotum is usually lower because the left spermatic cord is longer.

The scrotal skin is thin, pigmented and often rugose. It bears thinly scattered, crisp hairs, whose roots are visible through the skin. It has sebaceous glands, whose secretion has a characteristic odour, and also numerous sweat glands, pigment cells and nerve endings. These nerve endings respond to mechanical stimulation of the hairs and skin and to variations in temperature. There is no subcutaneous adipose tissue. The external appearance varies. When warm, and in the elderly and debilitated, the scrotum is smooth, elongated and flaccid. When cold, and in the young and robust, it is short, corrugated and closely applied to the testes because of the contraction of the dartos muscle.

The dartos muscle is a thin layer of smooth muscle continuous beyond the scrotum with the superficial inguinal and perineal fasciae. It extends into the scrotal septum, which connects the raphe to the inferior surface of the penile radix. The septum contains all the layers of the scrotal wall except the skin. The dartos muscle is closely united to the skin, but is connected to subjacent parts by delicate loose connective tissue. A fibromuscular ‘scrotal ligament’ extends from the dartos sheet to the inferior testicular pole, and may play a role in thermoregulation of the testis.

Vascular supply and lymphatic drainage

The arteries supplying the scrotum include the external pudendal branches of the femoral artery, the scrotal branches of the internal pudendal artery, and a cremasteric branch from the inferior epigastric artery. Dense subcutaneous plexuses of scrotal vessels carry a substantial blood flow, facilitating heat loss. Arteriovenous anastomoses of a simple but large-calibre type are also prominent. The veins follow the corresponding arteries. The skin of the scrotum is drained by vessels that accompany the external pudendal blood vessels to the superficial inguinal nodes (Fig. 76.3A).

Innervation

The scrotum is innervated by the ilioinguinal nerve, the genital branch of the genitofemoral nerve, the two posterior scrotal branches of the perineal nerve, and the perineal branch of the posterior femoral cutaneous nerve. The anterior third of the scrotum is supplied mainly from the first lumbar spinal segment (by way of the ilioinguinal and genitofemoral nerves), and the posterior two-thirds are innervated principally from the third sacral spinal segment (via the perineal and posterior femoral cutaneous nerves). The ventral axial line of the lower limb passes between these areas which means that a spinal anaesthetic must be injected much higher to anaesthetize the anterior region.

TESTES AND EPIDIDYMIS

TESTES

The testes are the primary reproductive organs or gonads in the male. They are ovoid, reproductive and endocrine organs responsible for sperm production and testosterone production. They are suspended in the scrotum by scrotal tissues including the dartos muscle and spermatic cords. Average testicular dimensions are 4–5 cm in length, 2.5 cm in breadth and 3 cm in anteroposterior diameter; their weight varies from 10.5–14 g. The left testis usually lies lower than the right testis. Each testis lies obliquely within the scrotum, the upper pole tilted anterolaterally and the lower posteromedially. The anterior aspect is convex, whereas the posterior aspect is nearly straight and has the spermatic cord attached to it. Anterior, medial and lateral surfaces and both poles are convex, smooth and covered by the visceral layer of the serosal tunica vaginalis, the parietal layer and the scrotal tissues, in that order from within outwards (Fig. 76.4). Each testis is separated from its fellow by a fibrous median raphe which is deficient superiorly. The posterior aspect of each testis is only partly covered by serosa; the epididymis adjoins its lateral part (see below). The testis is invested by three coats, which are, from outside inwards, the tunica vaginalis, tunica albuginea and tunica vasculosa (Fig. 76.4).

Tunica vaginalis

The tunica vaginalis is the lower end of the peritoneal processus vaginalis, whose formation precedes the descent of the fetal testis from the abdomen to the scrotum (see p. 1320). After this migration, the proximal part of the tunica, from the internal inguinal ring almost to the testis, contracts and is obliterated, leaving a closed distal sac into which the testis is invaginated. The tunica is reflected from the testis onto the internal surface of the scrotum, so forming the visceral and parietal layers of the tunica. The visceral layer covers all aspects of the testis except most of the posterior aspect. Posteromedially it is reflected forwards to the parietal layer. Posterolaterally it passes to the medial aspect of the epididymis and lines the epididymal sinus, and then passes laterally to its posterior border where it is reflected forwards to become continuous with the parietal layer. The visceral and parietal layers are continuous at both poles, but at the upper pole the visceral layer surmounts the head of the epididymis before reflexion. There is always a very fine film of fluid between the two layers of the tunica vaginalis. This fluid layer can increase in inflammatory and neoplastic conditions of the testis, leading to a hydrocele (see below).

The more extensive parietal layer reaches below the testis and ascends in front of and medial to the spermatic cord. The inner surface of the tunica vaginalis has a smooth, moist mesothelium: the potential space between its visceral and parietal layers is termed the cavity of the tunica vaginalis.

Tunica albuginea

The tunica albuginea is a dense, bluish-white covering for the testis, composed mainly of interlacing bundles of collagen fibres. It is covered externally by the visceral layer of the tunica vaginalis, except at the epididymal head and tail and the posterior aspect of the testis, where vessels and nerves enter (Fig. 76.5A,B). The tunica vaginalis covers the tunica vasculosa and, at the posterior border of the testis, projects into the testicular interior as a thick, incomplete fibrous septum, the mediastinum testis, which extends from the upper to the lower end of the testis. Testicular vessels run within the mediastinum testis.

(From Sobotta 2006.)

Tunica vasculosa

The tunica vasculosa contains a plexus of blood vessels and delicate loose connective tissue, and extends over the internal aspect of the tunica albuginea, covering the septa and therefore all the testicular lobules.

Vascular supply and lymphatic drainage

Testicular arteries

The testicular arteries are two long, slender vessels which arise anteriorly from the aorta a little inferior to the renal arteries. Each passes inferolaterally under the parietal peritoneum on psoas major. The right testicular artery lies anterior to the inferior vena cava and posterior to the horizontal part of the duodenum, right colic and ileocolic arteries, root of the mesentery and terminal ileum. The left testicular artery lies posterior to the inferior mesenteric vein, left colic artery and lower part of the descending colon. Each artery crosses anterior to the genitofemoral nerve, ureter and the lower part of the external iliac artery and passes to the deep inguinal ring to enter the spermatic cord and travel via the inguinal canal to enter the scrotum (Figs 76.3A, 76.6). At the posterosuperior aspect of the testis the testicular artery divides into two branches on its medial and lateral surfaces: these pass through the tunica albuginea and ramify in the tunica vasculosa. Terminal branches enter the testis over its surface. Some pass into the mediastinum testis and loop back before reaching their distribution. Capillaries lying next to seminiferous tubules penetrate the layers of interstitial tissue and may form part of the ‘blood–testis’ barrier. They run either parallel to the tubules or across them but do not enter their walls. They are separated from germinal and supporting cells by a basement membrane and variable amounts of fibrous tissue containing interstitial cells: selective exchange phenomena involving androgens and immune substances occur here.

Fig. 76.6 Arterial blood supply and venous drainage of the testis.

(From Sobotta 2006.)

In the abdomen the testicular artery supplies perirenal fat, the ureter and iliac lymph nodes, and in the inguinal canal it supplies cremaster. Sometimes the right testicular artery passes posterior to the inferior vena cava. The testicular arteries represent persistent lateral splanchnic aortic branches that enter the mesonephros and cross ventral to the supracardinal vein, but dorsal to the subcardinal vein. Normally the lateral splanchnic artery – which persists as the right testicular artery – passes caudal to the suprasubcardinal anastomosis, which forms part of the inferior vena cava. When it passes cranial to the anastomosis, the right testicular artery lies behind the inferior vena cava.

The testis also receives blood from the cremasteric branch of the inferior epigastric artery, and from the artery to the vas deferens (Fig. 76.6). Interference with the testicular artery high in the abdomen therefore usually leaves the testis unharmed, whereas interruption in the region of the spermatic cord may interfere with all of these vessels and lead to infarction. Ligating both the testicular artery and vein high up interrupts the venae comitantes of the artery which anastomose with the internal spermatic veins and can be responsible for recurrence of a varicocele (see below).

Testicular veins

The testicular veins emerge posteriorly from the testis, drain the epididymis and unite to form the pampiniform plexus, a major component of the spermatic cord that ascends anterior to the vas deferens (Fig. 76.7). In the inguinal canal the pampiniform plexus is drained by three or four veins which run into the abdomen through the deep inguinal ring. Within the abdomen these veins coalesce into two veins, which ascend on each side of the testicular artery, anterior to psoas major and the ureter, and behind the peritoneum. The left veins pass behind the lower descending colon and inferior margin of the pancreas and are crossed by the left colic vessels, and the right veins pass behind the terminal ileum and horizontal part of the duodenum and are crossed by the root of the mesentery, ileocolic and right colic vessels. The veins join to form single right or left testicular veins: the right testicular vein opens into the inferior vena cava at an acute angle just inferior to the level of the renal veins, and the left testicular vein opens into the left renal vein at a right angle (Fig. 76.7). The testicular veins contain valves.

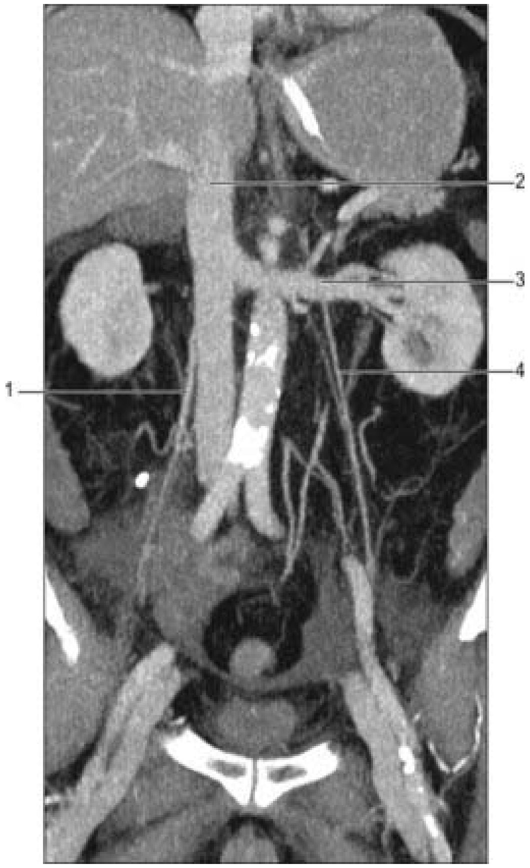

Fig. 76.7 Multislice CT of the inferior vena cava showing the left testicular vein draining to the left renal vein and the right testicular vein draining directly to the inferior vena cava. **1**. Right testicular vein. **2**. Inferior vena cava. **3**. Left renal vein. **4**. Left testicular vein.

The testicular veins in the scrotum and inguinal canal may be varicose in up to 15% of the male population. In fact between 25–35% of men with fertility problems may also have a varicocele. Varicocele formation, which is almost always on the left, may be due to the orthogonal junction of the left testicular and renal veins. There is evidence that the presence of a varicocele raises testicular temperature and impairs spermatogenesis. Varicoceles may also cause testicular pain, which is often a dragging type of pain experienced towards the end of the day after long periods of standing. Varicoceles may be treated surgically for pain but the role of varicocele surgery for treating male infertility is controversial. Varicoceles can also be treated by radiological embolization of the left testicular vein via a right femoral vein approach.

After ligation of a varicocele, venous return is by the small veins of the vas deferens, cremaster and scrotal tissues.

Lymphatic drainage

Testicular vessels start in a superficial plexus under the tunica vaginalis and a deep plexus in the substance of the testis and epididymis. Four to eight collecting trunks ascend in the spermatic cord and accompany the testicular vessels on psoas major, ending in the lateral aortic and pre-aortic nodes.

Innervation

Testicular nerves accompany the testicular vessels and are derived from the tenth and eleventh thoracic spinal segments via the renal and aortic autonomic plexuses. Catecholaminergic nerve fibres form plexuses around smaller blood vessels and among the interstitial cells in the testis and epididymis.

Microstructure

The surface of the testis is covered closely by the visceral tunica vaginalis, a layer of flat mesothelial cells similar to, and continuous with, the peritoneal lining. The visceral layer is separated from the parietal tunica vaginalis (the outer layer of the double fold of peritoneum that accompanies the descending testis (see p. 1320)), by a potential space containing serous fluid, which acts as a lubricant and allows movement of the testis within the scrotum. The testicular capsule proper, the tunica albuginea, is tough and collagenous and thickened posteriorly as the mediastinum testis. Beneath the tunica albuginea is a thin layer of connective tissue containing the superficial blood vessels. Blood vessels, lymphatics and the genital ducts enter or leave the body of the testis at the mediastinum (Fig. 76.8).

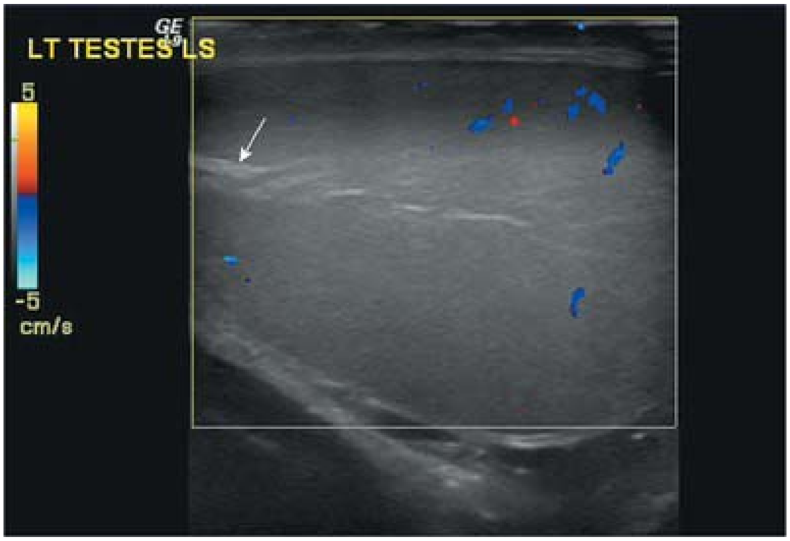

Fig. 76.8 Colour Doppler scan of the scrotal contents showing normal flow. The linear echogenic band (arrow) seen centrally represents the mediastinum testis composed of fibrofatty material.

Septa from the mediastinum extend internally to partition the testis into approximately 250 lobules (Fig. 76.5A). These differ in size, and are largest and longest in the centre. Each lobule contains one to four convoluted seminiferous tubules, much-coiled loops whose free ends both open into channels (the rete testis) within the mediastinum. The loose connective tissue between seminiferous tubules contains several layers of contractile peritubular myoid cells and clusters of androgen-producing interstitial (Leydig) cells.

There are 400–600 seminiferous tubules in each testis, each 70–80 cm long and 0.12–0.3 mm. in diameter. They are pale in early life, but in old age they contain much fat and are deep yellow. Each tubule is surrounded by a basal lamina, on which rests a complex, stratified seminiferous epithelium containing spermatogenic cells and supportive Sertoli cells (Fig. 76.9A). When active, the spermatogenic cells include basally situated spermatogonia and their progeny in the adluminal compartment, spermatocytes, spermatids and mature spermatozoa. Among the spermatids may be residual bodies, spherical structures derived from surplus spermatid cytoplasm shed during maturation and phagocytosed by Sertoli cells.

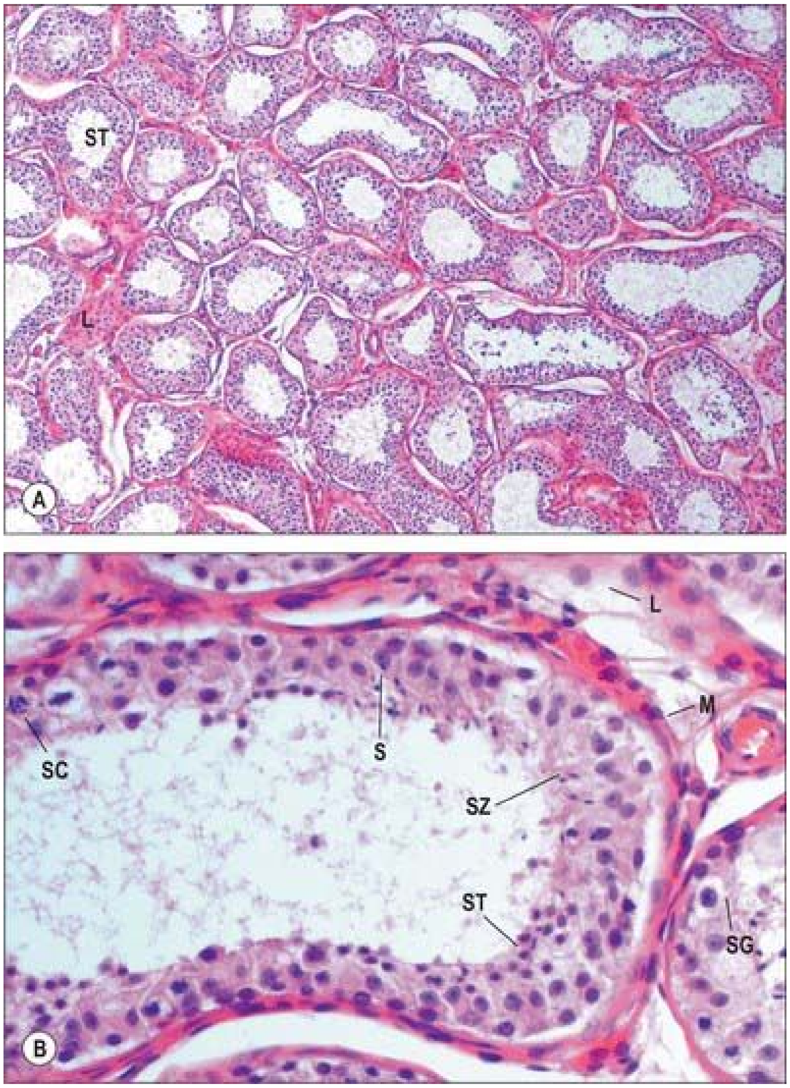

Fig. 76.9 **A**, Seminiferous tubules (ST; cut in various planes of section), and the interstitial tissue (Leydig cells, L) of the testis. The seminiferous tubules are highly convoluted and lined by a stratified epithelium which consists of cells in various stages of spermatogenesis and spermiogenesis (collectively referred to as the spermatogenic series). Non-spermatogenic cells are the Sertoli cells. **B**, Human seminiferous tubule showing the differentiation sequence of spermatozoa from basally situated spermatogonia (SG). Large primary spermatocytes (SC) have characteristic threadlike chromatin in various stages of prophase of the first meiotic division. Smaller haploid spermatids (ST) have round nuclei initially, but mature to possess the dense, elongated nuclei and flagellae of spermatozoa (SZ). Sertoli cells (S) are identified from their oval or pear-shaped nuclei

orientated perpendicular to the basal lamina, and prominent nucleoli. The tubule is surrounded by peritubular myoid cells (M). Clusters of large endocrine Leydig cells (L) are seen in the interstitial connective tissue.

Spermatogonia

Spermatogonia, the stem cells for all spermatozoa, are descended from primordial germ cells which migrate into the genital cords of the developing testis (Fig. 76.9B). In the fully differentiated testis they are located along the basal laminae of the seminiferous tubules. Several types of spermatogonia are recognized on the basis of cell and nuclear dimensions, distribution of nuclear chromatin (dark, condensed or pale, euchromatic) and histochemical and ultrastructural data. The three basic groups of spermatogonia are dark type A (Ad), pale type A (Ap), and type B. Ad cells divide mitotically to maintain the population of spermatogonia which, before puberty, is small but increases under androgenic stimulation. Some divisions give rise to Ap cells which also divide mitotically but remain linked in clusters by fine cytoplasmic bridges. These are the precursors of type B cells, which are committed to the spermatogenic sequence. At about the time that type B cells enter a final round of DNA synthesis, without undergoing cytokinesis, they leave the basal compartment and cross the blood–testis barrier to enter meiotic prophase as primary spermatocytes. These coordinated processes are under the control of Sertoli cells.

Primary and secondary spermatocytes

Primary spermatocytes have a diploid chromosome number but duplicated sister chromatids (DNA content is thus 4N, where N is the DNA content of haploid spermatozoa), and are all at some stage of a long meiotic prophase (p. 22) of approximately 3 weeks. Primary spermatocytes are large cells with large round nuclei in which the nuclear chromatin is condensed into dark, threadlike, coiled chromatids at different stages in the process of crossing over and genetic exchange between chromatids of maternal and paternal homologues. These cells give rise to secondary spermatocytes with a haploid chromosome complement (but 2N DNA content), the reduction division is designated as meiosis I. Few secondary spermatocytes are seen in tissue sections because they rapidly undergo the second meiotic (equatorial) division, where sister chromatids separate (DNA content now being N), to form haploid spermatids. Theoretically each primary spermatocyte produces four spermatids, but some degenerate during maturation so that the yield is lower.

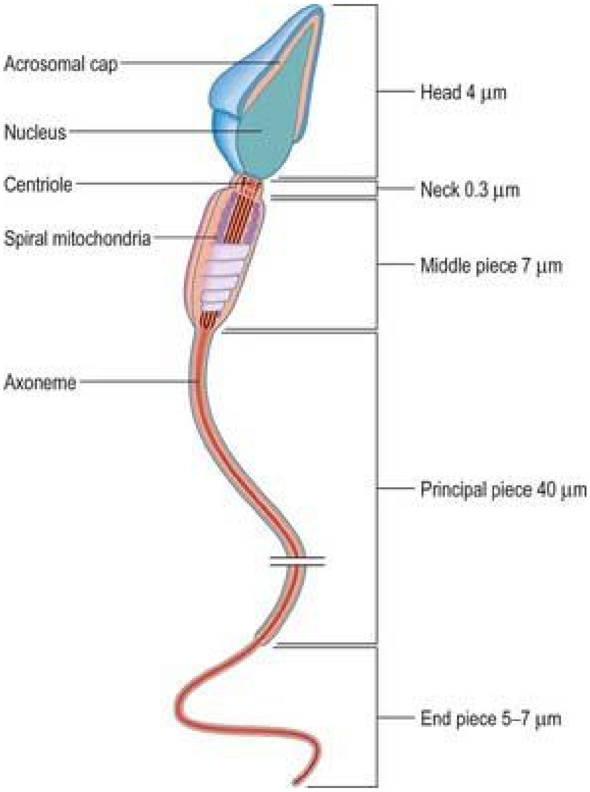
Spermatids

Spermatids do not divide again but gradually mature into spermatozoa by a series of nuclear and cytoplasmic changes known as spermiogenesis. All of these maturational changes take place while the spermatids remain closely associated with Sertoli cells and linked by cytoplasmic bridges with each other. The first phase of spermiogenesis is the Golgi phase, when hydrolytic enzymes accumulate in Golgi vesicles that subsequently coalesce into a single large acrosomal vesicle close to the nucleus. The pair of centrioles migrates to the opposite posterior pole. The distal centriole begins to generate the axoneme, a circular arrangement of nine microtubule doublets surrounding a central pair. In the cap phase, the acrosomal vesicle flattens and envelops the anterior half of the nucleus to form an acrosomal cap which comes to occupy the presumptive anterior pole of the spermatozoon, furthest from the lumen of the tubule.

During the acrosome phase, nuclear chromatin condenses and the nucleus elongates into a spearhead shape. The anterior cytoplasmic volume is considerably reduced, so that the wall of the acrosomal vesicle is brought into contact with the plasma membrane. A perinuclear sheath of microtubules develops from the posterior edge of the acrosome to form the manchette, which extends towards the posterior pole. The axonemal complex continues to extend into the developing tail region, which now protrudes into the tubule lumen. The neck region forms at the posterior pole of the nucleus: it contains the centrioles. Mitochondria migrate through the neck region and along the axoneme into the developing middle piece. Here, they assemble into a helical sheath and surround a ring of nine coarse fibres forming along the length of the axonemal complex in the developing tail. In the final phase of maturation, excess cytoplasm is detached as a residual body that is phagocytosed and degraded by Sertoli cells. During the formation of residual bodies, spermatids lose their cytoplasmic bridges and separate from each other before being released into their tubule.

Spermatozoa

A spermatozoon that is released from the wall of the seminiferous tubule into the lumen is non-motile but structurally mature. Its expanded head contains little cytoplasm and is connected by a short constricted neck to the tail. The tail is a complex flagellum, divided into middle, principal and end pieces, that greatly exceeds the head region in volume. The head has a maximum length of approximately 4 μm and a maximum diameter of 3 μm. It contains an elongated, flattened nucleus with condensed, deeply staining chromatin, and is covered anteriorly by an acrosomal cap. The latter contains acid phosphatase, hyaluronidase, neuraminidase and proteases necessary for fertilization (see p. 168). The neck is approximately 0.3 μm long. In its centre is a well-formed centriole that corresponds to the proximal centriole of the spermatid from which it differentiated. The axonemal complex is derived from the distal centriole. A small amount of cytoplasm exists in the neck, covered by a plasma membrane continuous with that of the head and tail (Fig. 76.10).



Acrosomal cap
Nucleus
Centriole
Spiral mitochondria
Axoneme
Head 4 µm
Neck 0.3 µm
Middle piece 7 µm
Principal piece 40 µm
End piece 5–7 µm

Fig. 76.10 The main ultrastructural features of a mature spermatozoon.

The middle piece of the tail is a long cylinder, approximately 1 µm in diameter and 7 µm long. It consists of an axial bundle of microtubules, the axoneme, outside which is a cylinder of nine dense outer fibres surrounded by a helical mitochondrial sheath. At the caudal end of the middle piece is an electron-dense body, the anulus. The principal piece of the tail becomes the motile part of the cell. It is approximately 40 µm long and 0.5 µm in diameter and forms the majority of the spermatozoon. The axoneme and the surrounding dense fibres are continuous from the neck region through the whole length of the tail except for its terminal 5–7 µm, in which the axoneme alone persists. The tail therefore has the typical structure of a flagellum, with a simple nine plus two arrangement of microtubules, in the terminal portion of the end piece.

Sertoli cells

Sertoli cells form a major cellular component of the tubule before puberty, and in the elderly. They are the supporting, non-spermatogenic cells of the seminiferous tubules. Variable in overall cell shape, they all contact the basal lamina and their cytoplasm extends to the tubule lumen where their apical plasma membranes form complex recesses which envelop spermatids and spermatozoa until the latter are mature enough for release. Long cytoplasmic processes also extend between the spermatogonia in the basal compartment and spermatocytes in the adluminal compartment of the tubule. Adjacent Sertoli cell processes are joined at this level by tight junctions, creating a diffusion barrier between the extratubular and intratubular compartments. This is the blood–testis barrier which, if breached by traumatic or inflammatory events, can allow immune responses to develop against sperm antigens, resulting in subfertility.

The Sertoli cell nucleus is euchromatic and irregular or pear-shaped, contains one or two prominent nucleoli, and is usually aligned perpendicular to the basal lamina. The cytoplasm is rich in lysosomes, consistent with its phagocytic phenotype. Sertoli cells provide trophic support for the surrounding germ cells, secrete androgen-binding protein and play an important role in controlling spermatocyte and spermatid differentiation and maturation. The proteinaceous fluid they secrete into the tubule lumen provides nutrients and facilitates the transport of spermatozoa into the excurrent duct system. Sertoli cells change considerably during the spermatogenic cycle and respond to the hypophysial hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). They also produce a hormonal substance, inhibin B, which is thought to be involved in local paracrine functions.

Spermatogenic cycle

At any locus in a seminiferous tubule, generation of germ cells occurs in a cycle with a periodicity of approximately 16 days. Stages in the cycle are characterized by the presence of different combinations of cells within the spermatogenic sequence. The generation of a mature spermatozoon from a spermatogonium takes four such cycles, or approximately 64 days. In cross-section, the seminiferous tubule shows more than one phase of the cycle around its circumference, because waves of progression through a spermatogenic cycle occur in spirals down the length of the tubule.

Testicular interstitial tissue

The tissues between the seminiferous tubules include various connective tissue components, peritubular myoid cells, vessels and nerves. The myoid cells are contractile: their rhythmic activity may propel non-motile spermatozoa through the tubule towards the rete testis and excurrent ductal system. Clusters of Leydig cells lie between the tubules. These large, polyhedral cells have eccentric nuclei with one to three nucleoli and pale staining cytoplasm containing a considerable amount of smooth endoplasmic reticulum, lipid droplets and unique needle-shaped crystalloid inclusions up to 20 μm long (crystals of Reinke), of unknown function. Leydig cells synthesize and secrete androgens and are stimulated by LH and by prolactin, which induces expression of the LH receptor. Their activity varies with age: they are active in fetal life in the development of the genital tract, but decline in function postpartum until the onset of puberty.

Age-related changes in the testis

Functionally, the fetal testis is predominantly an endocrine gland that produces testosterone and the anti-Müllerian hormone, a specifically fetal gonadal hormone. These two hormones play crucial roles in the induction and regulation of male sexual differentiation. Postnatally the testis gradually changes its role, but retains the ability to manufacture testosterone and other regulatory materials, e.g. the peptide hormone oxytocin, that act in either an endocrine or a paracrine fashion.

The seminiferous tubules do not become canalized until approximately the seventh month of gestation, although this may occur later. At puberty, the testis becomes primarily a source of spermatozoa. The fetal Leydig cells, responsible for the androgen-induced differentiation of the male genitalia, degenerate after birth, and are replaced, during puberty, by an adult population of androgen-producing cells that persist throughout adult life. The testes grow slowly until the age of 10 or 11 years, at which time there is a marked acceleration of growth rate, and spermatogenesis begins.

There is no definite age for the onset of the progressive testicular involution associated with advancing age. Testicular size, sperm quality and quantity, and the numbers of Sertoli cells and Leydig cells, have all been reported to decrease in the elderly. Leydig cell activity is driven by LH. The decrease in Leydig cell function in the elderly, as part of what has been described as the normal ageing process, may be affected by changes in the secretion of LH, which is controlled by the hypothalamus. The volume occupied by the seminiferous tubules decreases, whereas that occupied by interstitial tissue remains approximately constant. The most frequently observed histological change in the ageing testis is variation in spermatogenesis in different seminiferous tubules: it is complete, though reduced, in some, but absent in others, when sclerosis may occur. In tubules where spermatogenesis is complete, morphological abnormalities, e.g. multinucleation, may be observed in the germ cells.

Germ cell loss generally begins with the spermatids, but progressively affects the earlier germ cell types, i.e. the spermatocytes and spermatogonia. Sertoli cells are also affected by ageing, and show a range of morphological changes including dedifferentiation, mitochondrial metaplasia and multinucleation. In the Leydig cells, the quantity of smooth endoplasmic reticulum and mitochondria decrease, and lipid droplets, crystalline inclusions and residual bodies increase; some cells become multinucleate. Tubules in which the entire epithelium has been lost have been observed in testes where other tubules appeared normal. The development of tubular involution with advancing age is similar to that observed after experimental ischaemia, suggesting that vascular lesions may be involved in age-related testicular atrophy. However, there is no abrupt change in testicular function equivalent to the female climacteric.

Undescended testis

In the early fetal period the testes are located posteriorly in the abdominal cavity. Their descent to the scrotum appears to be under hormonal control (gonadotropins and androgens) (see p. 1320). Testicular descent may be arrested at any point along its route into the scrotum: a clinically undescended testis may be in the abdomen, at the deep inguinal ring, in the inguinal canal, or between the superficial inguinal ring and the scrotum. Occasionally, the testis may lie outside its normal path of descent and is termed an ectopic testis.

A unilateral undescended testis is present in 3% of boys at birth and 1% of boys by 3 months of age. Bilateral maldescent is seen in just over 1% of male births. Undescended testes can be associated with a higher risk of infertility and testicular tumours. There is evidence that surgical correction of an undescended testis at any age may not improve its spermatogenesis. Impairment of fertility can be seen in men with both bilateral and unilateral undescended testis. Leydig cell function is not usually affected by maldescent, so androgen production usually remains within the normal range. Patients with an undescended testis are at increased risk of developing testicular tumours, particularly seminoma. The risk is highest in abdominal testes. Surgery may not reduce the risk of tumour development, but maximizes the chance of early detection of any tumour. An undescended testis can usually be found by ultrasonography if it is in or close to the inguinal canal. Laparoscopy is more reliable in the pelvis. Magnetic resonance imaging may help localizing testis not seen on ultrasound. Retention in the inguinal canal is often complicated by congenital hernia, because the processus vaginalis remains patent. The testis may traverse the canal but reach an abnormal site.

Obliterated part of the processus vaginalis

The obliterated part of the processus vaginalis is often seen as a fibrous thread in the anterior part of the spermatic cord, extending from the internal end of the inguinal canal – where it is connected to the peritoneum – as far as the tunica vaginalis. Sometimes it disappears within the cord. However, its proximal part may remain patent, so that the peritoneal cavity communicates with the tunica vaginalis, or the proximal processus may persist, although it may be shut off distally from the tunica. Occasionally its cavity may persist at an intermediate level as a cyst. When patent, its cavity may admit a loop of intestine, to form an indirect inguinal hernia. The processus is usually obliterated by 18 months of age.

Hydrocele, spermatocele, epididymal cyst

In congenital hydrocele the fluid is in the tunical sac, which communicates with the peritoneal cavity through a non-obliterated processus vaginalis. Infantile hydrocele occurs when the processus is obliterated only at or near the deep inguinal ring. It resembles vaginal hydrocele, but fluid extends up the cord into the inguinal canal. If the processus is obliterated at both the deep inguinal ring and above the epididymis, leaving a central open part, this may distend as an encysted hydrocele of the cord. A spermatocele is a cyst related to the caput epididymis: it may contain spermatozoa and it is probably a retention cyst of one of the seminiferous tubules. Removal is usually unnecessary and may result in epididymal obstruction. The same applies to a simple epididymal cyst, which may have a similar aetiology to a spermatocele but remains free of sperm.

Testicular and epididymal appendices

At the upper extremities of the testis and epididymis are two small, stalked bodies, the appendix testis and appendix epididymis (Fig. 76.5A,B). They are developmental remnants of the paramesonephric (Müllerian) duct and the mesonephros, respectively. They may undergo torsion and produce symptoms that are difficult to differentiate from testicular torsion.

Testicular torsion

The testis and epididymis are usually fixed to their surrounding tissues. In some patients this fixation may be insufficient, so that the structures are able to twist within the tunica vaginalis. This is termed testicular torsion and normally results in severe scrotal pain, which is a surgical emergency.

Torsion produces an initial venous infarction followed by arterial occlusion: histopathological changes leading to gangrene occur in the testis if the twist is not reversed within 4–6 hours. Fertility may be affected by an episode of torsion. Other structures may also twist within the scrotum, e.g. the testicular appendix (otherwise termed the hydatid of Morgagni) and the appendix epididymis: torsion of these structures may also result in scrotal pain.

Male sub-fertility

Approximately one in seven couples will find difficulty in conceiving. In approximately 10% of couples the cause for their sub-fertility will be unknown: in 50% of couples, the reason will be due to male factors. A seminal analysis may demonstrate a spectrum of abnormalities from complete absence of sperm in the ejaculate (azoospermia) to too few sperm (oligozoospermia).

The causes of azoospermia are extensive but broadly can be classified into obstructive causes (rare) or testicular failure. Occasionally spermatogenesis may be arrested at a specific point in development, a condition known as maturation arrest.

Testicular failure is usually testicular in origin. It may have an underlying genetic aetiology, or may occur secondary to damage to the testis such as occurs following radiation therapy, torsion, trauma to the testis or undescended testis. Testicular failure resulting from these conditions may be associated with an increase in pituitary FSH and LH (hypergonadotrophic hypogonadism). Rarely, testicular failure may be the result of pituitary or hypothalamic damage leading to hypogonadotrophic hypogonadism. Histopathologically, testicular failure may be characterized by a spectrum of histopathological findings from Sertoli-cell-only syndrome (see Fig. 76.12) to varying degrees of hypospermatogenesis. Testicular sperm can be extracted from some men and injected into their partners’ eggs, a process known as intra-cytoplasmic sperm injection (ICSI).

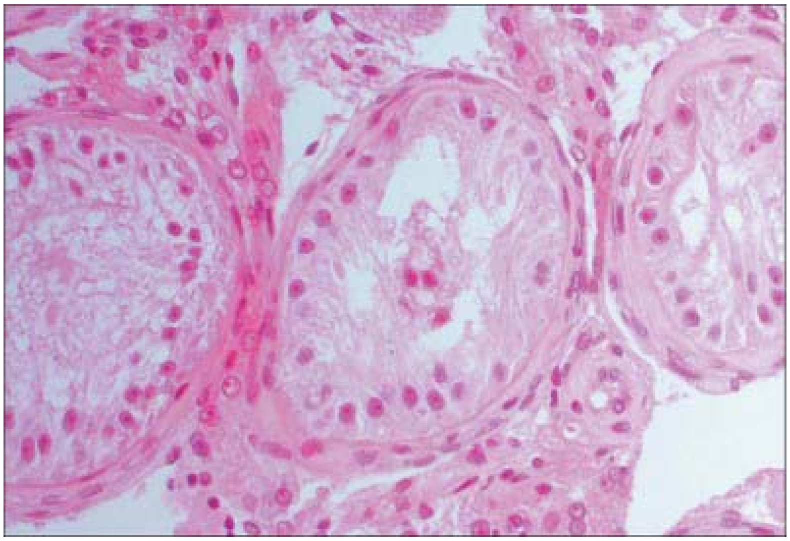


Fig. 76.12 Testis biopsy from a patient with azoospermia demonstrating Sertoli-cell-only syndrome. Only the Sertoli cells are present: this condition may also be caused by a deletion on the Y chromosome.

EPIDIDYMIS

The epididymis lies posteriorly and slightly lateral to the testis, and the vas deferens lies along its medial side (Fig. 76.5A,B). It has an expanded head or globus major superiorly, a body (corpus) and a tail (cauda or globus minor). The epididymis is invested by tunica vaginalis, somewhat less closely applied than it is to the testis, except at its posterior margin. Laterally there is a deep groove, the sinus epididymis, between the epididymis and the testis. The vas deferens ascends from the tail of the epididymis to the deep inguinal ring, lying within the spermatic cord (see below).

Microstructure

Spermatogenesis occurs in the highly coiled parts of the seminiferous tubules. As the latter reach the apical part of the lobule towards the mediastinum they become much less convoluted and form the short tubuli recti, lined by cuboidal epithelium that lacks spermatogenic cells. Tubuli recti enter the fibrous tissue of the mediastinum testis as a close network of anastomosing tubes, the rete testis, lined by a flat epithelium. At the upper pole of the mediastinum, 12–20 efferent ductules (ductuli efferentes) perforate the tunica albuginea and leave the testis for the epididymis. The efferent ductules are lined by a ciliated columnar epithelium that also contains shorter, actively endocytic, non-ciliated cells. External to the epithelium, the ductules are surrounded by a thin circular coat of smooth muscle (Fig. 76.11).

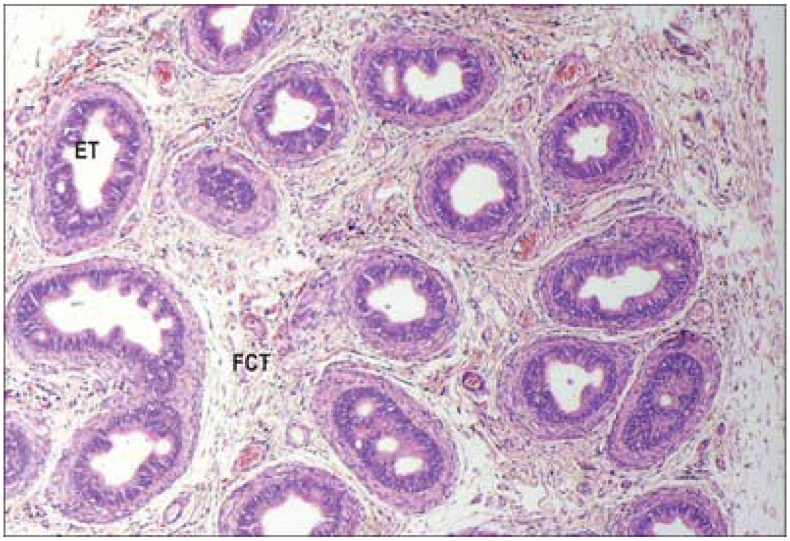

Fig. 76.11 Microstructure of the epididymis. ET, epididymal tubule; FCT, fibromuscular connective tissue.

Initially the ductules are straight. They become enlarged and very convoluted, forming the conical lobules of the epididymis that make up its head. Each lobular duct, 15–20 cm in length, opens into the single duct of the epididymis, whose coils form the epididymal body and tail. When the coils are unravelled, the tube measures more than 6 metres, increasing in thickness as it approaches the epididymal tail, where it becomes the vas deferens. The coils are held together by bands of fibrous connective tissue. In the epididymal duct the muscle is thicker and the epithelium is composed of columnar pseudostratified cells. The muscle undergoes peristaltic contractions to propel spermatozoa towards the tail region, where they are stored.

Epithelium

The epithelium contains two main cell types, principal and basal cells, and the less common apical and clear cells. Principal cells are tall columnar cells with basally located, elongated, oval nuclei. They bear long (15 µm) regular apical microvilli termed stereocilia, so named because they were once thought to be immotile cilia. These cells resorb fluid from the testicular secretions: approximately 90% of the total is absorbed in the epididymis.

They also secrete glycoproteins essential for the maturation of spermatozoa and endocytose various other components of the seminal fluid. Basal cells lie between the bases of the principal cells and are thought to be the precursors of principal cells. Apical cells have numerous mitochondria and are most abundant in the head of the epididymis. Clear cells are columnar cells, most numerous in the tail region, and have few microvilli but numerous endocytic vesicles and lipid droplets: their functions are unknown.

VAS DEFERENS, PARADIDYMIS AND EJACULATORY DUCT

VAS DEFERENS

The vas deferens is the distal continuation of the epididymis, starting as a muscular tube at the epididymal tail. It is 45 cm long and conveys sperm to the ejaculatory ducts (Fig. 76.5A,B). Initially very tortuous, the convoluted portion of the vas becomes straighter as it ascends along the posterior aspect of the testis, medial to the epididymis. From the superior pole of the testis it ascends in the posterior part of the spermatic cord, and traverses the inguinal canal. At the deep inguinal ring the vas deferens leaves the cord, curves round the lateral side of the inferior epigastric artery and ascends for approximately 2.5 cm anterior to the external iliac artery. It then turns back and inclines slightly down and obliquely across the external iliac vessels to enter the lesser pelvis. In the pelvis it is situated retroperitoneally, coursing posteriorly and medially to the obliterated umbilical artery, the obturator nerve and vessels, and the vesical vessels. It crosses the ureter and bends acutely to pass anteromedially between the posterior surface of the bladder and the upper pole of the seminal vesicle. It then descends in contact with the seminal vesicle, gradually approaching the opposite duct, lying between the base of the bladder and the rectum, from which it is separated by Denonvillier's fascia. At the base of the prostate, the vas deferens joins the duct of the seminal vesicle at an acute angle to form the ejaculatory duct. It feels cord-like when grasped because of its thick wall and small lumen. Posterior to the bladder the lumen becomes dilated and tortuous and is termed the ampulla; beyond this, where it joins the duct of the seminal vesicle, it is again greatly diminished in calibre. In men with azoospermia or no sperm in the ejaculate, testicular exploration may be undertaken to exclude an obstruction.

The vasa deferentia may be congenitally absent, a condition known as vasal aplasia. This can occur in association with cystic fibrosis: men with congenital absence of the vas deferens should be screened for cystic fibrosis mutations. This condition results in azoospermia, although spermatogenesis is usually normal.

Aberrant ductules

A narrow, blind, caudal aberrant ductule often occurs, usually connected with the caudal part of the epididymal duct or with the start of the vas deferens. Uncoiled, it varies in length from 5 to 35 cm; it may be dilated near its end, but is otherwise uniform in calibre and in structure is similar to the vas deferens. Occasionally it is not connected with the epididymis. A rostral aberrant ductule may occur in the epididymal head, connected with the rete testis. Aberrant ductules are derived from mesonephric tubules (see p. 1305).

PARADIDYMIS

The paradidymis is a small collection of convoluted tubules, found anteriorly in the spermatic cord above the epididymal head. The tubules are lined by ciliated columnar epithelium and probably represent the remains of the mesonephros (see p. 1305).

EJACULATORY DUCTS

The ejaculatory ducts are formed on each side by the union of the duct of the seminal vesicle with the ampulla of the vas deferens. Each is almost 2 cm in length, and starts from the base of the prostate, running anteroinferiorly between its median and right or left lobes. They skirt the prostatic utricle to end on the verumontanum at two slit-like orifices on, or just within, the utricular opening. The ducts diminish and converge towards their ends. Ejaculatory duct obstruction is rare and can lead to azoospermia or severe oligozoospermia: it may be caused by congenital cysts such as Müllerian duct cysts.

Vascular supply, lymphatic drainage and innervation

Each vas deferens has its own artery, usually derived from the superior vesical artery, which anastomoses with the testicular artery to supply the epididymis and testis. Veins drain from the vas deferens and seminal vesicles to the pelvic venous plexus. Lymphatic vessels drain to the external and internal iliac nodes. The vasa deferentia are innervated by a rich autonomic plexus composed mainly of sympathetic nerve fibres derived from the pelvic plexus.

Microstructure

The wall of the vas deferens has loose connective tissue externally, a thick middle muscular layer and an internal mucosal layer. The muscular layer is composed of smooth muscle fibres arranged in external longitudinal and internal circular sheets. An additional internal longitudinal layer is present at the origin of the duct where it leaves the tail of the epididymis, and all muscle layers intermingle. The mucosa is folded longitudinally and its epithelium is columnar and non-ciliated through most of the duct. Towards its distal end a pseudostratified columnar epithelium appears, the tallest cells of which bear non-motile stereocilia (elongated microvilli), similar to those of the epididymis. The connective tissue of the lamina propria contains elastic fibres (Fig. 76.13A,B).

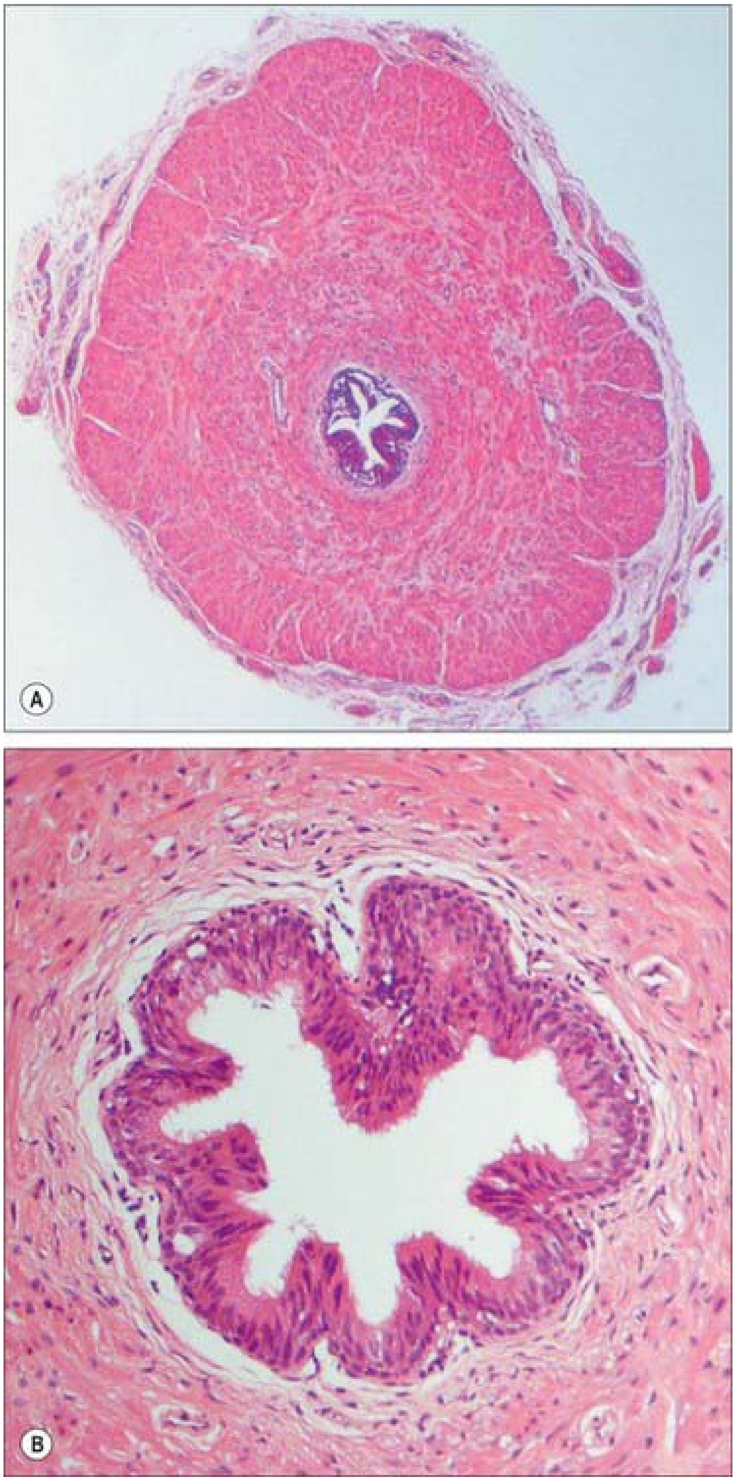

Fig. 76.13 Vas deferens. **A**, Low power view, transverse section. **B**, Higher power view. The convoluted lumen is lined by pseudostratified columnar epithelial cells.

The walls of the ejaculatory ducts are thin. They contain an outer fibrous layer, which is much reduced beyond their entrance into the prostate, a thin layer of smooth muscle fibres with an outer circular and inner longitudinal orientation, and a mucosa lined by columnar epithelium. The ducts dilate during ejaculation.

Maturation of spermatozoa

Functional maturation is a complex process. Spermatozoa show little independent motility while still in the male genital tract: when removed from the epididymis they may display circular or even forward directional movements if taken from the cauda epididymis near the beginning of the vas deferens. Apart from this immature motility, spermatozoa are largely transported through the genital tract initially by ciliary action and then by peristaltic contractions of the duct walls. Human spermatozoa do not undergo any demonstrable structural changes during their passage through the epididymis, but there is evidence of biochemical and functional modifications. Evidence from restorative surgery after vasectomy indicates that at least part of the human epididymis is essential for acquisition of mature motile activity.

ACCESSORY GLANDULAR STRUCTURES

SEMINAL VESICLES

The two seminal vesicles are sacculated, contorted tubes located between the bladder and rectum. Each vesicle is approximately 5 cm long, somewhat pyramidal, the base being directed up and posterolaterally. In essence, the seminal vesicle is a single coiled tube with irregular diverticula, the coils and diverticula being connected by fibrous tissue. The diameter of the tube is 3–4 mm and its uncoiled length is 10–15 cm. The upper pole is a cul-de-sac, the lower narrows to a straight duct which joins the vas deferens to form the ejaculatory duct. The anterior surface contacts the posterior aspect of the bladder, and extends from near the entry of the ureter to the prostatic base: the prostate is intimately located to the seminal vesicles (Fig. 76.14A,B; see Fig. 74.21). The posterior surface is related to the rectum, from which it is separated by Denonvillier’s fascia. The seminal vesicles diverge superiorly. On each side they are related to the vas deferens and the termination of the ureter, and they are partly covered by peritoneum. Each has a dense, fibromuscular sheath. The ampulla of the vas deferens lies along the medial margin of each seminal vesicle and the veins of the prostatic venous plexus, which drain posteriorly to the internal iliac veins, lie laterally.

*(**A** from Sobotta 2006.)*

Vascular supply, lymphatic drainage and innervation

The arteries to the seminal vesicles are derived from the inferior vesical and middle rectal arteries. The veins and lymphatics accompany these arteries. The innervation of the seminal vesicles and bulbourethral glands is derived from the pelvic plexuses.

Microstructure

The paired seminal vesicles, together with the ampulla of the vas deferens and the ejaculatory ducts, form a functional unit which develops slowly until the onset of puberty. After puberty the vesicles form sac-like structures which contribute up to 85% of the seminal fluid. They are mainly concerned with secretion of seminal coagulating proteins, fructose, prostaglandins and other specific proteins in an alkaline, viscous yellowish fluid.

The wall of the seminal vesicle is composed of an external connective tissue layer, a middle smooth muscle layer (thinner than in the vas deferens and arranged in external longitudinal and internal circular layers) and an internal mucosal layer with a highly folded, labyrinthine structure (Fig. 76.15). The cuboidal to pseudostratified columnar epithelium of the mucosa shows features typical of protein-secreting cells. The vesicles are not reservoirs for spermatozoa as their name suggests, because spermatozoa are stored mainly in the epididymis. They contract during ejaculation, and their secretion forms most of the ejaculate.

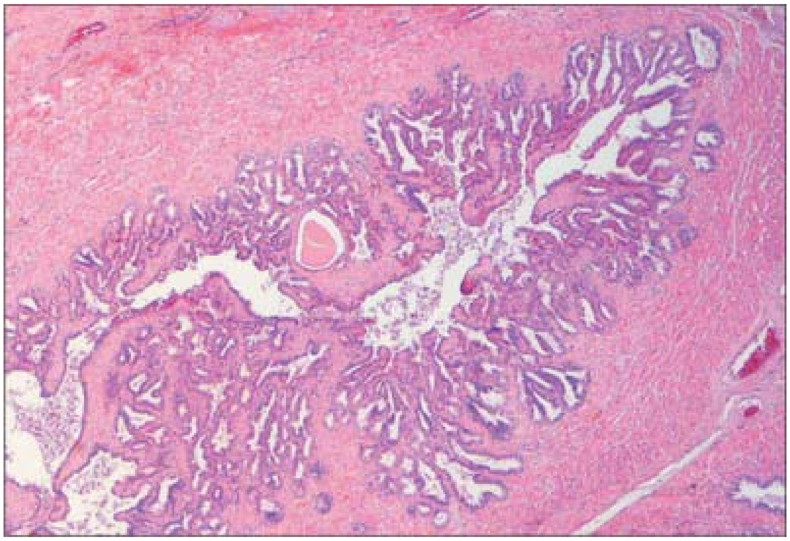

Fig. 76.15 Microstructure of the seminal vesicles showing tubulo-acinar structure.

BULBOURETHRAL GLANDS

The two bulbourethral glands are small, round, yellow, somewhat lobulated masses approximately 1 cm in diameter. They lie lateral to the membranous urethra above the perineal membrane and penile bulb and are enclosed by fibres of the urethral sphincter. The excretory duct of each, almost 3 cm long, passes obliquely forwards external to the mucosa of the membranous urethra and penetrates the perineal membrane. It opens by a minute orifice on the floor of the bulbar urethra, approximately 2.5 cm below the perineal membrane. In later decades the glands generally diminish in size.

Microstructure

Each bulbourethral gland consists of several lobules held together by a fibrous capsule. The secretory units are mainly tubulo-alveolar in form. The glandular epithelium is columnar and secretes acid and neutral mucins into the penile (spongiose) urethra prior to ejaculation: these have a lubricating function. The main secretory duct is lined by a stratified columnar epithelium. Diffuse mucosa-associated lymphoid tissue (MALT) is associated with the glands.

PENIS

The penis consists of an attached root (radix) in the perineum and a free, pendulous, body (corpus), which is completely enveloped in skin.

Skin

The penile skin is thin and loosely connected to the tunica albuginea. At the corona of the penis it is folded to form the prepuce or foreskin, which invariably overlaps the glans. The internal preputial layer is confluent at the neck with the thin skin covering and adhering firmly to the glans, and by this with the urethral mucosa at the external urethral orifice. On the urethral aspect of the glans a median fold, the frenulum, passes from the deep surface of the prepuce to the glans immediately proximal to the orifice. Cutaneous sensitivity is greatest over the glans penis. The prepuce and glans penis enclose a potential cleft, the preputial sac, and two shallow fossae flank the frenulum (Fig. 76.16).

(From Drake, Vogl and Mitchell 2005.)

Root

The root of the penis consists of three masses of erectile tissue in the urogenital triangle, namely the two crura and the bulb, which are firmly attached to the pubic arch and perineal membrane respectively. The crura are the posterior extremities of the corpora cavernosa, and the bulb is the dilated posterior end of the corpus spongiosum.

Each penile crus starts behind as a blunt, elongated but rounded structure, attached firmly to the everted edge of the ischiopubic ramus and covered by ischiocavernosus (Fig. 76.17). Anteriorly it converges towards the contra-lateral crus and is slightly enlarged posterior to this. Near the inferior symphysial border the two crura come together and continue as the corpora cavernosa of the body of the penis.

*(**A** and **B** from Drake, Vogl and Mitchell 2005; **C** adapted from Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)*

The bulb of the penis lies between the crura and is firmly connected to the inferior aspect of the perineal membrane, from which it receives a fibrous covering (Figs 76.16D, 76.17). Oval in section, the bulb narrows anteriorly into the corpus spongiosum, down and forwards at this point. Its convex superficial surface is covered by bulbospongiosus and its flattened deep surface is pierced above its centre by the urethra, which traverses it to reach the corpus spongiosum.

Body

The main body of the penis consists of three masses of erectile tissue, the right and left corpora cavernosa, and the median corpus spongiosum, which are continuations of the crura and bulb of the penis respectively (Figs 76.17A, 76.18A,B). They become engorged with blood during penile erection (Fig. 76.19A). The penis is cylindrical when flaccid, but becomes triangular when erect. The surface which is posterosuperior during erection is termed the dorsum of the penis and the opposite aspect is the ventral surface.

Corpora cavernosa

The corpora cavernosa form most of the body of the penis. They share a common fibrous envelope, the tunica albuginea, and are in close apposition throughout their length, although separated by a median fibrous septum. On the urethral surface their combined mass has a wide median groove that adjoins the corpus spongiosum (Figs 76.17-76.19); dorsally a similar but narrower groove contains the dorsal neurovascular bundle. The corpora end distally within the proximal aspect of the glans penis in a rounded cone, in which each has a small terminal projection (Fig. 76.16D).

The strong fibrous tunica albuginea consists of superficial and deep strata. The superficial fibres run longitudinally, forming a single tube that surrounds both corpora, whereas the deep fibres are circularly arranged and surround each corpus separately. The deep fibres join to form the median septum of the penis. This is thick and complete proximally, so that the corporal bodies can be separated proximally for 5–7 cm. Distally the median septum consists of a pectiniform (comb-like) series of bands, the pectiniform septum, which is incomplete and allows cross-circulation of blood between the two corpora.

Corpus spongiosum

The corpus spongiosum of the penis is traversed by the urethra (Figs 76.17A, 76.18B, 76.19). It adjoins the median groove on the urethral surface of the conjoined corpora cavernosa. It is cylindrical, tapering slightly distally, and surrounded by a tunica albuginea. Near the end of the penis it expands into the glans penis which projects dorsally over the end of the corpora cavernosa and has a shallow concave surface to which they are attached. The corona glandis projects from its base, overhanging an obliquely grooved neck of the penis. Numerous small preputial glands on the corona glandis and penile neck secrete sebaceous smegma. The navicular fossa of the urethra is in the glans and opens by a sagittal slit on or near its apex.

Superficial penile fascia

The superficial penile fascia is devoid of fat, and consists of loose connective tissue invaded by fibres of the dartos muscle from the scrotum. Clinically, it is commonly referred to as the dartos layer. As in the suprapubic abdominal wall, the deepest layer is condensed to form a distinct tough fascial sheath, Buck’s fascia (Fig. 76.18B). It surrounds both corpora cavernosa and splits to enclose the corpus spongiosum, separating the superficial and deep dorsal veins. At the penile neck it blends with the fibrous covering of all three corpora. Proximally, it is continuous with the dartos muscle and with the fascia covering the urogenital region of the perineum (see p. 1094).

Suspensory ligaments of penis

The body of the penis is supported by two ligaments, the fundiform and triangular ligaments, which are continuous with its fascia and consist largely of elastin fibres (Fig. 76.17B). The fundiform ligament stems from the lowest part of the linea alba and splits into two lamellae which skirt the penis and unite below with the scrotal septum. The triangular suspensory ligament, deep to the fundiform ligament, is attached above to the front of the pubic symphysis and blends below with the fascia penis on each side. Damage to the suspensory ligament may occur after trauma and results in ventral angulation of the body of the penis.

Vascular supply and lymphatic drainage

Perineal artery

The perineal artery (Fig. 76.20) leaves the internal pudendal artery near the anterior end of its canal and approaches the scrotum in the superficial perineal region, between bulbospongiosus and ischiocavernosus. Beyond the perineal membrane, and near its base, a small transverse branch passes medially, inferior to the superficial transverse perineal muscle, to anastomose with its contralateral fellow and with the posterior scrotal and inferior rectal arteries; collectively these vessels supply tissues between the anus and the penile bulb. The posterior scrotal arteries, distributed to the scrotal skin, dartos and perineal muscles, are usually terminal branches of the perineal artery but may also arise from its transverse branch.

(From Sobotta 2006.)

Artery of the bulb of the penis

The artery of the bulb of the penis is short but wide, and runs medially through the deep transverse perineal muscle to the penile bulb, which it penetrates (Fig. 76.20). It supplies the corpus spongiosum and the bulbourethral gland.

Cavernosal artery (deep artery of the penis)

The cavernosal artery is a terminal branch of the internal pudendal artery (Fig. 76.20). It passes through the perineal membrane, enters the crus penis on each side and runs the length of the corpus cavernosum, supplying the erectile tissue. Within the corpus, the cavernosal arteries divide into branches that either end directly in capillary networks which open into the cavernous spaces, or become convoluted and somewhat dilated helicine arteries, which also open into the cavernous spaces. Helicine arteries are most abundant in the posterior regions of the corpora cavernosa.

Dorsal artery of the penis

The dorsal artery of the penis is the other terminal branch of the internal pudendal artery (Figs 76.20, 76.21). It runs between the crus penis and pubic symphysis, and then pierces the suspensory ligament of the penis to run along its dorsum to the glans, where it forks into branches to the glans and prepuce. In the penis it lies deep to Buck’s fascia between the dorsal nerves and the deep dorsal vein, the latter being most medial. It supplies penile skin by branches that run through the dartos layer. It gives off circumflex branches that run laterally across the shaft of the penis, first deep to and then within Buck’s fascia, to supply the tunica albuginea of the corpus cavernosum, anastomosing through the tunica with the cavernosal system; these branches also supply the corpus spongiosum.

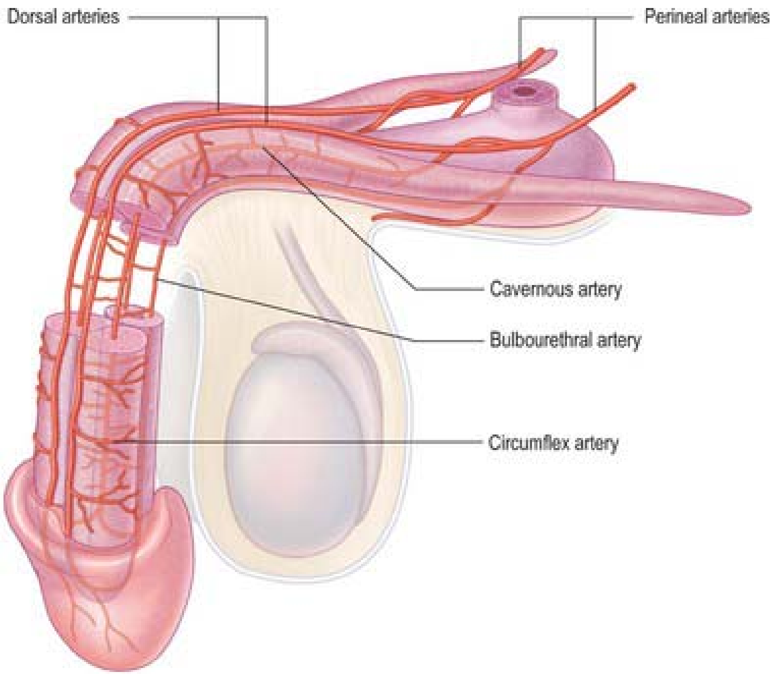

Fig. 76.21 Arterial blood supply to the body of the penis.

Dorsal veins of the penis

The veins that drain the corpora cavernosa leave the corpora by passing obliquely through the tunica albuginea via a series of small vessels called sub-tunical veins. These drain into the circumflex veins (Fig. 76.22) which run circumferentially around the shaft of the penis from its ventral aspect, where they receive tributaries from the corpus spongiosum, to its dorsal aspect, where they drain into the deep dorsal vein. The dorsal veins, superficial and deep, are unpaired. The superficial dorsal vein drains the prepuce and penile skin: it runs back in subcutaneous tissue and inclines either right or left before it opens into one of the external pudendal veins. The deep dorsal vein lies deep to Buck's fascia. It receives blood from the glans penis and corpora cavernosa penis, and courses back in the midline between the paired dorsal arteries. Near the root of the penis it passes deep to the suspensory ligament and through a gap between the arcuate pubic ligament and anterior margin of the perineal membrane. It divides into right and left branches that connect below the symphysis pubis with the internal pudendal veins and ultimately enter the prostatic plexus.

Peri-prostatic venous plexus

Fig. 76.22 Perineal vessels.

(Adapted from Drake, Vogl and Mitchell 2005.)

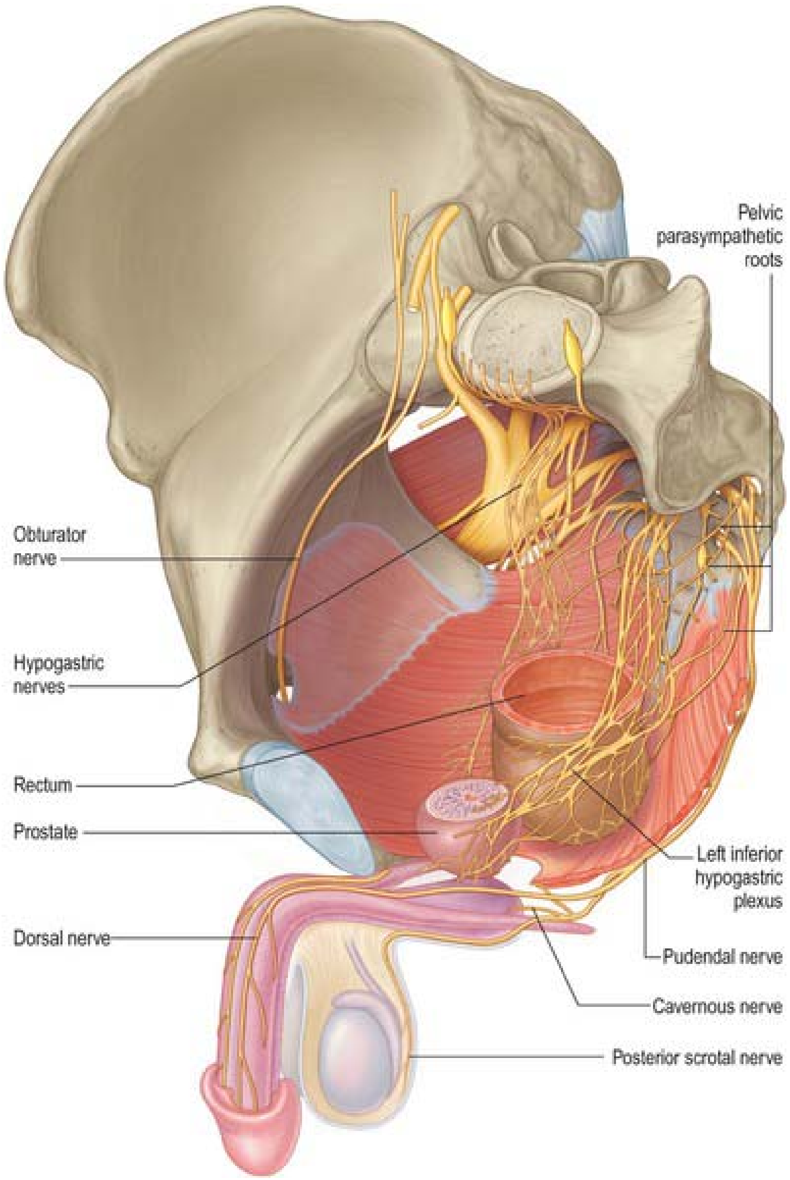
Lymphatic drainage

The penile and perineal skin is drained by lymph vessels that accompany the external pudendal blood vessels to the superficial inguinal nodes. Lymph vessels from the glans pass to the deep inguinal and external iliac nodes.

Lymph vessels from the erectile tissue and penile urethra pass to the internal iliac lymph nodes.

Innervation

The nerves to the corpora cavernosa mainly consist of the cavernous nerves, which arise from the pelvic plexus and contain both sympathetic and parasympathetic components (Fig. 76.23). The cavernous nerves pierce the fibrous penile sheath proximally to supply the erectile tissue of the corpus spongiosum and penile urethra. During their course they run postero-laterally to the apex of the prostate. The sympathetic supply to the male genital organs is derived from spinal cord segments T11–L2: stimulation produces vasoconstriction, contraction of the seminal vesicles and prostate, and seminal emission. Parasympathetic fibres are derived from spinal cord segments S2–4 via the pelvic plexuses: stimulation produces vasodilatation.



Pelvic parasympathetic roots
Obturator nerve

Posterior scrotal nerve

Fig. 76.23 The nerve supply to the penis. The corpus cavernosum of penis receives both a parasympathetic and sympathetic innervation from the cavernous nerves. The afferent fibres from the glans pass via the dorsal nerves of the penis and via the pudendal nerve.

(Adapted from Drake, Vogl and Mitchell 2005.)

The main sensory nerve of the penis is the dorsal nerve of the penis. On the glans and bulb of the penis some cutaneous filaments innervate lamellated corpuscles. Afferent fibres from the glans penis and perigenital skin pass via the pudendal nerve to the spinal cord.

Microstructure

The internal surfaces of the fibrous sheaths of the corpora cavernosa and their dividing septum give rise to numerous trabeculae. These cross the corpora cavernosa in all directions and divide them into a series of cavernous spaces, giving them a spongy appearance. The trabeculae are composed of collagen and elastin fibres and smooth muscle and contain numerous vessels and nerves. The cavernous spaces are lined by an endothelium similar to that in other blood vessels. The spaces are empty in the flaccid state but become filled with blood during erection. The fibrous tunica albuginea of the corpus spongiosum is thinner, whiter and more elastic than that of the corpora cavernosa. It is formed partly of smooth muscle cells: a layer of the same tissue surrounds the urethral epithelium and the para-urethral glands.

ERECTION AND EJACULATION

Penile erection is a neurovascular process. The ischiocavernosi and bulbospongiosus may contribute to maximum rigidity although the main process is initiated by relaxation of the smooth muscle of the corpora cavernosa. Sexual arousal leads to rapid inflow from the helicine arteries following relaxation of the smooth muscle of the corpora cavernosa. This inflow of blood fills the cavernous spaces leading to tumescence. The resulting distension converts tumescence to an erection by pressure on the subtunical veins, which drain the erectile tissue, thereby obstructing them. This is known as the veno-occlusive mechanism. The smooth muscle of the corpora cavernosa relaxes in response to a number of neurotransmitters produced via the parasympathetic nerves and the endothelium. The most important neurotransmitter initiating penile erection appears to be nitric oxide, mainly produced from non-adrenergic, non-cholinergic nerves within the penis and acting via its second messenger, cyclic GMP.

Continuing cutaneous stimulation of the glans and frenulum contributes significantly to maintaining erection and initiating orgasm and ejaculation. Erection is thus dependent on a normal psychogenic response to stimulation, intact parasympathetic nerves, corporal smooth muscle capable of relaxation, patent arteries capable of delivering blood at the required rate, and a normal venous system. Following ejaculation the above process is reversed: smooth muscle contraction in response to sympathetic stimulation leads to penile detumescence.

Ejaculation consists of two processes, emission and ejaculation. Emission is the transmission of seminal fluid from the vasa, prostate and seminal vesicles into the prostatic urethra under sympathetic control. Ejaculation is the expulsion of seminal fluid from the prostatic urethra to the exterior, a phenomenon that has autonomic and somatic components. The first discernible part of the process is contraction of bulbospongiosus, which contracts about six times under somatic control. The way in which seminal fluid crosses the external urethral sphincter to enter the bulbar urethra is not clear, although it is known to be under autonomic control. It is timed so the ejaculate appears from the external meatus between the second to the final contraction of bulbospongiosus. In some younger men, ejaculation may be pulsatile.

Motility of spermatozoa

It is now generally accepted that the spermatic tail executes undulatory movements in one plane. It has been suggested that a helical component is superimposed upon these movements, and that there are perhaps two separable mechanisms to account for sperm motility, one involving flat waves travelling along the tail, the other associated with torsional activity. The latter type of movement has been linked with the unequal size and distribution of the dense fibres, and the asymmetry of the spermatozoon head. The central pair of fine fibrils may act as axial stiffeners.

As soon as they are ejaculated, spermatozoa display their full pattern of motility. The factors which trigger these movements are not yet clear: the other constituents of semen, which are derived from the epididymis, testis, seminal vesicle and prostate, are generally considered to exert an activating influence. Spermatozoa have been recovered in a motile state in human cervical mucus several days after insemination and will survive in this condition for as long as 7 days when implanted into such secretions *in vitro*. In view of the speed with which spermatozoa reach the infundibulum of the uterine tube, and the brevity of their fertilizing power, these survival periods may be of little significance. Spermatozoa have been shown to reach their tubal destination in a manner of minutes after ejaculation in some mammals; experiments on recently excised human uteri and tubes indicate a time of approximately 70 minutes. The conclusion must be that factors other than their own motility (1.5–3.0 mm/min) are responsible for the transport of spermatozoa from the site of deposition in the vaginal fornix to the ovarian end of the uterine tube, and there is considerable evidence that contraction of the uterine and tubal musculature is responsible.

Capacitation

After ejaculation into the female genital tract, spermatozoa undergo the final step in their maturation, a process known as capacitation. This normally requires exposure to the secretions of the uterine tube: a spermatozoon is unable to penetrate the corona radiata to fertilize an ovum until it has been within the female genital tract for a period of time, usually a few hours.

ERECTILE DYSFUNCTION AND PRIAPISM

Failure to achieve tumescence with adequate stimulation is termed erectile dysfunction. The mechanism of erection is complex: failure in any of the previously mentioned components can lead to erectile dysfunction. The commonest causes include psychogenic disturbance with failure to relax cavernous smooth muscle; arterial insufficiency as a result of atheromatous disease; and damage to the parasympathetic nervous system secondary to diabetes or following pelvic surgery such as radical prostatectomy, radical cystectomy or bowel resection. Oral pharmacotherapy is directed at achieving cavernosal smooth muscle relaxation by enhancing the effects of cyclic GMP.

Some men are prone to develop an erection which fails to subside after ejaculation and is termed a priapism. This can be either high flow or low flow, the latter condition being more common. Low flow priapism can occur spontaneously but is also seen in conditions such as sickle cell disease or leukaemia, or as a result of injection of drugs, such as intracavernosal prostaglandin E1, directly into the penis in men with erectile dysfunction. It leads to ischaemia of the corporal smooth muscle, which causes pain within the penis and will result in erectile dysfunction if left untreated. High flow priapism, where too much blood enters the penis, is usually secondary to an abnormal connection or fistula between the cavernosal arteries and sinusoidal spaces.

Peyronie’s disease may result in a bend in the erect penis that most commonly presents as a dorsal curvature that results from a localized thickening or plaque within the corpora cavernosa which prevents expansion of a segment during erection. Penile cancer is a rare malignancy of the penis and usually presents with a mass or ulceration of the penis. MRI scanning may be used in preoperative planning of Peyronie’s disease and local staging of penile cancer (see Fig. 76.19).

CHAPTER 77

Female reproductive system

The female reproductive system consists of the lower genital tract (vulva and vagina) and the upper tract (uterus and cervix with associated uterine (Fallopian) tubes and ovaries).

LOWER GENITAL TRACT

VULVA

The female external genitalia or vulva include the mons pubis, labia majora, labia minora, clitoris, vestibule, vestibular bulb and the greater vestibular glands (Fig. 77.1A–D).

Mons pubis

The mons pubis is the rounded hair-bearing area of skin over the pubic symphysis and adjacent pubic bone. It is formed by a mass of subcutaneous adipose connective tissue. Before puberty, the mons pubis is relatively flat and the labia minora are poorly formed. During adolescence, coarse hair forms over the mons and labia majora and the labia minora become more prominent and flap like. In adults, the mons is covered by coarse hair that is usually limited above by a horizontal boundary; in males there is a continuation of pubic hair to the umbilicus. After the menopause, pubic hair thins and labial tissue atrophies slightly.

Labia majora

The labia majora are two prominent, longitudinal folds of skin that extend back from the mons pubis to the perineum (Fig. 77.1B). They form the lateral boundaries of the vulva. Each labium has an external, pigmented surface covered with hairs and a smooth, pink internal surface with large sebaceous follicles. Between these surfaces there is loose connective and adipose tissue, intermixed with smooth muscle (resembling the scrotal dartos muscle), vessels, nerves and glands. The uterine round ligament may end in the adipose tissue and skin in the anterior part of the labium. A persistent processus vaginalis and congenital inguinal hernia may also reach a labium. The labia are thicker anteriorly, where they join to form the anterior commissure. Posteriorly they do not join, but instead merge into neighbouring skin, ending near and almost parallel to each other. The connecting skin between them posteriorly forms a ridge, the posterior commissure, that overlies the perineal body and is the posterior limit of the vulva. The distance between this and the anus is 2.5–3 cm thick and is termed the ‘gynaecological’ perineum.

Labia minora

The labia minora are two small cutaneous folds, devoid of fat, that lie between the labia majora. They extend from the clitoris obliquely down, laterally and back, flanking the vaginal orifice. Anteriorly, each labium minus bifurcates. The upper layer of each side passes above the clitoris to form a fold, the hood or prepuce, which overhangs the glans of the clitoris. The lower layer of each side passes below the clitoris to form the frenulum of the clitoris (Fig. 77.1A,C). Sebaceous follicles are numerous on the apposed labial surfaces. Sometimes an extra labial fold (labium tertium) is found on one or both sides between the labia minora and majora.

Vestibule

The vestibule is the cavity that lies between the labia minora. It contains the vaginal and external urethral orifices and the openings of the two greater vestibular (Bartholin's) glands and of numerous mucous, lesser vestibular glands. There is a shallow vestibular fossa between the vaginal orifice and the frenulum of the labia minora.

Urethra

The urethra opens into the vestibule about 2.5 cm below the clitoris and above the vaginal opening via a short, sagittal cleft with slightly raised margins, the urethral meatus. The meatus is very distensible and varies in shape: the aperture may be rounded, slit-like, crescentic or stellate. The ducts of the para-urethral glands (Skene's glands) open on each side of the lateral margins of the urethra.

Bulbs of the vestibule

The bulbs of the vestibule lie on each side of the vestibule. They are two elongated masses of erectile tissue, 3 cm long, which flank the vaginal orifice and unite anterior to it by a narrow commissura bulborum (pars intermedia). Their posterior ends are expanded and are in contact with the greater vestibular glands. Their anterior ends taper and are joined by a commissure and also to the clitoris by two slender bands of erectile tissue. Their deep surfaces contact the inferior aspect of the urogenital diaphragm, and superficially each is covered by bulbospongiosus posteriorly (Fig. 77.2A–C).

Greater vestibular glands (Bartholin’s glands)

The greater vestibular glands are homologues of the male bulbourethral glands. They consist of two small, round or oval, reddish-yellow bodies that flank the vaginal orifice, in contact with, and often overlapped by, the posterior end of the vestibular bulb. Each opens into the postero-lateral part of the vestibule by a 2 cm duct, situated in the groove between the hymen and the labium minus (Fig. 77.1D). The glands are composed of tubulo-acinar tissue. The secretory cells are columnar and secrete a clear or whitish mucus with lubricant properties. They are stimulated by sexual arousal.

Clitoris

The clitoris is an erectile structure partially enclosed by the anterior bifurcated ends of the labia minora. It has a root, a body, and a glans. The body can be palpated through the skin. It contains two corpora cavernosa, composed of erectile tissue and enclosed in dense fibrous tissue, and separated medially by an incomplete fibrous pectiniform septum. The fibrous tissue forms a suspensory ligament that is attached superiorly to the pubic symphysis. Each corpus cavernosum is attached to its ischiopubic ramus by a crus that extends from the root of the clitoris. The glans clitoris is a small round tubercle of spongy erectile tissue at the end of the body and connected to the bulbs of the vestibule by thin bands of erectile tissue. It is exposed between the anterior ends of the labia minora. Its epithelium has high cutaneous sensitivity, important in sexual responses (Fig. 77.2).

Veins

Venous drainage of the vulval skin is via external pudendal veins to the long saphenous vein. Venous drainage of the clitoris is via deep dorsal veins to the internal pudendal vein and superficial dorsal veins to the external pudendal and long saphenous veins (Fig. 77.3A).

Lymphatic drainage

A meshwork of connecting vessels join to form three or four collecting trunks around the mons pubis which drain to superficial inguinal nodes lying on the cribriform fascia covering the femoral artery and vein; these nodes drain through the cribriform fascia to the deep inguinal nodes lying medial to the femoral vein. The deep inguinal nodes drain via the femoral canal to the pelvic nodes. The last of the deep inguinal nodes lies under the inguinal ligament within the femoral canal and is often called Cloquet's node. Lymph vessels in the perineum and lower part of the labia majora drain to the rectal lymphatic plexus. Lymph vessels from the clitoris and labia minora drain to deep inguinal nodes and direct clitoral efferents may pass to the internal iliac nodes (Fig. 77.3B).

The sensory innervation of the anterior and posterior parts of the labium majus differ. The anterior third of the labium majus is supplied by the ilioinguinal nerve (L1), the posterior two-thirds are supplied by the labial branches of the perineal nerve (S3), and the lateral aspect is also innervated by the perineal branch of the posterior cutaneous nerve of the thigh (S2).

VAGINA

The vagina is a fibromuscular tube lined by non-keratinized stratified epithelium. It extends from the vestibule (the opening between the labia minora) to the uterus. The upper end of the vagina surrounds the vaginal projection of the uterine cervix. The annular recess between the cervix and vagina is the fornix: the different parts of this recess are given separate names, i.e. anterior, posterior and right and left lateral, but they are continuous (Fig. 77.6).

Anterior lip of cervix
Left vaginal wall
Right vaginal wall
Posterior fornix of vagina
Posterior lip of cervix
Cuscoe's speculum

Fig. 77.6 Cervix and vaginal fornices as seen via a Cuscoe's bivalve speculum.

The vagina ascends posteriorly and superiorly at an angle of over 90° to the uterine axis: this angle varies with the contents of the bladder and rectum. The width of the vagina increases as it ascends. Above the level of the hymen, the inner surfaces of the anterior and posterior vaginal walls are ordinarily in contact with each other forming a transverse slit. The vaginal mucosa is attached to the uterine cervix higher on the posterior cervical wall than on the anterior: the anterior wall is approximately 7.5 cm long and the posterior wall is approximately 9 cm long. The anterior wall of the vagina is related to the base of the bladder in its middle and upper portions and to the urethra (which is embedded in it) inferiorly. The posterior wall is covered by peritoneum in its upper quarter. It is separated from the rectum by the recto-uterine pouch superiorly, and by moderately loose connective tissue (Denonvillier's fascia) in its middle half. In its lower quarter it is separated from the anal canal by the musculofibrous perineal body. Laterally are levator ani and pelvic fascia (see Fig. 75.1A). As the ureters pass anteromedially to reach the fundus of the bladder, they pass close to the lateral fornices. As they enter the bladder the ureters are usually anterior to the vagina, and at this point, each ureter is crossed transversely by a uterine artery (Fig. 77.7).

(From Drake, Vogl and Mitchell 2005.)

The vagina opens externally via a sagittal introitus positioned below the urethral meatus. The size of the introitus varies: it is capable of great distension during childbirth and to a lesser degree during sexual intercourse. The hymen is a thin fold of mucous membrane situated just within the vaginal orifice. The internal surfaces of the folds are normally in contact each other and the vaginal opening appears as a cleft between them. The hymen varies greatly in shape and dimensions. When stretched, it is annular and widest posteriorly; it may also be semilunar and concave towards the mons pubis, cribriform, fringed, absent or complete and imperforate. The hymenal ring normally ruptures after first sexual intercourse, but can rupture earlier during non-sexual physical activity. Small round carunculae hymenales (also known as carunculae myrtiformis) are its remnants after it has been ruptured. It has no established function.

Remnants of the duct of Gartner (embryologically the caudal end of the mesonephric duct) (see Ch. 78), are occasionally seen protruding through the lateral fornices or lateral parts of the vagina; these can cause cysts (Gartner's cysts).

Vascular supply and lymphatic drainage

Arteries

The arterial supply of the vagina is derived from the internal iliac arteries. The vaginal arteries form two median longitudinal vessels, the azygos arteries of the vagina, which descend anterior and posterior to the vagina. They descend on the vagina and supply the mucous membrane. Branches are also sent to the vestibular bulb, fundus of the bladder, and adjacent part of the rectum. The uterine, internal pudendal and middle rectal branches of the internal iliac artery may also contribute to the blood supply.

Veins

The vaginal veins, one on each side, form from lateral plexuses that connect with uterine, vesical and rectal plexuses and drain to the internal iliac veins. The uterine and vaginal plexuses may provide collateral venous drainage to the lower limb.

Lymphatics

Vaginal lymphatic vessels link with those of the cervix, rectum and vulva. They form three groups but the regions drained are not sharply demarcated. Upper vessels accompany the uterine artery to the internal and external iliac nodes; intermediate vessels accompany the vaginal artery to the internal iliac nodes; vessels draining the vagina below the hymen, and from the vulva and perineal skin, pass to the superficial inguinal nodes.

Innervation

The lower vagina is supplied by the pudendal nerve (S2, S3 and S4). The upper vagina is supplied by the splanchnic nerves (S2, S3 and sometimes S4).

Microstructure

The vagina has an inner mucosal and an external muscular layer. The mucosa adheres firmly to the muscular layer. There are two median longitudinal ridges on its epithelial surface, one anterior and the other posterior. Numerous transverse bilateral rugae extend from these vaginal columns. They are divided by sulci of variable depth, giving an appearance of conical papillae, which are most numerous on the posterior wall and near the orifice, and which are especially well developed before parturition. The epithelium is non-keratinized, stratified, squamous similar to, and continuous with, that of the ectocervix. After puberty it thickens and its superficial cells accumulate glycogen, which gives them a clear appearance in histological preparations.

(From Sobotta 2006.)

The vaginal epithelium does not change markedly during the menstrual cycle, but its glycogen content increases after ovulation and then diminishes towards the end of the cycle. Natural vaginal bacteria, particularly *Lactobacillus acidophilus*, break down glycogen in the desquamated cellular debris to lactic acid. This produces a highly acidic (pH 3) environment, which inhibits the growth of most other microorganisms. The amount of glycogen is less before puberty and after the menopause, when vaginal infections are more common. There are no mucous glands, but a fluid transudate from the lamina propria and mucus from the cervical glands lubricate the vagina (Fig. 77.8). The muscular layers are composed of smooth muscle and consist of a thick outer longitudinal and an inner circular layer. The two layers are not distinct but connected by oblique interlacing fibres. Longitudinal fibres are continuous with the superficial muscle fibres of the uterus. Half way along the vagina is a U-shaped muscular sling, called the pubo-vaginalis. The lower vagina is also surrounded by the skeletal muscle fibres of bulbospongiosus. A layer of loose connective tissue, containing extensive vascular plexuses, surrounds the muscle layers.

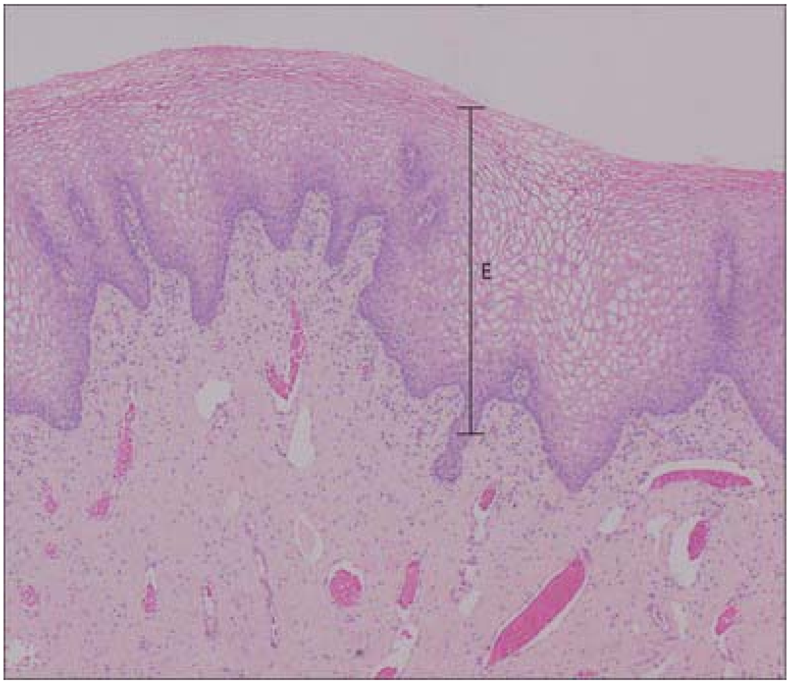

Fig. 77.8 Stratified squamous non-keratinizing epithelium (E) covering the ectocervix and vagina. The cells of the middle and upper layers appear clear due to their content of glycogen.

UPPER GENITAL TRACT

UTERUS

The uterus is a thick-walled, muscular organ situated in the pelvis between the urinary bladder and the rectum (Figs 77.9-77.11). It lies posterior to the bladder and uterovesical space and anterior to the rectum and recto-uterine pouch: it is mobile, which means that its position varies with distension of the bladder and rectum. The broad ligaments are lateral.

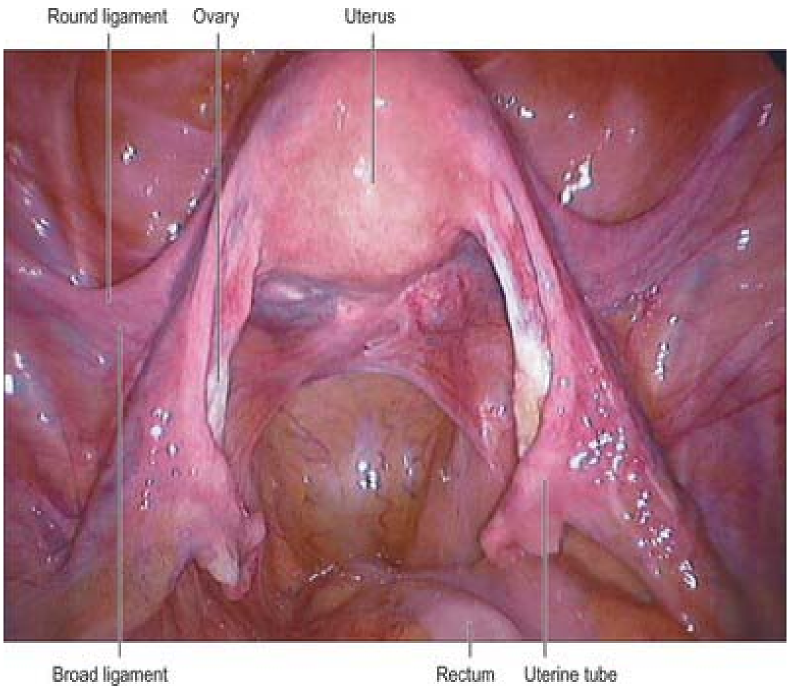

Fig. 77.11 Laparoscopic view of the uterus – the patient is tilted head down so that the small bowel is moved away from the uterus to give this view.

The uterus is divided into two main regions: the body of the uterus (corpus uteri) forms the upper two-thirds, and the cervix (cervix uteri) forms the lower third. In the adult nulliparous state the cervix tilts forwards relative to the axis of the vagina (anteversion), and the body of the uterus tilts forward relative to the cervix (anteflexion) (Fig. 77.12). In 10 to 15% of women the whole uterus leans backwards at an angle to the vagina and is said to be retroverted. A uterus that angles backwards on the cervix is described as retroflexed.

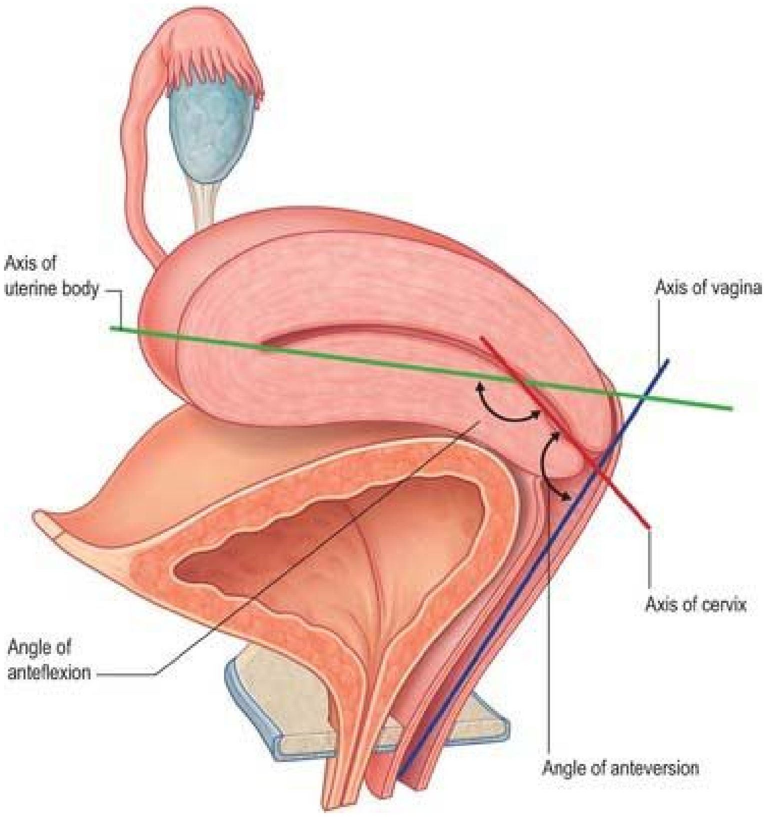

Fig. 77.12 Angles of anteflexion and anteversion.

(From Drake, Vogl and Mitchell 2005.)

Body

The body of the uterus is pear shaped and extends from the fundus superiorly to the cervix inferiorly. Near its upper end, the uterine tubes enter the uterus on both sides at the uterine cornua. Inferoanterior to each cornu is the round ligament and inferoposterior is the ovarian ligament. The dome-like fundus is superior to the entry points of the uterine tubes and covered by peritoneum which is continuous with that of neighbouring surfaces. The fundus is in contact with coils of small intestine and occasionally by distended sigmoid colon. The lateral margins of the body are convex, and on each side their peritoneum is reflected laterally to form the broad ligament, which extends as a flat sheet to the pelvic wall (Fig. 77.13). The anterior surface of the uterine body is covered by peritoneum which is reflected onto the bladder at the uterovesical fold (Fig. 77.14). This normally occurs at the level of the internal os, the most inferior margin of the body of the uterus. The vesico-uterine pouch between the bladder and uterus is obliterated when the bladder is distended, but may be occupied by small intestine when the bladder is empty. The posterior surface of the uterus is convex transversely. Its peritoneal covering continues down to the cervix and upper vagina and is then reflected back to the rectum along the surface of the recto-uterine pouch (of Douglas), which lies posterior to the uterus (Fig. 77.15). The sigmoid colon and occasionally the terminal ileum lie posterior to the uterus.

towards the rectum.

The cavity of the uterine body usually measures 6 cm from the external os of the cervix to the wall of the fundus and is flat in its anteroposterior plane. In coronal section, it is triangular, broad above where the two uterine tubes join the uterus, and narrow below at the internal os of the cervix (Fig. 77.16).

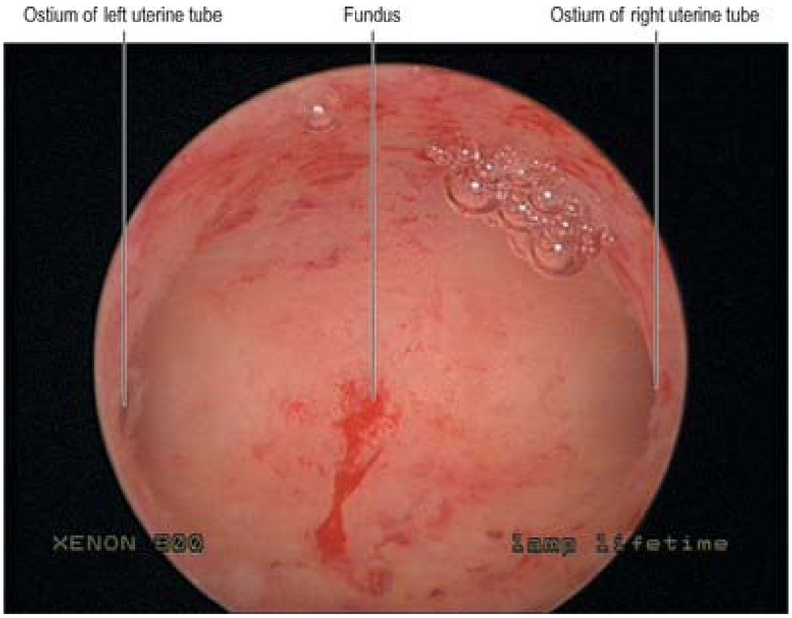

Fig. 77.16 Hysteroscopic view of the endometrial cavity of the uterus.

There may be failure in fusion of the paramesonephric (Müllerian) ducts, which results in a uterus that is not pear shaped. There may just be a septum (septate uterus) or partial clefting of the uterus (bicornuate uterus); the most extreme example is a septate vagina, two cervices, and two discrete uteri, each with one uterine tube (uterus didelphys).

Cervix

The adult, non-pregnant cervix is narrower and more cylindrical than the body of the uterus and is typically 2.5 cm long. The upper end communicates with the uterine body via the internal os and the lower end opens into the vagina at the external os. In nulliparous women, the external os is usually a circular aperture, whereas after childbirth it is a transverse slit. Two longitudinal ridges, one each on its anterior and posterior walls, give off small oblique palmate folds that ascend laterally like the branches of a tree (arbor vitae uteri): the folds on opposing walls interdigitate to close the canal. The narrower isthmus forms the upper third of the cervix. Although unaffected in the first month of pregnancy, it is gradually taken up into the uterine body during the second month to form the 'lower uterine segment' (see below). In non-pregnant women the isthmus undergoes menstrual changes, although these are less pronounced than those occurring in the uterine body. The external end of the cervix enters the upper end of the vagina, thereby dividing the cervix into supravaginal and vaginal parts. The supravaginal part is separated anteriorly from the bladder by cellular connective tissue, the parametrium, which also passes to the sides of the cervix and laterally between the two layers of the broad ligaments.

Pelvic ligaments and peritoneal folds

The uterus is connected to a number of 'ligaments'. Some are true ligaments in that they have a fibrous composition and provide support to the uterus, some provide no support to the uterus, and others are simply folds of peritoneum.

Peritoneal folds

The parietal peritoneum is reflected over the upper genital tract to produce anterior (uterovesical), posterior (rectovaginal) and lateral peritoneal folds. The lateral folds are commonly called the broad ligaments.

Uterovesical and rectovaginal folds

The anterior or uterovesical fold consists of peritoneum reflected onto the bladder from the uterus at the junction of its cervix and body. The posterior or rectovaginal fold consists of peritoneum reflected from the posterior vaginal fornix on to the front of the rectum, thereby create the deep recto-uterine pouch of Douglas. The pouch of Douglas is bounded anteriorly by the uterus, supravaginal cervix and posterior vaginal fornix, posteriorly by the rectum and laterally by the uterosacral ligaments.

Broad ligament

The lateral folds or broad ligaments extend on each side from the uterus to the lateral pelvic walls, where they become continuous with the peritoneum covering those walls (Figs 77.17, 77.18). The upper border is free and the lower border is continuous with the peritoneum over the bladder, rectum and pelvic side-wall. The borders are continuous with each other at the free edge via the uterine fundus and diverge below near the superior surfaces of levatores ani. A uterine tube lies in the upper free border on either side. The broad ligament is divided into an upper mesosalpinx, a posterior mesovarium and an inferior mesometrium.

Mesosalpinx

The mesosalpinx is attached above to the uterine tube and posteroinferiorly to the mesovarium. Superior and laterally it is attached to the suspensory ligament of the ovary and medially it is attached to the ovarian ligament. The fimbria of the tubal infundibulum projects from its free lateral end. Between the ovary and uterine tube the mesosalpinx contains vascular anastomoses between the uterine and ovarian vessels, the epoophoron, and the paroophoron (Fig. 77.19). The mesovarium projects from the posterior aspect of the broad ligament, of which it is the smaller part. It is attached to the hilum of the ovary and carries vessels and nerves to the ovary.

(From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)

Mesometrium

The mesometrium is the largest part of the broad ligament, and extends from the pelvic floor to the ovarian ligament and uterine body. The uterine artery passes between its two peritoneal layers typically 1.5 cm lateral to the cervix: it crosses the ureter shortly after its origin from the internal iliac artery and gives off a branch that passes superiorly to the uterine tube, where it anastomoses with the ovarian artery (Fig. 77.19). Between the pyramid formed by the infundibulum of the tube, the upper pole of the ovary, and the lateral pelvic wall, the mesometrium contains the ovarian vessels and nerves lying within the fibrous suspensory ligament of the ovary (infundibulopelvic ligament). This ligament continues laterally over the external iliac vessels as a distinct fold. The mesometrium also encloses the proximal part of the round ligament of the uterus, as well as smooth muscle and loose connective tissue.

Ligaments of the pelvis

The ligaments of the pelvis consist of the round, uterosacral, transverse cervical and pubocervical ligaments.

Round ligament

The round ligaments are narrow, somewhat flattened bands 10–12 cm long. Each is attached medially to the upper part of the uterus just below and anterior to the lateral cornua. From here, each passes laterally within the upper part of the broad ligament to the pelvic side-wall. At the start of the inferior epigastric artery, the round ligament enters the deep inguinal ring. It traverses the inguinal canal and splits into strands that merge with the surrounding connective tissue before terminating in the mons pubis above the labium majus. Near the uterus the round ligament contains a considerable amount of smooth muscle but this gradually diminishes and the terminal portion is purely fibrous. The round ligament contains blood vessels, nerves and lymphatics. The latter drain the uterine region around the entry of the uterine tube to the superficial inguinal lymph nodes.

In the fetus a projection of peritoneum (processus vaginalis) is carried with the round ligament for a short distance into the inguinal canal. This is generally obliterated in adults, although it is sometimes patent even in old age. In the canal the ligament receives the same coverings as the spermatic cord, although they are thinner and blend with the ligament itself, which may not reach the mons pubis. The round and ovarian ligaments both develop from the gubernaculum and are continuous.

Uterosacral, transverse cervical and pubocervical ligaments

The uterosacral ligaments are recto-uterine folds and contain fibrous tissue and smooth muscle (Fig. 77.18). They pass back from the cervix and uterine body on both sides of the rectum, and they are attached to the front of the sacrum. The ligaments can be palpated laterally on rectal examination. On vaginal examination they can be felt as thick bands of tissue passing downwards on both sides of the posterior fornix. The transverse cervical ligaments (cardinal ligaments, ligaments of Mackenrodt) (Fig. 77.20) extend from the side of the cervix and lateral fornix of the vagina to attach extensively on the pelvic wall. At the level of the cervix, some fibres interdigitate with fibres of the uterosacral ligaments. They are continuous with the fibrous tissue around the lower parts of the ureters and pelvic blood vessels. Fibres of the pubocervical ligament pass forward from the anterior aspect of the cervix and upper vagina to diverge around the urethra (Fig. 77.20). These fibres attach to the posterior aspect of the pubic bones.

Fig. 77.20 Supporting ligaments of the pelvis showing the transverse cervical ligaments.

(From Sobotta 2006.)

While the uterosacral and transverse cervical ligaments may act in varying measure as mechanical supports of the uterus, levatores ani and coccygei, the urogenital diaphragm and the perineal body appear at least as important in this respect. There has been renewed interest in the supporting structures of the pelvis, and the subject has been reviewed in detail by Delancey (2000).

Vascular supply and lymphatic drainage

Arteries

The arterial supply to the uterus comes from the uterine artery (Fig. 77.21). This arises as a branch of the anterior division of the internal iliac artery. From its origin, the uterine artery crosses the ureter anteriorly in the broad ligament before branching as it reaches the uterus at the level of the cervico-uterine junction. One major branch ascends the uterus tortuously within the broad ligament until it reaches the region of the ovarian hilum, where it anastomoses with branches of the ovarian artery. Another branch descends to supply the cervix and anastomoses with branches of the vaginal artery to form two median longitudinal vessels, the azygos arteries of the vagina, which descend anterior and posterior to the vagina. Although there are anastomoses with the ovarian and vaginal arteries, the dominance of the uterine artery is indicated by its marked hypertrophy during pregnancy.

(From Sobotta 2006.)

The tortuosity of the vessels as they ascend in the broad ligaments is repeated in their branches within the uterine wall. Each uterine artery gives off numerous branches. These enter the uterine wall, divide and run circumferentially as groups of anterior and posterior arcuate arteries. They ramify and narrow as they approach the anterior and posterior midline so that no large vessels are present in these regions. However, the left and right arterial trees anastomose across the midline and unilateral ligation can be performed without serious effects. Terminal branches in the uterine muscle are tortuous and are called helical arterioles. They provide a series of dense capillary plexuses in the myometrium and endometrium. From the arcuate arteries many helical arteriolar rami pass into the endometrium. Their detailed appearance changes during the menstrual cycle. In the proliferative phase helical arterioles are less prominent, whereas they grow in length and calibre, becoming even more tortuous in the secretory phase.

Veins

The uterine veins extend laterally in the broad ligaments, running adjacent to the arteries and passing over the ureters. They drain into the internal iliac veins (see Fig. 77.30). The uterine venous plexus anastomoses with the vaginal and ovarian venous plexuses.

Lymphatic drainage

Uterine lymphatics exist in the superficial (subperitoneal) and deep parts of the uterine wall. Collecting vessels from the body of the uterus and cervix pass laterally in the parametrium to three main groups of lymph nodes: the external and internal iliac and the obturator nodes. The external and internal iliac nodes surround their corresponding arteries. The obturator nodes lie in the obturator fossa between the external and internal iliac vessels; the obturator nerve passes through the lower part of this group of lymph nodes.

Lymph vessels from the fundus of the uterus and the uterine tubes may accompany the lymph drainage of the ovaries to para-aortic nodes (Fig. 77.3B). The region surrounding the isthmus of the uterine tube may drain along the round ligament to the superficial inguinal nodes.

Innervation

The nerve supply to the uterus is predominantly from the inferior hypogastric plexus. Some branches ascend with, or near, the uterine arteries in the broad ligament. They supply the uterine body and tubes, and connect with tubal nerves from the inferior hypogastric plexus and with the ovarian plexus. The uterine nerves terminate in the myometrium and endometrium, and usually accompany the vessels. Nerves to the cervix form a plexus that contains small paracervical ganglia. Sometimes one ganglion is larger and is termed the uterine cervical ganglion. Branches may pass directly to the cervix uteri or may be distributed along the vaginal arteries.

Efferent preganglionic sympathetic fibres are derived from neurones in the last thoracic and first lumbar spinal segments; the sites where they synapse on their postganglionic neurones are unknown. Preganglionic parasympathetic fibres arise from neurones in the second to fourth sacral spinal segments and relay in the paracervical ganglia. Sympathetic activity may produce uterine contraction and vasoconstriction and parasympathetic activity may produce uterine inhibition and vasodilatation, but these activities are complicated by hormonal control of uterine functions.

Microstructure

Body of the uterus

The uterus is composed of three main layers. From its lumen outwards these are the endometrium (mucosa), myometrium (smooth muscle layer) and serosa (or adventitia) (Fig. 77.22).

Fig. 77.22 The uterus, uterine tubes and ovaries.

(From Sobotta 2006.)

Endometrium

The endometrium is formed by a layer of connective tissue, the endometrial stroma, which supports a single-layered columnar epithelium. Before puberty, the epithelium is ciliated and cuboidal. It contains glands which are composed largely of columnar cells secreting glycoproteins and glycogen. After puberty, the structure of the endometrium varies with the stage of the menstrual cycle (see below). The glands are tubular, run perpendicular to the luminal surface and penetrate up to the myometrial layer. The stroma consists of a highly cellular connective tissue between the endometrial glands, and contains blood and lymphatic vessels.

Myometrium

The myometrium is composed of smooth muscle and loose connective tissue and contains blood vessels, lymphatic vessels and nerves. It is dense and thick at the uterine midlevel and fundus but thin at the tubal orifices. The body of the uterus has four muscular layers. The submucosal (innermost) layer is composed of longitudinal and some oblique smooth muscle fibres. Where the lumen of the uterine tube passes through the uterine wall, this layer forms a circular muscle coat. The vascular layer is external to the submucosal layer and is rich in blood vessels as well as longitudinal muscle, it is succeeded by a layer of predominantly circular muscle, the supravascular layer. The outer, thin, longitudinal muscle layer, the subserosal layer, lies adjacent to the serosa.

The muscular fibres of the outer two layers converge at the lateral angles of the uterus, and continue into the uterine tubes. Some fibres enter the broad ligaments as the round and ovarian ligaments; others turn back into the uterosacral ligaments. At the junction between the body and the cervix, the smooth muscle merges with dense irregular connective tissue containing both collagen and elastin, and forms the majority of the cervical wall. Bilateral longitudinal fibres extend in the lateral submucosal layer from the fundal angle to the cervix. Their muscle fibres differ structurally from those of typical myometrium, and they may provide fast conducting pathways which coordinate the contractile activities of the uterine wall.

Serosa

The serosa is composed of peritoneum (mesothelium overlying a thin connective tissue lamina propria), which covers the uterine body. Posteriorly it continues downwards to cover the supravaginal cervix.

Cervix uteri

The cervix (Figs 77.23, 77.24) consists of fibroelastic connective tissue and contains relatively little smooth muscle. The elastin component of the cervical stroma is essential to the stretching capacity of the cervix during childbirth. The cervical canal is lined by a deeply folded mucosa with a surface epithelium of columnar mucous cells. There are branched tubular glands present amongst the mucosa, which are lined by a similar secretory epithelium. The glands extend obliquely upwards and outwards from the canal. They secrete clear, alkaline mucus, which is relatively viscous except at the midpoint of the menstrual cycle, when it becomes more copious and less viscous to encourage the passage of sperm. At the vaginal end of the cervix, the aperture of a gland may block and it then fills with mucus to form a Nabothian follicle (or cyst). None of the mucosa is shed during menstruation and so, unlike the body of the uterus, it is not divided into functional and basal layers and lacks spiral arteries. The surface of the intravaginal part of the cervix (ectocervix) is covered by non-keratinizing stratified squamous epithelium, which contains glycogen.

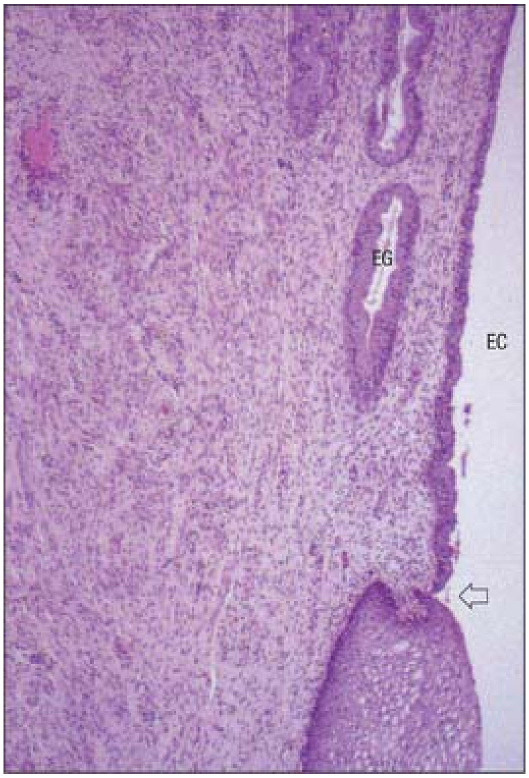

Fig. 77.23 Transformation zone of the uterine cervix. The single layered columnar epithelium lining the endocervical canal (EC) and its endocervical glands (EG) changes abruptly (arrow) to the stratified squamous non-keratinizing epithelium of the external os and ectocervix (below arrow).

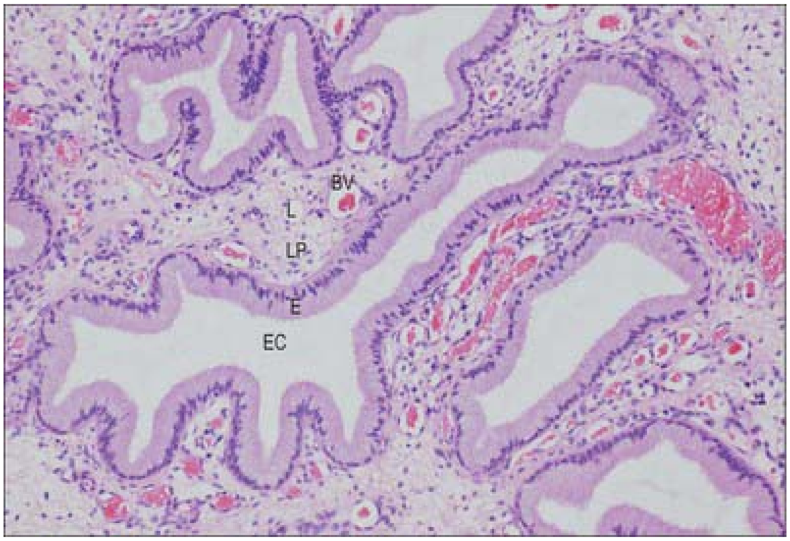

Fig. 77.24 Endocervical glands are deep infoldings of the lining of the endocervical canal (EC). The epithelium (E) is simple columnar and mucus-secreting. The underlying lamina propria (LP) is richly supplied with blood vessels (BV) and lymphatics (L).

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

The squamocolumnar junction, where the columnar secretory epithelium of the endocervical canal meets the stratified squamous covering of the ectocervix, is located at the external os before puberty. As oestrogen levels rise during puberty, the cervical os opens, exposing the endocervical columnar epithelium onto the ectocervix. This area of columnar cells on the ectocervix forms an area that is red and raw in appearance called an ectropion (cervical erosion). It is then exposed to the acidic environment of the vagina and through a process of squamous metaplasia transforms into stratified squamous epithelium. This area is thus known as the ‘transformation zone’. Other hyperoestrogenic states such as pregnancy and the use of oral contraceptive pills can also result in an ectropion. This area is the most usual site of cervical intraepithelial neoplasia (CIN) that may progress to malignancy. In postmenopausal women, the squamo-columnar junction recedes into the endocervical canal (Fig. 77.23).

Magnetic resonance imaging of the uterus

On T2-weighted magnetic resonance imaging (MRI), the uterus (Fig. 77.25A,B) displays a zonal anatomy, with three distinct zones: the endometrium; junctional zone; and myometrium. The endometrium and uterine cavity appear as a high-signal stripe; the thickness varies with the stage of the menstrual cycle. In the early proliferative phase it measures up to 5 mm, and widens to up to 1 cm in the mid-secretory phase. A band of low signal, the junctional zone, borders the endometrium. It represents the inner myometrium, which blends with the low-signal band of fibrous cervical stroma at the level of the internal os. The junctional zone appears low signal because the cells of the myometrium have low water content when compared to those of the outer myometrium. The junctional zone is of constant thickness and signal throughout the menstrual cycle, and usually measures 5 mm. The outer myometrium is of medium signal intensity in the proliferative phase, and of high signal intensity in the mid-secretory phase as a result of the increased vascularity and prominence of the arcuate vessels.

Sagittal T2-weighted MRI through a female pelvis showing the zonal anatomy of the uterus.

In prepubertal females, the uterus is smaller (only 4 cm in length) and on T2-weighted images the endometrium is minimal or absent, and the junctional zone is indistinct. In postmenopausal women, the corpus decreases in size and the zonal anatomy is indistinct.

On T2-weighted MRI the cervix has an inner low-signal stroma continuous with the junctional zone of the uterus. Often this is surrounded by an outer zone of intermediate signal intensity, which is continuous with the outer myometrium. The appearances do not change with the menstrual cycle or oral contraceptive pill use. The central stripe is very high signal and is a consequence of the secretions produced by the endocervical glands.

UTERINE (FALLOPIAN) TUBES

The uterine tubes (Fig. 77.26) are attached to the upper part of the body of the uterus and their ostia open into the uterine cavity (Fig. 77.27). The medial opening of the tube (the uterine os) is located at the superior angle of the uterine cavity. The tube passes laterally and superiorly and consists of four main parts: intramural, isthmus, ampulla, fimbria. The intramural part is 0.7 mm wide, 1 cm long, and lies within the myometrium. It is continuous laterally with the isthmus, which is 1–5 mm wide and 3 cm long, and is rounded, muscular and firm. The isthmus is continuous laterally with the ampulla, the widest portion of the tube with a maximum luminal diameter of 1 cm. The ampulla is 5 cm long and has a thin wall and a tortuously folded luminal surface. Typically, fertilization takes place in its lumen. The ampulla opens into the trumpet-shaped infundibulum at the abdominal os. Fimbriae, numerous mucosal finger-like folds, 1 mm wide, are attached to the ends of the infundibulum and extend from its inner circumference beyond the muscular wall of the tube. One of these, the ovarian fimbria, is longer and more deeply grooved than the others, and is typically applied to the tubal pole of the ovary. At the time of ovulation, the fimbriae swell and extend as a result of engorgement of the vessels in the lamina propria, which aids capture of the released oocyte. All fimbriae are covered, like the mucosal lining throughout the tube, by a ciliated epithelium whose cilia beat towards the ampulla.

Fig. 77.27 Laparoscopic view of the origin of the uterine tube from the uterus.

Vascular supply and lymphatic drainage

Arteries

The blood supply to the uterine tubes is derived from ovarian and uterine arteries. The lateral third of the tube is supplied by the ovarian artery, which continues in the mesosalpinx to anastomose with branches from the uterine artery. The medial two-thirds of the tube is supplied by the uterine artery.

Veins

Venous drainage is similar to the arterial supply. The venous drainage of the lateral two-thirds of the uterine tube is via the pampiniform plexus to the ovarian veins which open into the inferior vena cava on the right side and the renal vein on the left side. The medial two-thirds of the tube drain via the uterine plexus to the internal iliac vein.

Lymphatic drainage

Lymph drainage is via ovarian vessels to the para-aortic nodes and uterine vessels to the internal iliac chain. It is possible for lymph to reach the inguinal nodes via the round ligament.

Innervation

The uterine tube is innervated by autonomic fibres that are distributed mainly with the ovarian and uterine arteries. Most of the tube has a dual sympathetic and parasympathetic supply. Preganglionic parasympathetic fibres are derived from the vagus for the lateral half of the tube, and pelvic splanchnic nerves for the medial half. Sympathetic supply is derived from neurones in the tenth thoracic to the second lumbar spinal segments. Visceral afferent fibres travel with the sympathetic nerves, and enter the cord through corresponding dorsal roots: they may also travel with parasympathetic fibres. The ampullary submucosa contains modified Pacinian corpuscles.

Microstructure

The walls of the uterine tubes show typical visceral mucosal, muscular and serosal layers (Fig. 77.28). The mucosa is thrown into longitudinal folds, which are most pronounced distally at the infundibulum and decrease to shallow bulges in the intrauterine (intramural) portion. The mucosa is lined by a single-layered, tall, columnar epithelium, which contains mainly ciliated cells and secretory (peg) cells (so-called because they project into the lumen further than their ciliated neighbours), and occasional intraepithelial lymphocytes. In the tube, ciliated cells predominate distally and secretory cells proximally. Their activities vary with the stage in the menstrual cycle and with age. Secretory cells are most active around the time of ovulation. Their secretions include nutrients for the gametes and aid capacitation of the spermatozoa. Ciliated cells increase in height and develop more cilia in the oestrogenic first half of the menstrual cycle. Their cilia waft the oocyte from the open-ended infundibulum towards the uterus in fluids secreted by the peg cells. The epithelium regresses in height towards the end of the cycle and postmenopausally, when ciliated cells are reduced in number.

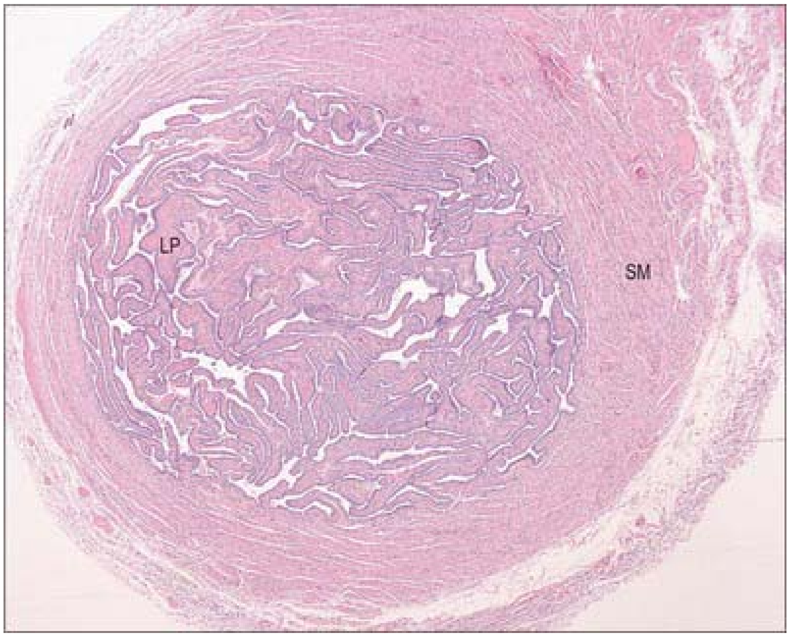

Fig. 77.28 Uterine tube (ampulla) with the mucosal lining thrown into extensive folds that fill the lumen. The superficial epithelium includes both secretory and ciliated cells, covering a lamina propria (LP). Smooth muscle (SM) occupies the wall of the tube.

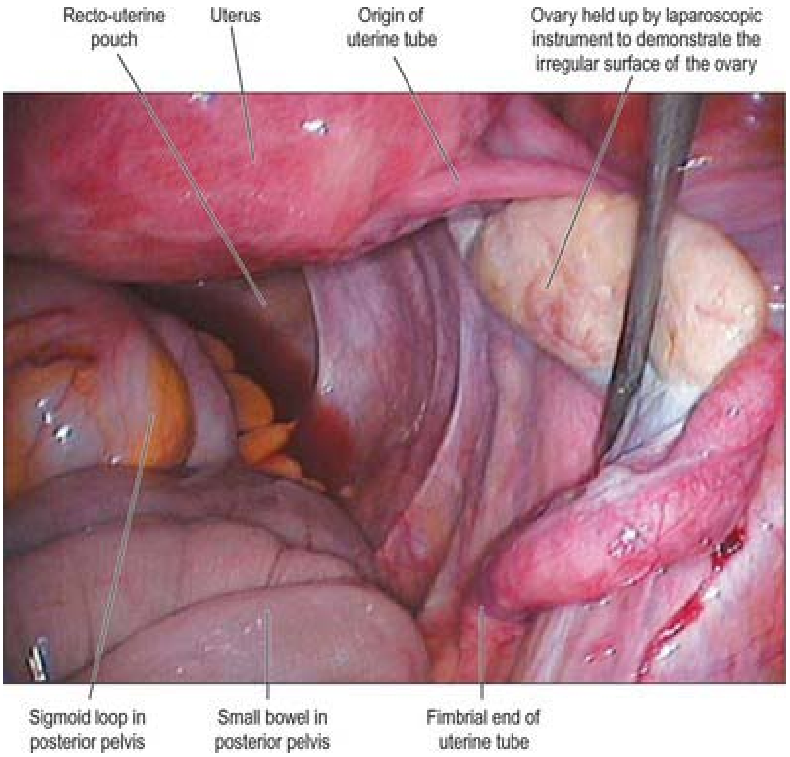
(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

The lamina propria provides vascular connective tissue support and abundant lymphatic drainage vessels. The smooth muscle of the muscularis is arranged as an inner circular, or spiral, layer and an outer, thinner, longitudinal layer. Together, their contractile activity produces peristaltic movements of the tube, which assist propulsion of the gametes and the fertilized ovum. The uterine tubes are covered externally by a highly vascular serosa.

OVARIES

In the adult non-pregnant state, the ovaries lie on each side of the uterus close to the lateral pelvic wall, suspended in the pelvic cavity by a double fold of peritoneum, the mesovarium, which is attached to the upper limit of the posterior aspect of the broad uterine ligament. They are dull white in colour and consist of dense fibrous tissue in which ova are embedded. Before regular ovulation begins they have a smooth surface, but thereafter their surfaces are distorted by scarring that follows the degeneration of successive corpora lutea (Fig. 77.29). Their average dimensions are 4 × 2 × 3 cm in reproductively mature women; they more than double their size during pregnancy. In the neonate, their dimensions are 1.3 × 0.6 × 0.4 cm. Prior to the first menstrual period (menarche) the ovaries are about a third of the normal reproductive adult size; they gradually increase in size with body growth. After the menopause, the average size of the ovary reduces to 2.0 × 1.5 × 0.5 cm and further to 1.5 × 0.75 × 0.5 cm in late menopause.



Recto-uterine pouch
Uterus
Origin of uterine tube
Ovary held up by laparoscopic instrument to demonstrate the irregular surface of the ovary
Sigmoid loop in posterior pelvis
Small bowel in posterior pelvis
Fimbrial end of uterine tube

Fig. 77.29 Laparoscopic picture of right ovary showing distorted surface.

The lateral surface of the ovary contacts parietal peritoneum in the ovarian fossa. Behind the ovarian fossa are retroperitoneal structures, including the ureter, internal iliac vessels, obturator vessels and nerve, and the origin of the uterine artery (Fig. 77.30). The medial surface faces the uterus and uterine vessels in the broad ligament, and the peritoneal recess here is termed the ovarian bursa. Above the superior extremity are the fimbria and distal section of the uterine tube. The inferior extremity points downwards towards the pelvic floor. The anterior border faces the posterior leaf of the broad ligament and contains the mesovarium. The posterior border is free and faces the peritoneum, which overlies the upper part of the internal iliac artery and vein, and the ureter. On the right side, superior and lateral to the ovary, are the ileocaecal junction, caecum and appendix. On the left side, the sigmoid colon passes over the superior pole of the ovary and joins the rectum, which lies between the medial surfaces of both ovaries. The mesosalpinx lies below the uterine tube. The ovarian ligament is inferior and medial. The mesovarium and ovary lie inferiorly at its fimbrial end. The round ligament is anterior to the tube. The superior and posterior surfaces of the tube lie free in the peritoneal cavity (Fig. 77.18).

In embryonic and early fetal life the ovaries are situated in the lumbar region near the kidneys. They gradually descend along the gubernaculum, stopping at the lesser pelvis. Accessory ovarian tissue may occur in the mesovarium or along the course of the gubernacula; rarely the ovaries may descend along the whole course of the gubernacula and are found in the labia majora. During pregnancy, the ovaries are lifted high in the pelvis and, by 14 weeks of gestation, become partly abdominal structures. By the third trimester they are totally abdominal structures and lie vertically behind and lateral to the parous uterus (see Ch. 78).

Peritoneal and ligamentous supports of the ovary

The peritoneal and ligamentous supports of the ovary consist of the infundibulopelvic, ovarian, and mesovarian ligaments.

Infundibulopelvic (suspensory) ligament

The suspensory or infundibulopelvic ligament of the ovary is a peritoneal fold, which is attached to the upper part of the lateral surface of the ovary. It contains the ovarian vessels and nerves. On the right side the infundibulopelvic ligament is attached to a fold of peritoneum that is posterior and inferior to the caecum and appendix. On the left side the peritoneal attachment is higher than on the right, and is lateral to the junction of the descending and sigmoid colons. As it joins the peritoneum which covers the psoas major, it passes superiorly over the external iliac vessels, genitofemoral nerve and ureter.

Ovarian ligament

The ovarian ligament attaches the uterine (inferiomedial) extremity of the ovary to the lateral angle of the uterus, posteroinferior to the uterine tube. It lies in the posterior leaf of the broad ligament and contains some smooth muscle cells. It is continuous with the medial border of the round ligament, both of which are remnants of the gubernaculum.

Mesovarium

The mesovarium is a short peritoneal fold which attaches the ovary to the back of the broad ligament. It carries blood vessels and nerves to the ovarian hilum. The uterine tube arches over the ovary, and ascends in relation to its mesovarian border, then curves over its tubal end and passes down on its posterior, free border and medial surface.

Vascular supply and lymphatic drainage

Arteries

The ovarian arteries are branches of the abdominal aorta and originate below the renal arteries. Each descends behind the peritoneum, and at the brim of the pelvis crosses the external iliac artery and vein to enter the true pelvic cavity. Here the artery turns medially in the ovarian suspensory ligament and splits into a branch to the mesovarium that supplies the ovary, and a branch that continues into the uterine broad ligament, below the uterine tube, and supplies the tube. There are variations in the site of the division to the ovary and tube (Fig. 77.21). On each side, a branch passes lateral to the uterus to unite with the uterine artery. Other branches accompany the round ligaments through the inguinal canal to the skin of the labium majus and the inguinal region. Early in intrauterine life the ovaries flank the vertebral column inferior to the kidneys, and so the ovarian arteries are relatively short, they gradually lengthen as the ovaries descend into the pelvis.

Veins

The ovarian veins emerge from the ovary as a plexus (pampiniform plexus) in the mesovarium and suspensory ligament (Fig. 77.3). Two veins emerge from the plexus and ascend with the ovarian artery: they usually merge into a single vessel before entering either the inferior vena cava on the right side, or the renal vein on the left side.

Lymphatic drainage

The main lymphatic drainage of the ovaries is along vessels that follow the ovarian veins to para-aortic nodes situated near the origin of the renal arteries. Drainage may also occur via pelvic nodes into lower para-aortic nodes, and rarely may follow the round ligament to the inguinal nodes.

Innervation

The ovarian innervation is derived from autonomic plexuses. The upper part of the ovarian plexus is formed from branches of the renal and aortic plexuses, and the lower part is reinforced from the superior and inferior hypogastric plexuses. These plexuses consist of postganglionic sympathetic, parasympathetic and visceral afferent fibres. The efferent sympathetic fibres are derived from the 10th and 11th thoracic spinal segments and are probably vasoconstrictor, whereas the parasympathetic fibres, from the inferior hypogastric plexuses, are probably vasodilator.

Microstructure

In young females the surface of the ovary is covered by a single layer of cuboidal epithelium, which contains some flatter cells. It appears dull white, in contrast to the shiny smooth peritoneal mesothelial covering of the mesovarium, with which it is continuous. A white line around the anterior mesovarian border usually marks the transition between peritoneum and ovarian epithelium. The surface epithelium is also termed the germinal epithelium, but this is a misnomer, because it is not the source of germ cells. Immediately beneath the epithelium there is a tough collagenous coat, the tunica albuginea. The ovarian tissue it surrounds is divisible into a cortex, which contains the ovarian follicles, and a medulla, which receives the ovarian vessels and nerves at the hilum.

Ovarian cortex

Before puberty, the cortex forms 35%, the medulla 20%, and interstitial cells up to 45%, of the volume of the ovary. After puberty the cortex forms the major part of the ovary, and encloses the medulla except at the hilum. It contains the ovarian follicles at various stages of development, and corpora lutea and their degenerative remnants, depending on age or stage of the menstrual cycle. The follicles and structures derived from them are embedded in a dense stroma composed of a meshwork of thin collagen fibres and fusiform fibroblast-like cells arranged in characteristic whorls. Stromal cells differ from fibroblasts in general connective tissue in that they contain lipid droplets, which accumulate in pregnancy. Stromal cells give rise to the thecal layers of maturing ovarian follicles. The theca interna becomes steroid-secreting in the corpus luteum.

Ovarian follicles

Primordial follicles

The development of ovarian follicles can be divided into different stages (Fig. 77.31). At birth, the ovarian cortex contains a superficial zone of primordial follicles. These consist of primary oocytes 25 μm in diameter, each surrounded by a single layer of flat follicular cells. The oocyte nuclei are slightly eccentric and have a characteristically prominent nucleolus. They contain the diploid number of chromosomes (duplicated as sister chromatids), arrested at the diplotene stage of meiotic prophase since before birth (Fig. 77.32). Many follicles degenerate either during prepubertal (including prenatal) life, or through atresia at some stage after beginning the process of cyclical maturation during the child-bearing period. Their remnants are visible as atretic follicles, the remains of which accumulate throughout the period of reproductive life. After puberty, cohorts of up to 20 primordial follicles become activated in each menstrual cycle (fewer are activated with advancing age). Their development takes a number of cycles. Of the follicles activated in each cohort, usually only one follicle from one or other ovary becomes dominant, reaches maturity and releases its oocyte at ovulation.

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Primary follicles

Primary follicles develop from primordial follicles. The first sign is a change in the follicle cells from flattened to cuboidal. This is followed by their proliferation to give rise to a multilayered follicle consisting of granulosa cells surrounded by a thick basal lamina (Fig. 77.33). Stromal cells immediately surrounding the follicle begin to differentiate into spindle-shaped cells, which constitute the theca folliculi which will become the theca interna. They are later surrounded by a more fibrous layer called the theca externa. At the same time the oocyte increases in size and secretes a thick layer of extracellular proteoglycan-rich material, the zona pellucida, between its plasma membrane and the surrounding granulosa cells of the early follicle. This is important for the process of fertilization. The granulosa cells in contact with the zona pellucida send cytoplasmic processes radially inwards and these contact oocyte microvilli at gap junctions, indicating communication between them (see Motta et al 2003). The follicular cells, in particular the granulosa cells, which are in functional contact with each other through gap junctions, continue to proliferate and so the thickness of the late primary follicle wall increases.

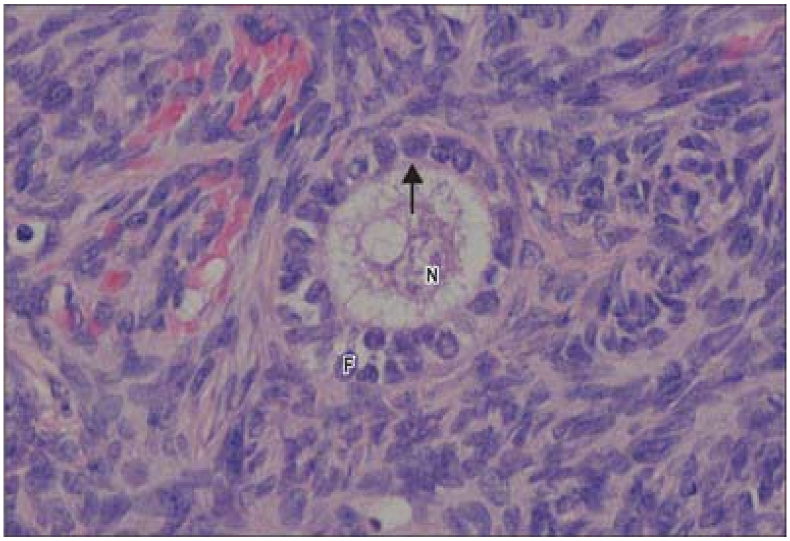

Fig. 77.33 High magnification micrograph of a primary follicle in a human ovarian cortex. The pale oocyte, with its eccentric nucleus (N) is separated from the follicle (F) by the zona pellucida (arrow). Cells of the follicle wall are in the early stages of proliferation to form a multilayered, late primary follicle.

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Secondary (antral) follicles

Secondary (antral) follicles develop from primary follicles. The number of granulosa cells continues to increase. Cavities begin to form between them filled with a clear fluid (liquor folliculi) containing hyaluronate, growth factors, and steroid hormones secreted by the granulosa cells. The follicle is now about 200 μm in diameter and usually lies deep in the cortex. These cavities coalesce to form one large fluid-filled space, the antrum. This is surrounded by a thin, uniform layer of granulosa cells, except at one pole of the follicle where a thickened granulosa layer envelops the eccentrically placed oocyte, to form the cumulus oophorus. The oocyte has now reached its maximum size of about 80 μm and the inner and outer thecae are clearly differentiated (Fig. 77.34). As follicles mature, the theca interna becomes more prominent and its cells more rounded and typical of steroid-secreting endocrine cells. These cells produce androstenedione from which the granulosa cells synthesize oestrogens (primarily oestradiol). Follicular development is stimulated by follicle-stimulating hormone (FSH).

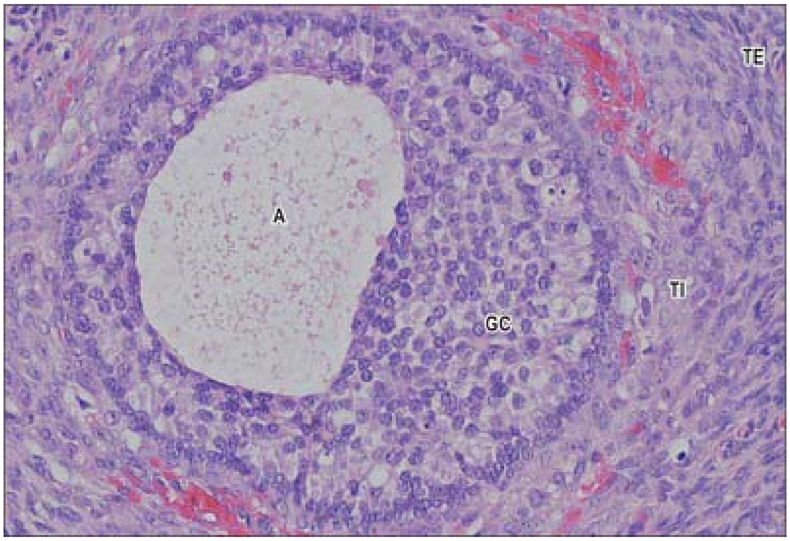

Fig. 77.34 Antral (secondary) follicle, showing the layers of the developing follicle wall. Granulosa cells (GC) enclose the antrum (A) filled with liquor folliculi and surround the oocyte (not seen in the plane of section) within an eccentric cellular mass (right). The outer theca interna (TI) is a highly vascular layer which develops steriod secretory activity and is enclosed by the outermost theca externa (TE).

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Tertiary (Graafian) follicle

Although a number of follicles may progress to the secondary stage by about the first week of a menstrual cycle, usually only one tertiary follicle develops. The remainder become atretic. The surviving follicle increases considerably in size as the antrum takes up fluid from the surrounding tissues and expands to a diameter of 2 cm. The term Graafian follicle is often used to describe this mature follicular stage (Fig. 77.34). The oocyte and a surrounding ring of tightly adherent cells, the corona radiata, breaks away from the follicle wall and floats freely in the follicular fluid. The primary oocyte, which has remained in the first meiotic prophase since fetal life, completes its first meiotic division to produce the almost equally large secondary oocyte and a small first polar body with very little cytoplasm. The secondary haploid oocyte immediately begins its second meiotic division, but when it reaches metaphase, the process is arrested until fertilization has occurred. The follicle moves to the superficial cortex, causing the surface of the ovary to bulge. The tissues at the point of contact (the stigma) with the tough tunica albuginea and ovarian surface epithelium are eroded until the follicle ruptures and its contents are released into the peritoneal cavity for capture by the fimbria of the uterine tube. The oocyte at ovulation is still surrounded by its zona pellucida and corona radiata of granulosa cells. If fertilization does not occur, it begins to degenerate after 24 to 48 hours.

Corpus luteum

After ovulation, the remainder of the follicle becomes the corpus luteum (Fig. 77.35). The walls of the empty follicle collapse and fold. The granulosa cells increase in size and synthesize a cytoplasmic carotenoid pigment (lutein) giving them a yellowish colour (hence corpus luteum). These large (30–50 μm) granulosa lutein cells form most of the corpus luteum. The basal lamina surrounding the follicle breaks down, and numerous smaller theca lutein cells infiltrate the folds of the cellular mass, accompanied by capillaries and connective tissue. Extravasated blood from thecal capillaries accumulates in the centre as a small clot, but this rapidly resolves and is replaced by connective tissue. All lutein cells have a cytoplasm filled with abundant smooth endoplasmic reticulum, characteristic of steroid synthesizing endocrine cells. Granulosa lutein cells secrete progesterone and oestradiol (from aromatization of androstenedione, which is synthesized by theca lutein cells). The two cell types also respond differently to circulating gonadotropins. Theca lutein cells express receptors for human chorionic gonadotrophin (hCG). If the oocyte is not fertilized, the corpus luteum (of menstruation) functions for 12 to 14 days after ovulation, then atrophies. The lutein cells undergo fatty degeneration, autolysis, removal by macrophages and gradual replacement with fibrous tissue. Eventually, after 2 months, a small, whitish scar-like corpus albicans is all that remains.

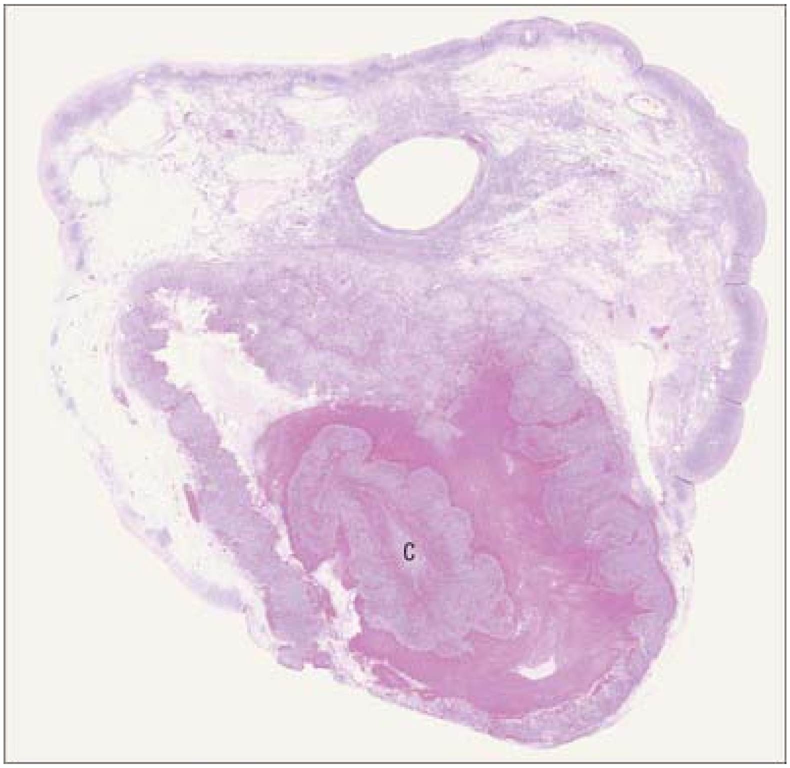

Fig. 77.35 Low power view of a section of a human ovary, containing a corpus luteum (C).

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

If fertilization does occur, implantation of the blastocyst into the uterine endometrium usually begins seven days later and the embryonic trophoblast then starts to produce hCG. The chorionic gonadotrophin stimulates the corpus luteum of menstruation to grow, and it becomes a corpus luteum of pregnancy. It normally increases in size from 10 mm in diameter to 25 mm at 8 weeks of gestation and can be seen clearly on ultrasound. It secretes progesterone, oestrogen and relaxin, and functions throughout pregnancy, although it gradually regresses as its endocrine functions are largely replaced by the placenta after 8 weeks gestation. Its diameter is reduced by the end of pregnancy to 1 cm. In the next few months it degenerates, like the corpus luteum of menstruation, to form a corpus albicans.

Ovarian medulla

The medulla is highly vascular. It contains numerous veins and spiral arteries, which enter the hilum from the mesovarium and lie within a loose connective tissue stroma. Small numbers of cells (hilus cells) with characteristics similar to interstitial (Leydig) cells in the testis are found in the medulla at the hilum, and they may be a source of androgens.

Menopause

At the menopause, ovulation ceases and various microscopic changes ensue within the ovarian tissues. The stroma becomes denser, the tunica albuginea thickens and the ovarian surface epithelium thins. However, many follicles persist within the cortex.

MENSTRUAL CYCLE

The uterus, ovaries and vagina undergo change during the menstrual cycle. The normal cycle is 28 days. A follicle begins a period of rapid development in the ovary on day 1 of the cycle, and matures and ruptures on day 14 to release a secondary oocyte. The wall of the follicle is then transformed into the corpus luteum, which secretes progesterone (luteal phase). About 10 days after ovulation the corpus luteum begins to regress, then ceases to function and is replaced by fibrous tissue. The breakdown of the endometrium that follows this cessation of function is due to the reducing levels of progesterone and oestrogen as the corpus luteum degenerates.

The changes that occur in the endometrium during the menstrual cycle may be divided into three phases: proliferative, secretory and menstrual (Fig. 77.36).

The ten lower panels are histological sections of endometrium at the cycle times indicated (low magnification on top and high magnification below in each case).

PROLIFERATIVE PHASE

In the early proliferative phase, even before the menstrual flow ceases, the epithelium from the persisting basal parts of the uterine glands grows over the surface of the endometrium which has been denuded by menstruation. Re-epithelialization is complete 5 to 6 days after the start of menstruation. Initially the tissue is only 1–2 mm thick and lined by low cuboidal epithelium. The glands are straight and narrow and their lining cells are short columnar. The apical cell surface contains microvilli; some cells are ciliated. The stroma is dense and contains small numbers of lymphocytes. During days 10 to12 of the proliferative phase, the endometrium thickens. Cells divide in response to rising levels of oestrogen which is produced by the ovary and which acts through receptors present on both the stromal and epithelial cells. The glands become tortuous and their lining epithelial cells become tall columnar in nature.

SECRETORY PHASE

The secretory phase coincides with the luteal phase of the ovarian cycle. The endometrial changes are driven by progesterone and oestrogen secreted by the corpus luteum. Steroid receptors in the endometrium activate a programme of new gene expression that produces, in the following 7 days, a highly regulated sequence of differentiative events, presumably required to prepare the tissue for blastocyst implantation. Part of the response is direct, but there is evidence that some of the effects may be mediated through growth factors. The first morphological effects of progesterone are evident 24 to 36 hours after ovulation (which occurs 14 days before the next menstrual flow). In the early secretory phase, glycogen masses accumulate in the basal cytoplasm of the epithelial cells lining the glands, where they are often associated with lipid. Giant mitochondria appear and are associated with semi-rough endoplasmic reticulum. There is an obvious increased polarization of the gland cells: nuclei are displaced towards the centre of the cells and Golgi apparatus and secretory vesicles accumulate in the supranuclear cytoplasm. The nuclear channel system is prominent and nuclei enlarge. Nascent secretory products may be detected immunohistochemically within the cells. Progestational effects on the stroma (known as the decidual reaction) are also evident in the early secretory phase. Nuclear enlargement occurs and the packing density of the resident stromal cells increases, due in part to the increase in volume of gland lumina and onset of secretory activity in the epithelial compartment.

By the mid-secretory phase the endometrium may be up to 6 mm deep. The basal epithelial glycogen mass is progressively transferred to the apical cytoplasm, and nuclei return to the cell bases. The Golgi apparatus becomes dilated and products including glycogen, mucin and other glycoproteins are released from the glandular epithelium into the lumen by a combination of apocrine and exocrine mechanisms: this activity reaches a maximum 6 days after ovulation. These secretory changes are considerably less pronounced in the basal gland cells and the luminal epithelium than in the glandular cell population of the stratum functionalis. There is a notable stromal oedema and a corresponding decrease in the density of collagen fibrils. At the same time the endoplasmic reticulum and Golgi apparatus become more prominent; there is evidence for collagen synthesis and degradation, presumably reflecting ongoing matrix remodelling.

In the late secretory phase, glandular secretory activity declines. Decidual differentiation occurs in the superficial stromal cells that surround blood vessels: this transformation includes nuclear rounding and an increased cytoplasmic volume, reflecting an increase in and dilatation of the rough endoplasmic reticulum and Golgi systems, and cytoplasmic accumulation of lipid droplets and glycogen. The cells begin to produce basal lamina components including laminin and type IV collagen.

Ultrasound is frequently used in the clinical evaluation of the endometrium. In the early secretory phase the endometrium is identified as a thin echogenic line, a consequence of specular reflection from the interface between opposing surfaces of endometrium. During the late proliferative phase the endometrium appears as a triple layer: a central echogenic line (due to the opposed endometrial surfaces), surrounded by a thicker hypoechoic functional layer, and bounded by an outer echogenic basal layer. During the secretory phase the functional layer surrounding the echogenic line becomes more hyperechoic as a result of the increased mucus and glycogen within the glands and the increased number of interfaces caused by the development of tortuous spiral arteries (Fig. 77.37).

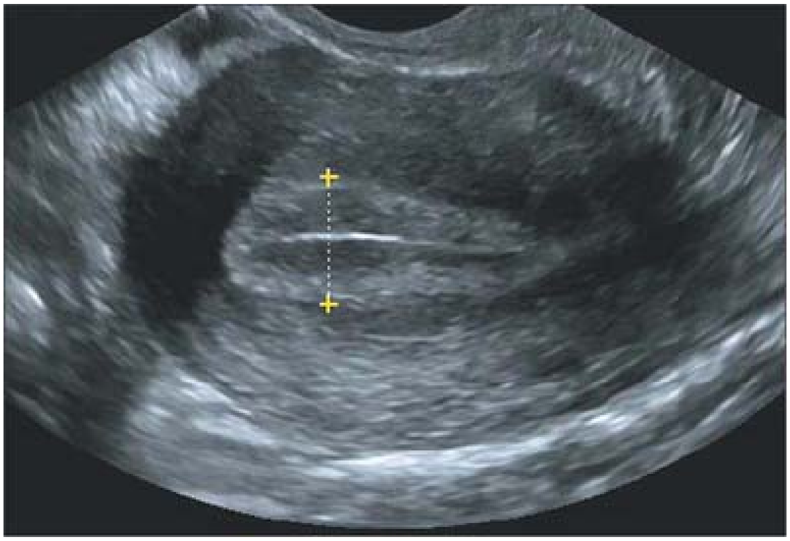

Fig. 77.37 Transvaginal ultrasound of the uterus showing the triple-layered endometrium. The central echogenic line is produced by the interface of the opposing surfaces of the endometrium. The functional layer of the endometrium surrounding the echogenic line is hypoechoic on the left, in keeping with late proliferative phase, but is becoming more hyperechoic on the right indicating the early secretory phase.

MENSTRUAL PHASE

Prior to menstruation three layers can be recognized in the endometrium: the strata compactum, spongiosum and basale. In the stratum compactum, which is next to the free surface, the necks of the glands are only slightly expanded and the stromal cells show a distinct decidual reaction. In the stratum spongiosum, the uterine glands are tortuous, dilated and ultimately only separated from one another by a small amount of interglandular tissue. The stratum basale, next to the uterine muscle, is thin and contains the tips of the uterine glands embedded in an unaltered stroma.

The two upper strata are often grouped together as the functional layer, stratum functionalis, of the endometrium; the lower (basal) layer is called the stratum basalis. As regression of the corpus luteum occurs, those parts of the stroma showing a decidual reaction, together with the glandular epithelium, undergo degenerative changes and the endometrium often diminishes in thickness. Blood escapes from the superficial vessels of the endometrium forming small haematomata beneath the surface epithelium (see below). The stratum functionalis, next to the free surface, is shed piecemeal, leaving mainly the stratum basalis, adjacent to the uterine muscle: 65–75% of the thickness of the endometrium may be shed. Blood and necrotic endometrium then begin to appear in the uterine lumen, to be discharged from the uterus through the vagina as the menstrual flow, which lasts from 3 to 6 days. The amount of tissue lost is variable, but usually the stratum compactum and most of the spongiosum are desquamated.

VASCULAR CHANGES WITHIN THE UTERUS DURING THE MENSTRUAL CYCLE

The vascular bed of the endometrium undergoes significant changes during the menstrual cycle. The arteries to the endometrium arise from a myometrial plexus and consist of short, straight vessels to the basal portion of the endometrium and more muscular spiral arteries to its superficial two-thirds. The venous drainage, consisting of narrow perpendicular vessels that anastomose by cross branches, is common to both the superficial and basal layers of the endometrium. The capillary bed consists of an endothelium with a basal lamina that is discontinuous in the proliferative phase, but becomes more distinct by the mid-secretory phase. Pericytes are present, some of which resemble smooth muscle cells, and these are sometimes enclosed within the basal lamina. The pericytes make contact with the endothelial cells by means of cytoplasmic extensions that project through the basal lamina. Enlargement of the pericytes starts in the early secretory phase, and leads to a conspicuous cuff of cells in the mid- and late-secretory phases. The arterial supply to the basal part of the endometrium remains unchanged during the menstrual cycle. However, the spiral arteries to the superficial strata lengthen disproportionately. They become increasingly coiled and their tips approach the uterine epithelium more closely. This leads to a slowing of the circulation in the superficial strata with some vasodilation. Immediately before the menstrual flow, these vessels begin to constrict intermittently, causing stasis of the blood and anaemia of the superficial strata. During the periods of relaxation of the vessels, blood escapes from the devitalized capillaries and veins, causing the menstrual blood loss. The breakdown of the endometrium is a consequence of the reducing levels of progesterone and oestrogen as the corpus luteum degenerates.

PREGNANCY AND PARTURITION

During pregnancy many morphological changes occur in the female reproductive system and associated abdominal structures. The uterus enlarges to accommodate the developing fetus and placenta, and various alterations take place in the pelvic walls, floor and contents which allow for this expansion, and which anticipate parturition. At the end of gestation, dramatic changes occur that facilitate the passage of the baby through the birth canal and subsequently allow the pelvic organs to return to the non-pregnant state (involution).

THE UTERUS IN PREGNANCY

The function of the uterus in pregnancy is to retain the developing fetus and to provide a protected environment until a stage at which the fetus is capable of surviving *ex utero*. The uterus must grow, facilitate delivery of the fetus and then involute. At the same time smooth muscle cells must be stretched by the growing fetus without producing miscarriage or premature labour.

The uterus grows dramatically during pregnancy, increasing in weight from about 50 g at the beginning of pregnancy to up to 1 kg at term. Most of the weight gain is the result of increased vascularity and fluid retention in the myometrium. The increased growth of the uterine wall is driven by a combination of mechanical stretching and endocrine input. The mechanical load that the growing fetus imposes on the uterine wall induces hypertrophy of uterine smooth muscle cells, and is the major stimulus that increases smooth muscle mass. Some hyperplasia occurs early on in pregnancy, mainly from the growth of the media of the myometrial arteries and veins. The myometrium is relatively unresponsive to additional endocrine stimulation during most of pregnancy, a relative quiescence that is in part attributed to progesterone. However, a number of growth factors, e.g. insulin-like growth factor-1 (IGF-1), have been identified which interact with oestrogen in promoting uterine growth. The myometrium thins with advancing gestation from 2–3 cm thick in early pregnancy to 1–2 cm at term.

The upper third of the cervix (isthmus) is gradually taken up into the uterine body during the second month to form the ‘lower segment’ (Fig. 77.38). The isthmus hypertrophies like the uterine body during the first trimester and triples in length to about 3 cm. From the second trimester the wall of the isthmus and that of the body are the same thickness and their junction is no longer visible externally. This condition persists until the middle of the third trimester when the junction between the body and the isthmus can sometimes be recognized as a transverse linear depression; the musculature above the depression is thicker than that below. The depression forms just below the vesico-uterine pouch and is thought to correspond to the level of the anatomical internal os (upper margin of lower segment). It is the anatomical landmark used at the time of a lower segment caesarean section to ensure that the uterine incision is not in the body of the uterus. The lower segment is less vascular than the upper part of the uterus. Moreover, the risk of rupture of a lower segment uterine scar in subsequent pregnancies is significantly reduced compared to rupture of a scar in the body of the uterus (classical caesarean section).

stages in gestation. The isthmus forms the lower uterine segment with advancing gestation.

Growth of the uterus in pregnancy

Anatomical surface landmarks can be used to estimate uterine size and therefore gestational age. The uterus is usually palpable just above the pubic symphysis by the 12th week; if is retroverted it may not be palpable in the abdomen until a little later. By the 20th week of pregnancy the uterine fundus is at the level of the umbilicus, and by 36 weeks the fundus has reached the xiphisternum. In practice the gestational age is now calculated by ultrasound measurement of the fetal crown–rump length in the first trimester (Fig. 77.39). For women presenting after the first trimester, dating is less accurate and is based on measurement of the head circumference. Subsequent assessment of fetal size up to 24 weeks relies on abdominal palpation and correlating gestational age with anatomical landmarks. From 24 weeks of gestation serial measurement of the distance between the pubic symphysis and the uterine fundus is used. The symphysis–fundal height (SFH) measurement acts primarily as a screening method, and if there is a concern that the SFH is either above or below the normal range a more accurate assessment of fetal size and amniotic fluid volume is made using ultrasound. Dating of pregnancy based on fetal biometry rather than menstrual history has significantly reduced the number of pregnancies requiring induction of labour for post-term.

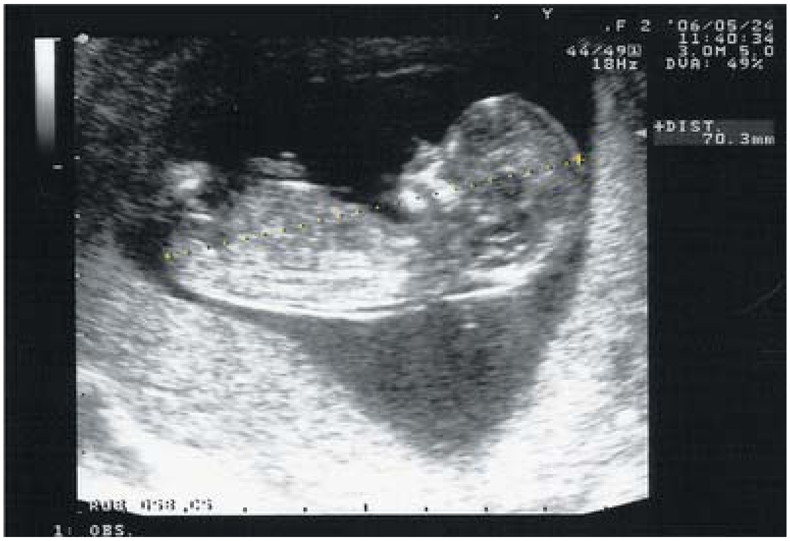

Fig. 77.39 Transabdominal ultrasound at 12 weeks showing measurement of the crown rump length to calculate the gestational age.

Doppler can be used to assess the placental and fetal circulations. Doppler assessment of the uterine arteries can play an important role in screening for impaired placentation and its complications of pre-eclampsia, intrauterine growth restriction and perinatal death, and assessment of the fetal circulation (e.g. umbilical artery, middle cerebral artery) can aid clinical management, such as timing of delivery in a growth restricted baby (Fig. 77.40A,B).

Cervix and pregnancy

The uterine cervix is required to serve two functions in relation to pregnancy and parturition. During pregnancy it is a relatively rigid fibromuscular structure which retains the developing fetus within the uterus. During active labour the cervix dilates to allow the fetus to descend through the birth canal.

Considerable softening and shortening of the cervix occurs in the weeks before the onset of labour; a corresponding increase in uterine activity is usually apparent during this pre-labour period. The rigidity of the cervix appears to be related to the orientation of its collagen fibres within a regular connective tissue matrix. The exact processes that allow softening, effacement and dilatation of the cervix are unclear, but are believed to include remodeling of the connective tissue matrix, probably mediated by an increase in the activity of enzymes such as matrix metalloproteinase 1, a reduction in collagen concentration, a significant increase in the water content in the cervix, an infiltration of macrophages and neutrophils, and an increased level of apoptosis.

The cervix can be viewed during pregnancy by transvaginal ultrasound examination. The cervical length, dilatation of the internal os and bulging of the membranes into the canal can be assessed (Fig. 77.41A,B). Measurement of cervical length on ultrasound appears to be a strong predictor of preterm labour: the shorter the cervix, the greater the risk of premature delivery. In clinical practice cervical length has been used to screen women at high risk of preterm labour or to screen symptomatic women in threatened preterm labour in order to plan appropriate management.

Relations of the uterus in pregnancy

With uterine expansion, the ovaries and uterine tubes are displaced upwards and laterally. The round ligaments become hypertrophied and their course from the cornual regions of the uterus down to the internal inguinal ring becomes more vertical. The broad ligament tends to open out to accommodate the massive increase in the sizes of the uterine and ovarian vessels. The uterine veins in particular can reach about 1 cm in diameter and they appear to act as a significant reservoir for blood during uterine contractions. Lymphatics and nerves expand their territories (the significance of this increased innervation is not clear, because paraplegic women are able to labour normally, albeit painlessly). Later in pregnancy the increase in intra-abdominal pressure produced by the gravid uterus may produce eversion of the umbilicus. On the skin over the abdomen, a combination of stretching and hormonal changes may produce stretch marks (striae gravidarum). In multiparous patients, separation (diverification) of right and left rectus abdominis may occur allowing the uterine fundus to fall forwards to some extent. In the supine position, the pregnant woman in late pregnancy is vulnerable to aorto-caval compression, as the gravid uterus presses on, and reduces blood flow in, the great vessels. Aorto-caval compression can cause symptoms of nausea and faintness; these symptoms are minimized if the woman lies on her left side thereby reducing compression of the inferior vena cava.

The jejunum, ileum and transverse colon tend to be displaced upwards by the enlarging uterus, whereas the caecum and appendix are displaced to the right, and the sigmoid colon posteriorly and to the left. Upward and lateral displacement of the appendix in later pregnancy can cause difficulties in the diagnosis of appendicitis. The ureters are pushed laterally by the enlarging uterus and in late pregnancy can be compressed at the level of the pelvic brim, resulting in hydronephrosis and loin pain. However, mild ureteric dilatation is normal in pregnancy, and is caused by progesterone-induced relaxation of smooth muscle in the ureteric walls. The axis of the uterus is shifted or dextrorotated by the presence of the sigmoid colon which may lead to inadvertent incision into large uterine vessels at the time of lower segment caesarean section unless the operator is aware of any such rotation.

PELVIC CHANGES IN PREGNANCY

The presence of a pregnant uterus results in a change in the centre of gravity of the body, especially in late pregnancy (Fig. 77.42). In order to compensate for this, the mother tends to straighten her cervical and thoracic spine, and throw her shoulders back, resulting in a compensatory lumbar lordosis. There is also a softening of the pubic symphysis and sacroiliac joints, caused by production of relaxin and other pregnancy hormones. This increased mobility produces a form of pelvic instability, so that the pregnant woman tends to walk with a waddling gait. Softening also produces an increase in pelvic diameter, which is of benefit during the time of labour. Significant joint relaxation can be associated with pain, called symphysis pubis diastasis: in severe cases radiographs show that when a woman stands on one leg the two halves of the symphysis are at different levels.

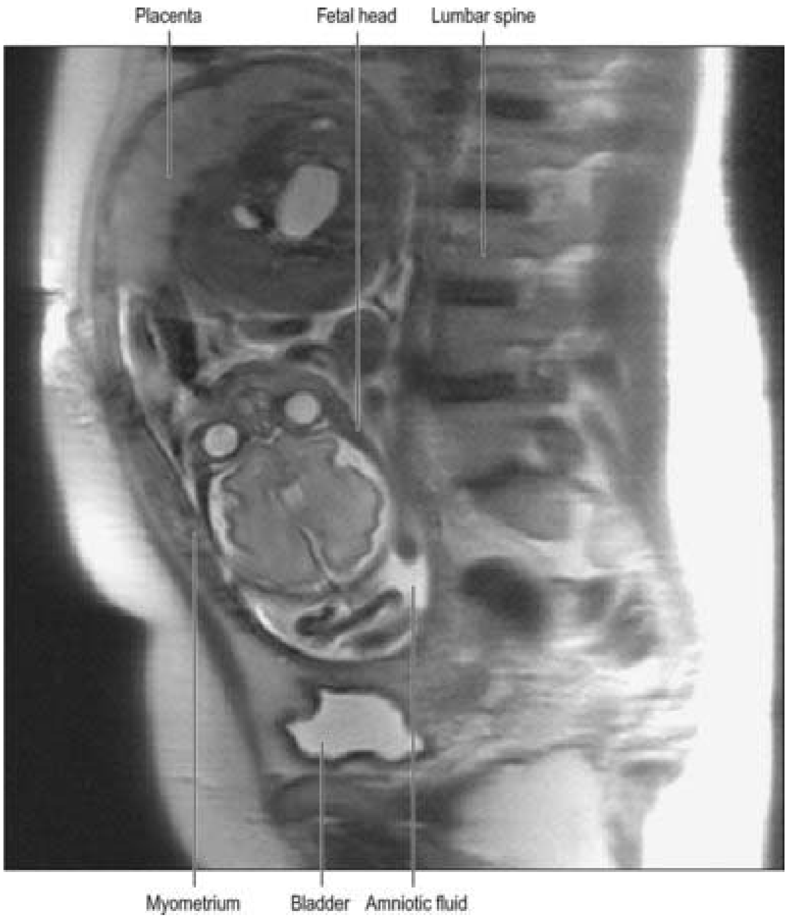

Fig. 77.42 Sagittal T2-weighted scan showing a normal cephalic presentation.

PLACENTAL LOCATION

The placenta may be attached at any point on the uterine wall. The site of attachment is determined by the point where the blastocyst becomes embedded: the factors on which this depends are not understood. In early pregnancy the placental disc occupies a large proportion of the uterine cavity and will often appear to be situated near the internal os. In the majority of cases growth and stretching of the uterus will usually draw the placenta upwards away from the cervix by the end of pregnancy.

In about 1% of pregnancies the position of the placenta will remain over, or in close proximity to, the internal cervical os at the end of pregnancy (Figs 77.41B, 77.43). This condition is called placenta praevia and is associated with vaginal bleeding during pregnancy and labour. If the placenta covers the internal os, or the lower edge is less than 2 cm from the internal os, delivery by caesarean section is likely to be needed. Women with placenta praevia are at an increased risk of having a morbidly adherent placenta if they have an anterior placenta praevia and have had previous uterine surgery, e.g. caesarean section. Pathological forms of adherence or penetration include placenta accreta, where the placenta displays exceptional adherence to the decidua basalis; placenta increta, where the myometrium is invaded; and placenta percreta, when the invasion by placental tissue passes completely through the uterine wall (Fig. 77.44).

LABOUR

The onset of labour is defined as the combination of regular uterine contractions that are of sufficient intensity to produce progressive effacement and dilatation of the cervix. The process of labour is described in three main stages.

First stage

This is the period during which the cervix dilates as it is drawn up into the lower portion of the uterus until there is no longer any cervix palpable on vaginal examination. There is little change in the uterine volume, because myometrial contractions are isometric and so there is minimal shortening of the muscle fibres. Progress is determined by the equilibrium between forces generated by myometrial contractions, especially from the fundus, and the resistance of the cervix. The ‘give’ from a compliant cervix attenuates the tension generated by the myometrium, which means that a compliant cervix not only dilates quickly but does so with less uterine activity.

Second stage

This begins once the cervix is fully dilated, and ends with the delivery of the baby. Cervical resistance is lost and myometrial activity results in isometric contractions that aid descent of the baby in the birth canal. The second stage is usually divided into a passive phase where there is descent of the presenting part and an active phase which starts with maternal pushing and results in delivery of the baby. The head of the baby usually enters the pelvis with the occiput facing laterally. As the head descends further, the occiput contacts the gutter-shaped pelvic floor formed by levator ani and this promotes flexion and rotation of the occiput to the anterior position. With further descent the occiput escapes under the symphysis pubis and the head is born by extension. At this point, the baby’s head regains its normal relationship with its shoulders, and slight rotation (or restitution) of the head is seen. Further external rotation occurs as the leading shoulder is directed medially by the maternal pelvic floor. The body of the baby is now born by lateral flexion as one shoulder slips underneath the symphysis and the posterior shoulder is drawn over the frenulum.

Third stage

This is the time from delivery of the fetus until delivery of the placenta. Prior to separation of the placenta, a large proportion of the mother's cardiac output passes through the uterine circulation. After separation in the third stage of labour, maternal exsanguination is only prevented by marked uterine contraction: the criss-crossing myometrial fibres act as a tourniquet, restricting blood flow to the area that was the placental site. This process is usually expedited clinically by the administration of oxytocic drugs in an attempt to limit maternal blood loss. Any condition that predisposes to poor uterine contraction, such as retained placental tissue, will increase the likelihood of haemorrhage immediately after delivery (postpartum haemorrhage).

The placenta after delivery

Separation of the placenta from the uterine wall takes place along the plane of the stratum spongiosum. It extends beyond the placental area, detaching the villous placenta, with associated fibrinoid matrix and small amounts of decidua basale, the chorio-amnion, together with a superficial layer of the fused decidua capsularis, and the decidua parietalis. When the placenta and membranes have been expelled, a thin layer of stratum spongiosum is left as a lining for the uterus: it soon degenerates and is cast off in the early part of the puerperium. A new epithelial lining for the uterus is regenerated from the remaining stratum basale. The expelled placenta is a flattened discoid mass with an approximately circular or oval outline (Fig. 77.45). It has an average volume of 500 ml (range 200–950 ml), a weight of 470 g (range 200–800 g), a diameter of 185 mm (range 150–200 mm), a thickness of 23 mm (range 10–40 mm), and a surface area of approximately 30,000 mm^2. It is thickest at its centre (the original embryonic pole), and rapidly thins towards its periphery where it continues as the chorion laeve.

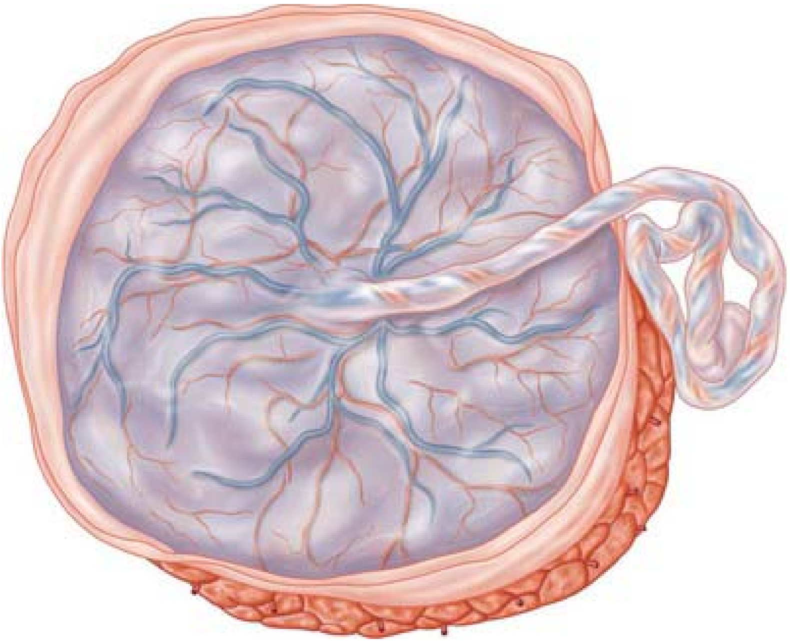

Fig. 77.45 The fetal surface of a recently delivered placenta. The spiral umbilical vessels in the umbilical cord and their radiating branches shine through the transparent amnion. The maternal surface is exposed in the lower and right corner of the figure. Note the fringes of amnion and chorion, the majority of which have been cut away near the placental margin.

Macroscopically, the fetal or inner surface, covered by amnion, is smooth, shiny and transparent, so that the mottled appearance of the subjacent chorion, to which it is closely applied, can be seen. The umbilical cord is usually attached near the centre of the fetal surface, and branches of the umbilical vessels radiate out under the amnion from this point; the veins are deeper and larger than the arteries. The maternal surface of the placenta is finely granular and mapped into some 15–30 lobes by a series of fissures or grooves. The placental lobes, which are often somewhat loosely termed cotyledons, correspond in large measure to the major branches of the umbilical vessels. The grooves correspond to the bases of incomplete placental septa, which become increasingly prominent from the third month onwards. They extend from the maternal aspect of the intervillous space (the basal plate) towards, but do not quite reach, the chorionic plate. The septa are complex structures composed of components of the cytotrophoblastic shell and residual syncytium, together with maternally derived material including decidual cells, occasional blood vessels and gland remnants, collagenous and fibrinoid extracellular matrix and, in the later months of pregnancy, foci of degeneration.

In multiple pregnancies the number of placentas is determined by the zygosity. Dizygotic pregnancies will always have two placentas (dichorionic); monozygotic pregnancies usually have a single placenta (monochorionic) but 33% will have two placentas. The number of placentas in monozygotic pregnancies is determined by the timing of splitting of the embryonic mass. If the single embryonic mass splits into two within 3 days of fertilization, each fetus will have its own placenta and amniotic sac (dichorionic diamniotic); splitting after the 3rd day following fertilization results in a monochorionic diamniotic (two amniotic sacs) pregnancy and vascular communication within the two placental circulations (Fig. 77.46); splitting after the 9th day results in a single placenta and single amniotic sac (monochorionic monoamniotic); and splitting after the 12th day results in conjoined twins.

Placental variations

The umbilical cord is usually attached near the centre of the placenta. It may insert at any point between its centre and margin, a condition known as a battledore placenta (Fig. 77.47). Occasionally the cord fails to reach the placenta itself and ends in the membranes as a velamentous insertion. When insertion of the cord is velamentous, the larger branches of the umbilical vessels traverse the membranes before they reach and ramify on the placenta (Fig. 77.48). They travel unprotected through the membranes to the placenta, which puts the fetus at risk because compression or tearing of the vessels can disrupt blood flow to and from the fetus. This can be particularly problematic when the vessels present themselves across the cervical os, a condition called vaso previa. A small accessory (succenturiate) placental lobe is occasionally present, connected to the main organ by membranes and blood vessels. It may be retained *in utero* after delivery of the main placental mass and cause postpartum haemorrhage. Other variations include placenta membranacea, in which villous stems and their branches persist over the whole chorion; and placenta circumvallate, where the placental margin is undercut by a deep groove (Fig. 77.49A,B).

CHAPTER 78

Development of the urogenital system

URINARY SYSTEM

The urinary and reproductive systems develop from intermediate mesenchyme and are intimately associated with one another especially in the earlier stages of their development. The urinary system develops ahead of the reproductive or genital systems.

Intermediate mesenchyme is disposed longitudinally in the trunk, subjacent to the somites (in the folded embryo), at the junction between the splanchnopleuric mesenchyme (adjacent to the gut medially) and the somatopleuric mesenchyme (subjacent to the ectoderm laterally) (Fig. 78.1). In lower vertebrates, intermediate mesenchyme typically develops serial, segmental epithelial diverticuli termed nephrotomes. Each nephrotome encloses a cavity, the nephrocele, which communicates with the coelom through a peritoneal funnel, the nephrostome (Fig. 78.2). The dorsal wall of a nephrotome evaginates as a nephric tubule. The dorsal tips of the cranial nephric tubules bend caudally and fuse to form a longitudinal primary excretory duct, which grows caudally and curves ventrally to open into the cloaca. The more caudally placed, and therefore chronologically later, tubules open secondarily into this duct or into tubular outgrowths from it. Glomeruli, specific arrangements of capillaries and overlying coelomic epithelium, arise from the ventral wall of the nephrocele (internal glomeruli) or the roof of the coelom adjacent to the peritoneal funnels (coelomic or external glomeruli), or in both situations (Fig. 78.2).

Fig. 78.2 Principal features of the primitive vertebrate nephric system for comparison with the development of the human nephric system. A considerable period of embryonic and fetal life has necessarily been compressed into a single diagram.

(Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd edn. Philadelphia: Lippincott.)

It has been customary to regard the renal excretory system as three organs, the pronephros, mesonephros and metanephros, succeeding each other in time and space, such that the last to develop is retained as the permanent kidney (Figs 78.1, 78.2). However, it is difficult to provide reliable criteria by which to distinguish these stages or to define their precise limits in embryos.

Pronephros

The intermediate mesenchyme becomes visible in stage 10 embryos and can be distinguished as a nephrogenic cord when 10 somites are present. A pronephros is present in human embryos only as clusters of cells in the most cranial portions of the nephrogenic cord (Figs 78.1, 78.2). More caudally, similar groups of cells appear and become vesicular. The dorsal ends of the most caudal of the vesicles join the primary excretory duct. Their central ends are connected with the coelomic epithelium by cellular strands, which probably represent rudimentary peritoneal funnels. Glomeruli do not develop in association with these cranially situated nephric tubules, which ultimately disappear. It is doubtful whether external glomeruli develop in human embryos.

Primary excretory duct

In stage 11 embryos of approximately 14 somites, the primary excretory duct can be seen as a solid rod of cells in the dorsal part of the nephrogenic cord. Its cranial end is about the level of the ninth somite and its caudal tip merges with the undifferentiated mesenchyme of the cord. It differentiates before any nephric tubules, and when the latter appear it is at first unconnected with them. In older embryos the duct has lengthened and its caudal end becomes detached from the nephrogenic cord to lie immediately beneath the ectoderm. From this level it grows caudally, independent of the nephrogenic mesenchyme, and then curves ventrally to reach the wall of the cloaca. It becomes canalized progressively from its caudal end to form a true duct, which opens into the cloaca in embryos at stage 12 (Fig. 78.1C). Clearly, up to this stage the name ‘duct’ is scarcely appropriate.

Mesonephros

From stage 12 mesonephric tubules, which develop from the intermediate mesenchyme between somite levels 8–20, begin to connect to the primary excretory duct, which is now renamed the mesonephric duct. More caudally, a continuous ridge of nephrogenic mesenchyme extends to the level of somite 24. The mesonephric tubules (nephrons) are not metameric – there may be two or more mesonephric tubules opposite each somite.

Within the mesonephros, each tubule first appears as a condensation of mesenchyme cells, which epithelialize and form a vesicle. One end of the vesicle grows towards and opens into the mesonephric duct, while the other dilates and invaginates. The outer stratum forms the glomerular capsule, while the inner cells differentiate into mesonephric podocytes, which clothe the invaginating capillaries to form a glomerulus. The capillaries are supplied with blood through lateral branches of the aorta. It has been estimated that 70–80 mesonephric tubules and a corresponding number of glomeruli develop. However, these tubules are not all present at the same time, it is rare to find more than 30–40 in an individual embryo, because the cranial tubules and glomeruli develop and atrophy before the development of those situated more caudally.

By the end of the sixth week each mesonephros is an elongated, spindle-shaped organ that projects into the coelomic cavity, one on each side of the dorsal mesentery, from the level of the septum transversum to the third lumbar segment. This whole projection is called the mesonephric ridge, mesonephros, or Wolffian body (Figs 78.1B,C, 78.3). It develops subregions, and a gonad develops on its medial surface (p. 1311). There are striking similarities in structure between the mesonephros and the permanent kidney or metanephros, but the mesonephric nephrons lack a segment that corresponds to the descending limb of the loop of Henle. The mesonephros is believed to produce urine by stage 17. A detailed comparison of the development and function of the mesonephros and metanephros in staged human embryos is not available.

(Redrawn with permission from Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)

In stage 18 embryos (13–17 mm) the mesonephric ridge extends cranially to about the level of rib 9. In both sexes the cranial end of the mesonephros atrophies, and in embryos 20 mm in length (stage 19) a mesonephros is found only in the first three lumbar segments, although it may still possess as many as 26 tubules. The most cranial one or two tubules persist as rostral aberrant ductules (see Fig. 78.13); the succeeding five or six tubules develop into either the efferent ductules of the testis and lobules of the head of the epididymis (male), or the tubules of the epoöphoron (female);

the caudal tubules form the caudal aberrant ductules and the paradidymis (male), or the paroöphoron (female) (p. 1313).

Mesonephric duct

Once mesonephric nephrons connect to the primary excretory duct it is renamed the mesonephric duct. This runs caudally in the lateral part of the nephric ridge, and at the caudal end of the ridge it projects into the cavity of the coelom in the substance of a mesonephric fold (Fig. 78.3). As the mesonephric ducts from each side approach the urogenital sinus the two mesonephric folds fuse, between the bladder ventrally and the rectum dorsally, forming a transverse partition across the cavity of the pelvis, which is somewhat inappropriately called the genital cord (Fig. 78.3). In the male the peritoneal fossa between the bladder and the genital cord becomes obliterated, but it persists in the female as the uterovesical pouch. In the male the mesonephric duct itself becomes the canal of the epididymis, vas deferens and ejaculatory duct (p. 1317).

Urogenital sinus

The primitive hindgut ends in a cloacal region. This is connected ventrally with a blind-ending diverticulum, the allantois, which is intimately related to the development of the caudal portion of the urinary system. The enteric and allantoic portions of the hindgut are separated by the proliferation of the urorectal septum, a partition of mesenchyme and endoderm in the angle of the junction of hindgut and allantois (Fig. 78.4; see Fig. 78.7). The endodermal epithelium beneath the mesenchyme of the urorectal septum approaches but does not fuse with the cloacal membrane: it effectively divides the membrane into anal (dorsal) and urogenital (ventral) membranes, and the cloacal region into dorsal and ventral portions. The dorsal portion of the cloacal region is the putative rectum. The ventral portion can be further divided into: a cranial vesicourethral canal, continuous above with the allantoic duct; a middle, narrow channel, the pelvic portion; and a caudal, deep, phallic section, which is closed externally by the urogenital membrane. The second and third parts together constitute the urogenital sinus.

The sinus tubercle is the elevation on the posterior wall of the urogenital sinus, caused by the fusion with the paramesonephric ducts.

Metanephros

The pronephros and mesonephros are linear structures. They both contain stacks of tubules distributed along the craniocaudal axis of the embryo, an arrangement that results in the production of hypotonic urine. In marked contrast, the tubules in the metanephric kidney are arranged concentrically, and the loops of Henle are directed towards the renal pelvis. This arrangement allows different concentration gradients to develop within the kidney and results in the production of hypertonic urine. Metanephric nephrons do not join with the existing mesonephric duct but with an evagination of that duct, which branches dichotomously to produce a characteristic pattern of collecting ducts.

The metanephric kidney develops from three sources. An evagination of the mesonephric duct, the ureteric bud, and a local condensation of mesenchyme, the metanephric blastema, form the nephric structure (Fig. 78.5). Angiogenic mesenchyme migrates into the metanephric blastema slightly later to produce the glomeruli and vasa recta. It is possible that an intact nerve supply is also required for metanephric kidney induction.

Fig. 78.5 Overview of metanephric kidney development. **A**, The ureteric bud arises from the mesonephric duct. The metanephric mesenchyme proliferates and separates with each subdivision of the ureteric bud. **B**, The metanephric mesenchyme converts to epithelia, forms comma and S-shaped vesicles which become metanephric nephrons. **C**, All stages of metanephric development are present concurrently. The most recently formed nephrons are on the outer aspect of the kidney.

An epithelial/mesenchymal interaction between the duct system and the surrounding mesenchyme occurs in both mesonephric and metanephric systems. In the mesonephric kidney, development proceeds in a craniocaudal progression, and cranial nephrons degenerate before caudal ones are produced. In the metanephric kidney a proportion of the mesenchyme remains as stem cells that continue to divide and which enter the nephrogenic pathway later when the individual collecting ducts lengthen. The temporal development of the metanephric kidney is patterned radially, such that the outer cortex is the last part to be formed. The following interactions occur in the development of the metanephric kidney (Fig. 78.5). The ureteric bud undergoes a series of bifurcations within the surrounding metanephric mesenchyme, and forms smaller ureteric ducts. At the same time the metanephric mesenchyme condenses around the dividing ducts to form S-shaped clusters, which transform into epithelia and fuse with the ureteric ducts at their distal ends. Blood vessels invade the proximal ends of the S-shaped clusters to form vascularized glomeruli.

The ureteric bud bifurcates when it comes into contact with the metanephric blastema in response to extracellular matrix molecules synthesized by the mesenchyme. Both chondroitin sulphate proteoglycan synthesis and chondroitin sulphate glycosaminoglycan processing are necessary for the dichotomous branching of the ureteric bud. In metanephric culture, incubation of fetal kidneys in β-D-xyloside, an inhibitor of chrondroitin sulphate synthesis, dramatically inhibits ureteric bud branching.

Subsequent divisions of the ureteric bud and associated mesenchyme define the gross structure of the kidney and the major and minor calyces, the distal branches of the ureteric ducts that will form the collecting ducts of the kidney. The proximal position of the ureteric bud elongates to form the developing ureter (Fig. 78.6). As the collecting ducts elongate the metanephric mesenchyme condenses around them. An adhesion molecule, syndecan, can be detected between the mesenchymal cells in the condensate. The cells switch off expression of N-CAM, fibronectin and collagen I, and start to synthesize L-CAM (also called E cadherin) and the basal lamina constituents laminin and collagen IV. The mesenchymal clusters are thus converted to small groups of epithelial cells, which undergo complex morphogenetic changes. Each epithelial group elongates, and forms first a comma-shaped, then an S-shaped, body, which continues to elongate and subsequently fuses with a branch of the ureteric duct at its distal end, while expanding as a dilated sac at its proximal end (Fig. 78.5). The latter involutes, and cells differentiate locally such that the outer cells become the parietal glomerular cells, while the inner ones become visceral epithelial podocytes. The podocytes develop in close proximity to invading capillaries derived from angiogenic mesenchyme outside the nephrogenic mesenchyme. This third source of mesenchyme produces the endothelial and mesangial cells within the glomerulus. The (metanephric-derived) podocytes and the angiogenic mesenchyme produce fibronectin and other components of the glomerular basement membrane. The isoforms of type-IV collagen within this layer follow a specific programme of maturation as the filtration of macromolecules from the plasma becomes restricted.

(Redrawn from Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)

Platelet derived growth factor (PDGF) β-chain and the PDGF receptor β-subunit (PDGFR β) have been detected in developing human glomeruli between 54 and 109 days' gestation. PDGF β-chain is localized in the differentiating epithelium of the glomerular vesicle during its comma and S-shaped stages, while PDGFR β is expressed in the undifferentiated metanephric blastema, vascular structures and interstitial cells. Both PDGF β-chain and PDGFR β are expressed by mesangial cells, which may promote further mesangial cell proliferation.

Metanephric mesenchyme will develop successfully *in vitro*, which makes experimental perturbation of kidney development comparatively easy to evaluate. Early experimental studies demonstrated that other mesenchymal populations, and spinal cord, were able to induce ureteric bud division and metanephric development. Nerves enter the developing kidney very early, travelling along the developing ureter. If developing kidney rudiments are incubated with antisense oligonucleotides, which neutralize nerve growth factor receptor (NGF-R) mRNA, nephrogenesis is completely blocked, suggesting that metanephric mesenchyme induction is a response to innervation. The powerful inductive effect of the spinal cord on metanephric mesenchyme may be a further expression of this phenomenon.

All stages of nephron differentiation are present concurrently in the developing metanephric kidney (Fig. 78.5). Antigens for the brush border of the renal tubule appear when the S-shaped body has formed. They appear first in the inner cortical area.

The metanephric kidney is lobulated throughout fetal life, but this condition usually disappears during the first year after birth (see Fig. 78.8). Varying degrees of lobulation occasionally persist throughout life.

The growth of left and right kidneys is well matched during development. Fetal kidney volume increases most during the second trimester in both sexes. For reasons that are not understood, male fetuses show greater values for renal volume than female fetuses from the third trimester onwards.

Endocrine development of the kidney

The kidney functions not only as an excretory organ, but also as an endocrine organ, secreting hormones that are concerned with renal haemodynamics. Before birth homeostasis is controlled by the placenta. The fetal kidney produces amniotic fluid. The kidneys of premature babies of less than 36 weeks are immature. They contain incompletely differentiated cortical nephrons, which compromise their ability to maintain homeostasis. Problems of immaturity are further compounded by the effects of hypoxia and asphyxia, which modify renal hormones.

Renal hormones include the renin–angiotensin system, renal prostaglandins, the kallikrein–kinin system, and renal dopamine. Renin is found in the smooth muscle cells of arterioles, interlobular arteries and branches of the renal artery, and has also been described in the distal convoluted tubule cells. Kallikrein has been demonstrated in rat fetal kidney, and prostaglandins have been demonstrated in the renal medulla and renal tubule. Renal dopamine is produced (mainly) by the enzymatic conversion of L-dopa to dopamine in the early segments of the proximal convoluted tubule, and is also sourced locally from dopaminergic nerves. Other renal hormones include an antihypertensive lipid, which is produced in the interstitial cells of the renal medulla, and, possibly, histamine and serotonin. Growth factors produced by human embryonic kidney cells include erythropoietin and interleukin β (which stimulate megakaryocyte maturation) and transforming growth factor-β.

Ascent of the kidney

The metanephric kidney is initially sacral. As the ureteric outgrowth lengthens, it becomes positioned more and more cranially. The metanephric pelvis lies on a level with the second lumbar vertebra when the embryo reaches a length of about 13 mm. During this period the ascending kidney receives its blood supply sequentially from arteries in its immediate neighbourhood, i.e. the middle sacral and common iliac arteries. The definitive renal artery is not recognizable until the beginning of the third month. It arises from the most caudal of the three suprarenal arteries, all of which represent persistent mesonephric or lateral splanchnic arteries. Additional renal arteries are relatively common, and may enter at the hilum or at the upper or lower pole of the gland – they also represent persistent mesonephric arteries.

Ureter

The wall of the early ureter is initially highly permeable. Its lumen later becomes obliterated and is subsequently recanalized. Both of these processes begin in intermediate portions of the ureter and proceed cranially and caudally. Recanalization is not associated with metanephric function, but perhaps reflects the rapid elongation of the ureter as the embryo grows. Two fusiform enlargements appear at the lumbar and pelvic levels of the ureter at 5 and 9 months respectively (the pelvic enlargement is inconstant). As a result the ureter shows a constriction at its proximal end (pelviureteric region) and another as it crosses the pelvic brim. A third narrowing is always present at its distal end and is related to the growth of the bladder wall.

At first the distal end of the ureter is connected to the dorsomedial aspect of the mesonephric duct, but, as a result of differential growth, this connection comes to lie lateral to the duct.

Urinary bladder

The urinary bladder develops from the cranial vesicourethral canal, which is continuous above with the allantoic duct (Figs 78.4, 78.6, 78.7). The mesonephric ducts open into the urogenital sinus early in development. The ureters develop as branches of the mesonephric ducts, which attain their own access to the developing bladder, and their orifices open separately into the bladder on the lateral side of the opening of the mesonephric ducts. Later the two orifices become separated still further and, although the ureter retains its point of entry into the bladder, the mesonephric duct opens into that part of the urogenital sinus that subsequently becomes the prostatic urethra (Fig. 78.6). The triangular region of absorption of the mesonephric ducts contributes to the trigone of the bladder and dorsal wall of the proximal half of the prostatic urethra, i.e. as far as the opening of the prostatic utricle and ejaculatory ducts, or its female homologue, the whole female urethral dorsal wall. The remainder of the vesicourethral canal forms the body of the bladder and urethra, and its apex is prolonged to the umbilicus as a narrow canal, the urachus.

The fetal bladder can be identified by ultrasound examination at 9–11 weeks’ gestation and the absence of a bladder image is considered abnormal at 13 weeks or later.

Neonatal urinary system

At birth the two kidneys weigh approximately 23 g. They function early in development and produce the amniotic fluid that surrounds the fetus. The lobulated appearance of fetal kidneys is still present at birth (Fig. 78.8; see Fig. 14.4). Addition of new cortical nephrons continues in the first few months of postnatal life after which general growth of the glomeruli and tubules results in the disappearance of lobulation. The renal blood flow is lower in the neonate; adult values are attained by the end of the first year. The glomerular filtration rate at birth is approximately 30% of the adult value, which is attained by 3–5 months of age.

The neonatal urinary bladder is egg-shaped and the larger end is directed downwards and backwards (Figs 78.9, 78.10; see Figs 14.4, 14.5). Although described as an abdominal organ, nearly one half of the neonatal bladder lies below a line drawn from the promontory of the sacrum to the upper edge of the pubic symphysis, i.e. within the cavity of the true pelvis. From the bladder neck, the bladder extends anteriorly and slightly upwards in close contact with the pubis until it reaches the anterior abdominal wall. The apex of the contracted bladder lies at a point midway between the pubis and the umbilicus. When the bladder is filled with urine the apex may extend up to the level of the umbilicus. It is therefore possible to obtain urine by inserting a needle, connected to a syringe, into the bladder through the abdominal wall about 2 cm above the symphysis pubis and aspirating the contents into the sterile syringe. The success rate of the procedure is variable and depends upon the bladder being full: a much higher success rate has been reported by using an ultrasound scanner to locate the bladder and confirm that it contains urine prior to the insertion of the needle.

There is no true fundus in the fetal bladder as there is in the adult. Although the anterior surface is not covered with peritoneum, peritoneum extends posteriorly as low as the level of the urethral orifice. Because the apex of the bladder is relatively high, pressure on the lower abdominal wall will express urine from an infant bladder. Moreover, because the bladder remains connected to the umbilicus by the obliterated remains of the urachus (see Fig. 14.5), stimulation of the umbilicus can initiate micturition in babies.

The elongated shape of the bladder in neonates means that the ureters are correspondingly reduced in length and they lack a pelvic portion. The bladder does not gain its adult, pelvic, position until about the sixth year. A distinct interureteric fold is present in the contracted neonatal bladder.

Anomalies of the urinary system

Anomalies of the urinary system are relatively common (3% of live births). Renal agenesis is the absence of one or both kidneys. In unilateral renal agenesis, the remaining kidney exhibits compensatory hypertrophy and produces a nearly normal functional mass of renal tissue. Atresia of the ureter during development causes a non functional multicystic dysplastic kidney, thought to be secondary to urinary obstruction being present while the tubules are still forming. Problems with kidney ascent can result in a pelvic kidney. Alternatively, the kidneys may fuse together at their caudal poles producing a horseshoe kidney, which cannot ascend out of the pelvic cavity because the inferior mesenteric artery prevents further migration.

It was thought that renal cysts arose from clumps of vesicular cells, which persisted when the tips of branches from the ureteric diverticulum failed to fuse with metanephrogenic cap tissue. It is now believed that they are wide dilatations of a part of otherwise continuous nephrons. In most cases, autosomal dominant polycystic kidney disease results from mutations of *PKD1* or *PKD2* genes which are expressed in human embryos from 5–6 weeks of development within the mesonephros and later the metanephros (Chauvet et al 2002). In this condition the cystic dilatation may affect any part of the nephron, from Bowman’s capsule to collecting tubules. Less common is infantile cystic renal disease, inherited as a recessive trait, where the proximal and distal tubules are dilated to some degree but the collecting ducts are grossly affected.

Abnormalities of the ventral body wall caudal to the umbilicus, especially with inappropriate siting of the genital tubercle can result in exstrophy of the bladder (Fig. 78.11). In this condition the urorectal septum (internal) is associated with the genital tubercle (external), which means that the urogenital and anal membranes are widely separated. When the urogenital membrane involutes, the posterior surface of the bladder is exposed to the anterior abdominal wall. The lower part of the abdominal wall is therefore occupied by an irregularly oval area, covered with mucous membrane, on which the two ureters open. The periphery of this extroverted area, which is covered by urothelium, becomes continuous with the skin.

Fig. 78.11 Bladder exstrophy. Misalignment of the genital tubercle and urogenital swellings with the urogenital membrane during early development results in subsequent malposition of the bladder, urethra and associated sphincters. The disappearance of the urogenital membrane exposes the posterior wall of the bladder, and the urethral opening is on the superior side of the penis or clitoris.

The routine use of ultrasound as an aid to *in utero* diagnosis of abnormalities has revealed a prevalence of 1–2 abnormal fetuses per 1000 ultrasound procedures. Of these, 20–30% are anomalies of the genitourinary tract, and can be detected as early as 12–15 weeks' gestation. However, the decision to be made after such a diagnosis is by no means clear. Urinary obstruction is considered an abnormality, yet transient modest obstruction is considered normal during canalization of the urinary tract, and has been reported in 10–20% of fetuses in the third trimester. A delay in canalization, or in the rupture of the cloacal membrane, can produce a dilatation. Similarly, the closure of the urachus at 32 weeks may be associated with high-resistance outflow for the system, which again produces transient obstruction. The degree to which obstruction may cause renal parenchymal damage cannot be assessed in a developing kidney, which may have primary nephrogenic dysgenesis.

The volume of amniotic fluid is used as an indicator of renal function, but, because other sources produce amniotic fluid in early gestation, amniotic volume does not reflect fetal urinary output until the second trimester. Too little amniotic fluid is termed oligohydramnios, too much, polyhydramnios. Although variation in the amount of amniotic fluid may suggest abnormalities of either the gut or kidneys, it is not always possible to correlate even severe oligohydramnios with renal dysfunction. There is an important relationship between the volume of amniotic fluid, lung development and maturity, and oligohydramnios has been shown to be associated with pulmonary hypoplasia (see Ch. 59).

REPRODUCTIVE SYSTEM

Development of the reproductive organs from the intermediate mesenchyme starts from stage 14, about 10 days later than the urinary system. Bilateral paramesonephric (Müllerian) ducts develop alongside the mesonephric ducts, and the midportion of each mesonephros undergoes thickening to form the gonadal ridge. Although the primordial germ cells are delineated very early in development, they are sequestered in the extraembryonic tissues until the gonadal ridge is ready to receive them. It was thought that development to one or other sexual phenotype occurred after migration of the primordial germ cells to the indifferent gonads. However, it is now recognized that the development of male or female gonads, genital ducts and external genitalia is far more complicated, and is the result of a complex interplay between genetic expression, timing of development and the influence of sex hormones. As development proceeds, a significant proportion of early embryonic urinary tissue is incorporated into the reproductive tracts, especially in the male. The earliest stage of reproductive development, prior to the arrival of the primordial germ cells into the gonad, is termed the indifferent or ambisexual stage.

Early gonadal development (ambisexual or indifferent stage)

Essentially four different cell lineages contribute to the gonads. Cells are derived from: proliferating coelomic epithelium on the medial side of the mesonephros; underlying mesonephric mesenchyme; invading angiogenic mesenchyme already present in the mesonephros; and primordial germ cells that arise from the epiblast very early in development and later migrate from the allantoic wall.

The formation of the gonads is first indicated by the appearance of an area of thickened coelomic epithelium on the medial side of the mesonephric ridge in the fifth week, stage 16 (Figs 78.12, 78.13; see Fig. 78.16). Elsewhere on the surface of the ridge the coelomic epithelium is one or two cells thick, but over this gonadal area it becomes multilayered. Thickening rapidly extends in a longitudinal direction until it covers nearly the whole of the medial surface of the ridge. The thickened epithelium continues to proliferate, displacing the renal corpuscles of the mesonephros in a dorsolateral direction and forms a projection into the coelomic cavity, the gonadal ridge. Surface depressions form along the limits of the ridge, which is thus connected to the mesonephros by a broad mesentery, the mesogenitale. In this way the mesonephric ridge becomes subdivided into a lateral part, the tubal fold, containing the mesonephric and paramesonephric ducts, and a medial part, the gonadal fold. The tubal fold also contains the nephric tubules and glomeruli at its base (Fig. 78.3).

Up to the seventh week the ambisexual gonad possesses no sexually differentiating feature. From stage 16 the proliferating coelomic epithelium forms a number of cellular epithelial cords (sometimes called primary sex cords), separated by mesenchyme. The cords remain at the periphery of the primordium and form a cortex. Proliferation and labyrinthine cellular condensation of the mesonephric mesenchyme, including angiogenic mesenchyme, produces a central medulla (see Fig. 78.16).

Reproductive ducts

The paramesonephric, Müllerian, ducts develop in embryos of both sexes, but become dominant in the development of the female reproductive system. They are not detectable until the embryo reaches a length of 10–12 mm (early sixth week). Each begins as a linear invagination of the coelomic epithelium, the paramesonephric groove, on the lateral aspect of the mesonephric ridge near its cranial end. The blind caudal end continues to grow caudally into the substance of the ridge as a solid rod of cells, which becomes canalized as it lengthens. Throughout the extent of the mesonephros it is lateral to the mesonephric duct, which acts as a guide for it. The paramesonephric duct reaches the caudal end of the mesonephros in the eighth week. It turns medially and crosses ventral to the mesonephric duct to enter the genital cord, where it bends caudally in close apposition with its fellow from the opposite side (Fig. 78.13). The two ducts reach the dorsal wall of the urogenital sinus during the third month, and their blind ends produce an elevation called the Müllerian sinus tubercle (Fig. 78.7F; see Fig. 78.19).

Fig. 78.19 The development of the urogenital system from the indifferent stage to the definitive male and female conditions.

(Modified with permission from Williams PL, Wendell-Smith CP, Treadgold S 1969 Basic Human Embryology, 2nd edn. Philadelphia: Lippincott.)

At the end of the indifferent stage each paramesonephric duct consists of vertical cranial and caudal parts and an intermediate horizontal region. The mesonephric ducts course caudally, medial to the paramesonephric ducts, and both duct systems open into the urogenital sinus. The genital ducts possess an external serosa on some surfaces derived from coelomic epithelium, a smooth muscle muscularis derived from underlying mesenchyme, and an internal mucosa derived from either the mesonephric duct or from the invaginated tube of coelomic epithelium that forms the paramesonephic duct. The layers are invaded by angiogenic mesenchyme and by nerves.

Uterus and uterine tubes

In the female the mesonephric duct is vestigial. Cranially it becomes the longitudinal duct of the epoöphoron, while caudally it is referred to as Gartner's duct (Table 78.1). The cranial part of the paramesonephric ducts forms the uterine tubes, and the original coelomic invagination remains as the pelvic opening of the tube. The fimbriae become defined as the cranial end of the mesonephros degenerates. The caudal vertical parts of the two ducts fuse with each other to form the uterovaginal primordium (Figs 78.7, 78.13, 78.14; see Fig. 78.19). This gives rise to the lower part of the uterus and, as it enlarges, it takes in the horizontal parts to form the fundus and most of the body of the adult uterus. A constriction between the body of the uterus and the cervix can be found at 9 weeks. The stroma of the endometrium and the uterine musculature develop from the surrounding mesenchyme of the genital cord.

Failure of fusion of the two paramesonephric ducts can lead to a range of anomalies summarized in Fig. 78.15. These fusions can also contribute to anomalies of vaginal development.

(Redrawn from Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)

At birth the uterus is 2.5–5 cm long (average 3.5 cm), 2 cm wide between the uterine tubes, and a little over 1 cm thick (Fig. 78.9; see Figs 14.4, 14.5). The body of the uterus is smaller than the uterine cervix, which forms two-thirds or more of the length. The isthmus between the body and the cervix is absent. The fetal female reproductive tract is affected by maternal hormones and undergoes some enlargement in the fetus. The endocervical glands are active before birth and the cervical canal is usually filled with mucus. The uterus is relatively large at birth, and subsequently involutes to about one-third of its length and more than half of its weight; it does not regain its neonatal size and weight until puberty. The uterine tubes are relatively short and wide.

The position of the uterus in the pelvic cavity depends to a great extent on the state of the bladder anteriorly and the rectum posteriorly. If the bladder contains only a small amount of urine the uterus may be anteverted but it is often in a direct line with the vagina (Fig. 78.9; see Fig. 78.19).

Vagina

At approximately 60 mm crown rump (CR) length an epithelial proliferation, the sinuvaginal bulb, arises from the dorsal wall of the urogenital sinus in the region of the sinus tubercle (Figs 78.7F, 78.14B),. Its origin marks the site of the future hymen. The proliferation gradually extends cranially as a solid anteroposteriorly flattened plate inside the tubular condensation of the uterovaginal primordium, which will eventually become the fibromuscular vaginal wall. The caudal tip of the paramesonephric duct epithelium recedes until, at about 140 mm (CR), its junction with the epithelial proliferation lies in the cervical canal.

Starting from its caudal end, and gradually extending cranially through its whole extent, the solid plate formed by the sinus proliferation enlarges into a cylindrical structure. Thereafter the central cells desquamate to establish the vaginal lumen. The extent to which mesonephric and paramesonephric ducts contribute directly to the formation of the vagina is controversial. As the upper end of the vaginal plate enlarges it grows up to embrace the cervix, and then is excavated to produce the vaginal fornices. Anomalies of paramesonephric duct fusion can produce related vaginal anomalies (Fig. 78.15). The urogenital sinus undergoes relative shortening craniocaudally to form the vestibule, which opens on the surface through the cleft between the genital folds. The lower end of the vaginal plate grows caudally so that in 109 mm embryos the vaginal rudiment approaches the vestibule. In fetuses of 162 mm the vaginal lumen is complete except at the cephalic end where the fornices are still solid; they are hollow by 170 mm. At approximately half way through gestation (180 mm) the genital canal is continuous with the exterior. During the later months of fetal life the vaginal epithelium is greatly hypertrophied, apparently under the influence of maternal hormones, but after birth it assumes the inactive form of childhood.

In the neonate, the vagina is 2.5–3.5 cm long and 1.5 cm wide at the fornices, and the uterine cervix extends into the vagina for about 1 cm. The posterior vaginal wall is longer than the anterior wall, giving the vagina a distinct curve (Fig. 78.9; see Fig. 78.19 and Fig. 14.5). The cavity is filled with longitudinal columns covered with a thick layer of cornified, stratified squamous epithelium. These cells slough off after birth when the effect exerted by maternal hormones is removed.

The orifice of the vagina is surrounded by a thick elliptical ring of connective tissue, the hymen (Fig. 78.9). During childhood the hymen becomes a membranous fold along the posterior margin of the vaginal lumen. Should the fold form a complete diaphragm across the vaginal lumen it is termed an imperforate hymenal membrane.

Reproductive ducts in the male

In the male, most of the paramesonephric ducts atrophy (Fig. 78.13) under the influence of anti-Müllerian hormone (AMH), which is released into the mesonephric duct by the Sertoli cells of the testis. Vestigial structures are therefore most likely to persist cranially and/or caudally, at the limits of the local exocrine effects of AMH. A vestige of the cranial end of the duct persists as the appendix testis (Fig. 78.13; see Fig. 78.19, Table 78.1). The fused caudal ends of the two ducts are connected to the wall of the urogenital sinus by a solid utricular cord of cells, which soon merges with a proliferation of sinus epithelium, the sinu-utricular cord. The latter is similar to, but less extensive than, the sinus proliferation in the female. The proliferating epithelium is claimed to be an intermingling of the endoderm of the urogenital sinus with the lining epithelia of the mesonephric and paramesonephric ducts, which have extended on to the surface of the sinus tubercle. As the sinu-utricular cord grows, so the utricular cord recedes from the tubercle. In the second half of fetal life the composite cord acquires a lumen and becomes dilated to form the prostatic utricle, the lining of which consists of hyperplastic stratified squamous epithelium (Fig. 78.13; see Fig. 78.19). The sinus tubercle becomes the colliculus seminalis.

The main reproductive ducts in the male are derived from the mesonephric ducts; the latter persist under the action of androgens that are probably secreted down the ducts themselves, and are subsumed into the male reproductive system as the metanephric kidney develops. The mesonephric duct gives rise to the canal of the epididymis, vas deferens and ejaculatory duct. The seminal vesicle and the ampulla of the vas deferens appear as a common swelling at the end of the mesonephric duct during the end of the third and into the fourth month. Their appearance coincides with degeneration of the paramesonephric ducts, although no causal relation between the two events has been established. Separation into two rudiments occurs at about 125 mm crown–heel length. The seminal vesicle elongates, its duct is delineated and hollow diverticula bud from its wall. About the sixth month (300 mm crown–heel length) the growth rate of both vesicle and ampulla is greatly increased. Figure 78.10 shows the position of the ampulla of the vas deferens in the neonate, possibly in response to increased secretion of prolactin by the fetal or maternal hypophysis, or to the effects of placental hormones. The tubules of the prostate show a similar increase of growth rate at this time.

Primordial germ cells

The primordial germ cells are formed very early from the epiblast (see Fig. 10.3). They are larger (12 to 20 μm in diameter) than most somatic cells, and are characterized by vesicular nuclei with well-defined nuclear membranes and by a tendency to retain yolk inclusions long after these have disappeared from somatic cells. It is not yet clear whether the primordial germ cells are derived from particular blastomeres during cleavage, if they constitute a clonal line from a single blastomere, or if they are the product of a progressive concentration of the nucleus of the fertilized ovum by unequal partition at successive mitoses. Primordial germ cells spend the early stages of development within the extraembryonic tissues near the end of the primitive streak and in the connecting stalk (see Fig. 10.4). In this situation they are away from the inductive influences to which the majority of the somatic cells are subjected during early development.

Primordial germ cells can be identified in human embryos in stage 11 when the number of cells is probably not more than 20–30. When the tail fold has formed they appear within the endoderm and the splanchnopleuric mesenchyme and epithelium of the hindgut as well as in the adjoining region of the wall of the yolk sac. They migrate dorsocranially in the mesentery, by amoeboid movements and by growth displacement, and pass around the dorsal angles of the coelom (medial coelomic bays) to reach the genital ridges from stage 15 (Fig. 78.16). It is believed that the genital ridges exert long-range effects on the migrating primordial germ cells, in terms of controlling their direction of migration and supporting the primordial germ-cell population.

Primordial germ cells proliferate both during and after migration to the mesonephric ridges. Cells which do not complete this migration degenerate. After segregation, when they are often termed primary gonocytes, they divide to form secondary gonocytes.

Development of the gonads

The factors that lead to formation of either testis or ovary are described below and in Fig. 78.16. The morphological events which occur in each type of gonadal development are presented first.

Testis

Most studies support the hypothesis that the seminiferous tubules are formed from cords of epithelial cells derived from the proliferating coelomic epithelium (Figs 78.13, 78.16). The cords lengthen, partly by addition from the coelomic epithelium, and encroach on the medulla, where they unite with a network of cells derived from the mesonephric mesenchyme destined to become the rete testis. Primordial germ cells are incorporated into the cords, which later become enlarged and canalized to form the seminiferous tubules. The cells derived from the surface of the early gonad form the supporting Sertoli cells. The latter proliferate throughout development and perhaps into childhood; when they stop dividing they mature and cannot be reactivated. Each Sertoli cell can only support a fixed number of germ cells during their development into spermatozoa, i.e. the number of Sertoli cells produced at this time determines the maximal limit of sperm output. Because the germ cells make up the bulk of the adult testis, the number of Sertoli cells is a major determinant of the size to which the testes will grow (factors which impair the process of spermatogenesis, resulting in the loss of germ cells, will also affect testicular size). Variation in Sertoli cell number is probably the most important factor in accounting for the enormous variation in sperm counts between individual men, whether fertile or infertile. Indeed, the available data for adult men indicate that Sertoli cell numbers vary across a fifty-fold range. Although some of this variation may result from attrition of Sertoli cell numbers because of ageing, the major differences in Sertoli cell numbers will have been determined by events in fetal and/or childhood life.

The interstitial cells of the testis are derived from mesenchyme and possibly also from coelomic epithelial cells that do not become incorporated into the tubules. Among other cell lines they form the embryonic and fetal cells of Leydig, which secrete testosterone and insulin-like factor 3 (Insl3). A later migration of mesenchyme beneath the coelomic epithelium forms the tunica albuginea of the testis.

The cords of the rete testis become connected to the glomerular capsules in the persisting part of the mesonephros. Ultimately they become connected to the mesonephric duct by the five to twelve most cranial persisting mesonephric tubules. These become exceedingly convoluted and form the lobules of the head of the epididymis. The mesonephric duct, which was the primitive ‘ureter’ of the mesonephros, becomes the canal of the epididymis and the vas deferens of the testis. The seminiferous tubules do not acquire lumina until the seventh month; the tubules of the testicular rete become canalized somewhat earlier.

Disorders of development of the testis and reproductive tract in the male fetus seem to be increasing in incidence. Testicular maldescent (cryptorchidism) and hypospadias appear to have doubled or trebled in incidence in the last 30–50 years, while testicular cancer has increased by an even greater margin and is now the commonest cancer of young men. Although testicular cancer is primarily a disease of young men (95% of cases affect 15- to 45-year-old males) it is now established that this age-incidence reflects activation of premalignant carcinoma-*in-situ* (CIS) cells, which are present at birth and which almost certainly arise during fetal life. It has been suggested that CIS cells are primordial germ cells that have failed to develop normally. Abnormalities of development of the testis and reproductive tract (e.g. gonadal dysgenesis, cryptorchidism, small testes) are important risk factors for the development of testicular cancer. However, the most dramatic change that appears to have occurred in the relatively recent past is a fall in sperm counts of around 40–50% (1% per year over the last 50 years). Although this dramatic decrease is obviously manifest only in adulthood, as is the case with testicular cancer, it is thought that it may reflect impaired testicular development during fetal or childhood life.

Ovary

The ovary closely resembles the testis early in development, except that its characteristically female features are slower to differentiate (Figs 78.13, 78.16). Few, if any, of the epithelial cords invade the medulla. The majority remain in the cortex, where they may be joined by a second proliferation from the coelomic epithelium overlying the gonad. In histological sections of ovaries from the third and subsequent months, the epithelial cords appear as clusters of cells, which may contain primitive germ cells, separated by fine septa of undifferentiated mesenchyme. An ovarian rete condenses in the medullary mesenchyme and some of its cords may join mesonephric glomeruli. The medulla subsequently regresses, and connective tissue and blood vessels from this region invade the cortex to form the ovarian stroma. During this invasion the clusters of epithelial cortical cells break into individual groups of supporting cells (now identified as granulosa cells), which surround the primordial germ cells (now identified as primary oocytes) that have entered the prophase of the first meiotic division. Primary oocytes are derived from a mitotic division of the primordial germ cells (naked oogonia). Their epithelial capsules consist of flattened pregranulosa cells derived from proliferations of coelomic epithelium. The ovary now has its full complement of primary oocytes. The majority undergo atresia, a hormonally controlled apoptotic process, but the remainder resume development after puberty, when they complete the first meiotic division shortly before ovulation (p. 1296). The granulosa cells at this time enlarge and multiply to form the stratum granulosum; as they do so, they become surrounded by thecal cells, which differentiate from the stroma.

Only the middle part of the gonadal ridge produces the ovary. Its cranial part is sterile and becomes the suspensory ligament of the ovary (infundibulopelvic fold of peritoneum). Its caudal region, also sterile, is incorporated into the ovarian ligament.

Sex determination in the embryo

It was believed that the gonads were indifferent or ambisexual until the arrival of the primordial germ cells in the gonadal ridge, at which point the sex of the embryo was ‘turned on’ by the presence of the male or female germ cells. It now seems that the germ cells may be essentially irrelevant to testis determination; embryos in which the genital ridges are devoid of germ cells may still have morphologically normal testis development. It is not clear if the germ cells are necessary for ovarian determination. They are required for the proper organization and differentiation of the ovary, and their absence results in the development of ‘streak gonads’, where only lines of follicular cells can be seen, as in Turner’s syndrome.

The processes of sex determination and differentiation involve interacting pathways of gene activity, which lead to the total patterning of the embryo as either male or female.

In the current, generally accepted model of sex determination in humans, the female pathway is considered to be the default pathway. According to this model, the Y chromosome of a male embryo diverts development into the testicular pathway, and the resulting changes that convert an indifferent gonad to a testis produce a range of local and widely acting hormones, which collectively generate all the secondary sexual characteristics.

The possession of a Y chromosome is usually associated with a male developmental pathway. Deletion mapping of the Y chromosome in a class of XX males arising from abnormal X:Y interchange at meiosis showed that the male-determining region of the chromosome was a conserved sequence located near its tip, termed the testis-determining factor (TDF). This sequence contains a gene that is regarded by some as the ‘master switch’ that programmes the direction of sexual development, the so-called SRY gene (sex-determining region on Y chromosome). It is believed to be genetically and functionally equivalent to the TDF. The SRY gene acts initially within the epithelial cords of cells derived from the coelomic epithelium of the ambisexual gonad. These cells can potentially differentiate into either Sertoli or granulosa cells (the supporting cells for the germ cells in the testis and ovary respectively). Studies indicate that SRY initiates testis formation from the indifferent gonad by directing the development of supporting-cell precursors as Sertoli rather than granulosa cells (Albrecht & Eicher 2001). Gene expression is seen first in cells designated as pre-Sertoli located centrally in the developing gonad and then later in the cranial and caudal poles. Once the developmental pathway of Sertoli cells is directed this influences the differentiation of the other cell types in the testicular pathway, so that Leydig cells appear later, and the connective tissue becomes organized into a male pattern. The germ cells are also affected by this environment. When they arrive they become enclosed within the Sertoli cells and enter mitotic arrest (which is characteristic of spermatogenesis), instead of entering meiosis and meiotic arrest (which characterizes oogenesis). Thus the development of male characteristics follows the expression of SRY, and female characteristics develop in its absence.

The possession of a Y chromosome expressing SRY may, therefore, underlie the switch to development of the male phenotype, by initiating Sertoli cell differentiation. An alternative view is that the possession of SRY accelerates the development of the gonads in XY embryos generally, so that testes are larger and more advanced than ovaries of the same age. Male human fetuses are generally bigger than females from 12 weeks’ gestation; indeed males are already slightly ahead of females at six weeks’ gestation, just prior to testicular differentiation. It has been suggested that this difference in the growth rate is encoded in the sex chromosomes. Once gonadal development has started, the difference in size between testes and ovaries becomes proportionately much greater than the overall size difference between XY and XX fetuses. (Interestingly, the right gonad develops slightly ahead of the left, an observation which may be correlated with the finding that testes are more often on the right side, and ovaries on the left, in hermaphrodites.)

Subsequent development of the male phenotype requires fetal secretion of both testosterone and anti-Müllerian hormone (AMH), (also called Müllerian inhibiting substance or MIS), and the development of the appropriate cytoplasmic testosterone-binding protein. Sertoli cells synthesize AMH, which causes the regression of the Müllerian ducts, and Leydig cells produce testosterone, which promotes the development of the mesonephric ducts, sets into process the development of male external genitalia, and sensitizes other tissues to testosterone. Absence of the testosterone-binding protein in the complete androgen insensitivity syndrome (CAIS) results in XY individuals who have testes and degenerated Müllerian ducts, but cannot respond to the circulating testosterone produced by their testes: they therefore develop female secondary sexual characteristics.

Although fetuses of either sex are exposed to maternal hormones, the accelerated development of the testis at early embryological stages ensures arrest of meiosis of the germ cells, and the production of hormones that masculinize the male embryo before the development of the reproductive tract and ovaries of the female. The range of intersex conditions, of phenotypic sex that is not correlated to genotype, and the effect of multiple X chromosomes in males, suggests that the male developmental pathway involves many testis determining genes, whereas only a single X chromosome determines the female default pathway. Once testicular differentiation and male hormone secretion have begun, other Y-chromosomal genes are required to maintain spermatogenesis and complete spermiogenesis. The consequences of impairment of oogenesis by other chromosomal abnormalities are much less severe than the impairment of spermatogenesis.

Descent of the gonads

The gonads develop on the posterior abdominal wall bilaterally along the central portion of the mesonephros. This region receives a rich blood supply, which is directed to the gonads as the mesonephros involutes. Both gonads descend, the testis to lie outside the abdominal cavity, and the ovary to the pelvis, however, they both retain their early blood supply from the dorsal aorta.

Descent of the testis

The mechanism of testicular descent is not completely understood, and to some extent remains controversial. Recent evidence suggests that it involves two phases, transabdominal and inguinoscrotal, that are regulated by distinct morphological and endocrine factors.

Transabdominal phase

Each testis initially lies on the dorsal abdominal wall. As it enlarges, its cranial end degenerates and the remaining organ therefore occupies a more caudal position. It is attached to the mesonephric fold by the mesorchium (the mesogenitale of the undifferentiated gonad), a peritoneal fold that contains the testicular vessels and nerves and a quantity of undifferentiated mesenchyme. It also acquires a secondary attachment to the ventral abdominal wall, which has a considerable influence on its subsequent movements. At the point where the mesonephric fold bends medially to form the genital cord (Fig. 78.3), it becomes connected to the lower part of the ventral abdominal wall by an inguinal fold of peritoneum. The mesenchymal cells occupying the core of the inguinal fold condense as another cord, the gubernaculum (Figs 78.3, 78.13, 78.17). This extends from the inguinal abdominal wall, at the site of the future inguinal canal, through the inguinal fold and the mesorchium to the caudal pole of the testis. The future inguinal canal is formed around it by the differentiating muscles of the abdominal wall. At the end of the second month the caudal part of the ventral abdominal wall is horizontal but, after the return of the intestine to the peritoneal cavity, it grows in length and becomes progressively more vertical. As the umbilical artery runs ventrally from the dorsal to the ventral wall, it pulls up a falciform peritoneal fold, which forms the medial boundary of a peritoneal fossa, the saccus vaginalis or lateral inguinal fossa, into which the testis projects. This lower end of the fossa protrudes down the inguinal canal, within the ventrosuperior aspect of the gubernaculum, as the processus vaginalis (Fig. 78.17; see Fig. 78.19).

Fig. 78.17 The descent of the testis. The testis is retroperitoneal throughout development, **A**. It is held in apposition to the deep inguinal ring from the fourth month and descends into the scrotum surrounded by the processus vaginalis during the seventh month, after which time the proximal part of the processus vaginalis obliterates. The layers of the distal processus vaginalis which remain around the testis form the tunica vaginalis, **B–D**.

(Redrawn from Tuchmann-Duplessis H, Haegel P 1972 Illustrated Human Embryology, Vol 2 Organogenesis. London: Chapman and Hall. With kind permission of Springer Science+Business Media.)

Up to about 10 weeks the gubernaculum in male and female embryos is the same, but then production of insulin-like factor 3 (Insl3) from the Leydig cells stimulates enlargement (known as the ‘swelling reaction’) of the gubernaculum in males. This serves to anchor the fetal testis near the future inguinal canal as the abdominal cavity enlarges between 10 and 15 weeks. By comparison, the gubernaculum in females remains thin and subsequently develops into the round ligament (see below). The cranial attachment of the urogenital ridge, known as the cranial suspensory ligament, regresses in males under the action of androgens.

Inguinoscrotal phase

The caudal end of the gubernaculum initially remains embedded in the abdominal wall (hence the old name of genito-inguinal ligament). As the fetus grows, the distance between the future scrotum and the inguinal region increases. Between 25 and 35 weeks the male gubernaculum begins to bulge out from the abdominal muscles and the processus vaginalis elongates within it to create the inguinal canal. Elongation of the soft, gelatinous end of the gubernaculum, which in the early stage is formed mainly of hyaluronic acid, is controlled by androgens. The exact mechanism mediating elongation in humans is uncertain. In rodent models there is good evidence that androgens cause sexual dimorphism of the sensory branches of the genitofemoral nerve, which supplies the gubernaculum, the developing cremaster muscle within it, and part of the scrotum. The genital branch of the nerve releases calcitonin gene-related peptide (CGRP) which stimulates growth of the gubernacular tip along a chemotactic gradient to the scrotum.

The testis remains in apposition with the deep inguinal ring, held by the gubernaculum during the fourth to sixth months. During the inguinoscrotal phase the testis descends, surrounded by the elongating processus vaginalis, within the migrating gubernaculum. This occurs relatively rapidly about the seventh month, the left testis usually descending ahead of the right. In full-term male neonates over 95% have descended testes, although in premature babies descent may not be complete. After descent the distal processus vaginalis persists as a ‘tiny satellite peritoneal cavity’ around the testis as the tunica vaginalis, which becomes firmly attached to the surrounding scrotum within a few weeks. The proximal part of the processus vaginalis then obliterates, and there is evidence that this also is controlled by androgens indirectly via calcitonin gene-related peptide (CGRP) released from the genitofemoral nerve. Both exogenous CGRP and hepatocyte growth factor can cause obliteration *in vitro* of the processus vaginalis in hernial sacs excised from babies with indirect inguinal hernia.

At birth the processus vaginalis is narrowed and collapsed, but not necessarily completely obliterated. It remains patent for two weeks in nearly 70% of male infants, but by three weeks after birth it is at least partially obliterated in 80% of male infants, the left side before the right.

Persistent patency of the processus vaginalis leads to indirect inguinal hernia (widely patent and allowing prolapse of bowel), or hydrocele (narrow patency permitting only intraperitoneal fluid to trickle down into the tunica vaginalis). During obliteration fluid may trickle only part way down the processus vaginalis to produce an encysted hydrocele of the cord. This is a relatively common but transient state and usually resolves completely within a few weeks by further obliteration. Because of perinatal androgen exposure, the spermatic cord and scrotum are relatively large in the neonate, as are the seminal vesicles and adjacent ampullae of the vas deferens.

In aberrant testicular descent the testis may remain in the abdomen, although this is thought to be uncommon because the hormonal and morphological features of the transabdominal phase are relatively simple. By contrast, the indirect endocrine regulation and complex migratory process of the gubernaculum during the inguinoscrotal phase is frequently abnormal, leading to the testis lying in the inguinal or pubic region in 2–5% of neonates. Rarely the testis may lie in the perineum, upper part of the thigh or at the root of the penis. The cause for these aberrant locations is unknown, but is most likely to be secondary to aberrant migration of the gubernaculum, perhaps caused by a mislocated genitofemoral nerve.

Descent of the ovary

The relative movements of the ovary are less extensive than those of the testis and are not hormonally regulated. Like the testis, the ovary ultimately reaches a lower level than it occupies in the early months of fetal life, but it does not leave the pelvis to enter the inguinal canal, except in certain anomalies. The ovary is connected to the medial aspect of the mesonephric fold by the mesovarium (homologous with the mesorchium), and to the ventral abdominal wall by the inguinal fold (Figs 78.13, 78.18). A mesenchymatous gubernaculum develops in this fold but, as it traverses the mesonephric fold, it acquires an additional attachment to the lateral margin of the uterus near the entrance of the uterine tube. Its lower part, caudal to this uterine attachment, becomes the round ligament of the uterus and the part cranial to this becomes the ovarian ligament. Collectively these structures are homologous with the gubernaculum testis in the male (Figs 78.17-78.19). This new uterine attachment may be correlated with the restricted ovarian descent. At first the ovary is attached to the medial side of the mesonephric fold but, in accordance with the manner in which the two mesonephric folds form the genital cord, it is finally connected to the posterior layer of the broad ligament of the uterus (Figs 78.3, 78.13, 78.14B). The gubernacula thus develop in the female, unlike the male, as bilateral fibrous bands or ligaments in the absence of Insl3. They do not extend into the labia majora, but end in the connective tissue just external to the external ring of the inguinal canal, because, in the absence of androgens, there is no migratory phase analogous to inguinoscrotal migration in the male. The saccus vaginalis is present in the female. Its prolongation into the inguinal canal (sometimes termed the canal of Nuck) is normally completely obliterated, but may remain patent and form the sac of a potential indirect inguinal hernia.

In the neonate the ovaries lie in the lower part of the iliac fossae. The long axis of the ovary is almost vertical. It becomes temporarily horizontal during descent, but regains the vertical when it reaches the ovarian fossa. The ovaries complete their descent into the ovarian fossae in early childhood. Thus, at birth the ovary and the lateral end of the corresponding uterine tube lie above the pelvic brim. They do not sink into the lesser pelvis until the latter enlarges sufficiently to contain both of them and the other pelvic viscera, including the bladder. The combined weight of the ovaries at birth is 0.3 g, which is relatively large, and much larger than the combined weight of the testes (Fig. 78.9; see Fig. 14.4). The ovaries double in weight during the first 6 postnatal weeks. They bear surface furrows, which disappear during the second and third postnatal months. All of the primary oocytes for the reproductive life of a female are present in her ovaries by the end of the first trimester of pregnancy. Of the 7,000,000 primary oocytes estimated to be present at the fifth month of gestation, 1,000,000 remain at birth, 40,000 by puberty, and only 400 are ovulated during reproductive life.

Cloaca and external genitalia

The cloaca is that region at the end of the primitive hindgut which is continuous with the allantois (Figs 78.4, 78.7). The allantois, a ventral diverticulum, passes into the connecting stalk of the early embryo prior to tail folding and is then drawn into the body cavity after stage 10. It retains an extension into the connecting stalk, and later into the umbilicus, throughout embryonic life. The cloaca is a slightly dilated cavity lined with endoderm. It is initially connected cranially to the enteric hindgut, and ventrocaudally is in contact with overlying ectoderm at the cloacal membrane. Proliferation of mesenchyme at the angle of the junction of the hindgut and allantois produces a urorectal septum, which grows caudally promoting the movement, but not the fusion, of the endodermal epithelium toward the cloacal membrane (Figs 78.4, 78.7, 78.20). The cloaca becomes separated into a presumptive rectum and anal canal dorsally, and a presumptive urinary bladder and urogenital sinus ventrally, and the cloacal membrane is divided into anal and urogenital parts respectively. The nodal centre of division is the site of the future perineal body. The urogenital sinus receives the mesonephric and paramesonephric ducts.

Fig. 78.20 The development of the external genitalia from the indifferent stage to the definitive male and female conditions.

Anomalies of cloacal development may result in a range of defects. In extroversion of the cloaca (ectopia cloacae), the urorectal septum does not develop and there is failure of mesenchymal migration around the ventral body wall to support the umbilical cord: this results in a large abdominal defect with a central colonic portion and bilateral bladder components. With only partial development of the urorectal septum, the urogenital sinus may remain with a high confluence of bladder, vagina and rectum. The cloacal membrane may be abnormally elongated and prematurely ruptured throughout its whole extent, prior to the formation of the urorectal septum, or, in some cases, there may be only a small sinus opening externally at the skin. The anal musculature is often present but not associated with the anal canal.

Pelvic floor

The pelvic floor consists of the ligamentous supports of the cervix, and the pelvic and urogenital diaphragms, and constitutes another partition that traverses the body cavity. Little is known about pelvic floor development in the human. The striated muscle is derived from the dermomyotomes in a similar manner to the muscles of the ventrolateral body wall. Puborectalis appears in 20–30 mm embryos, following opening of the anal membrane, and striated muscle fibres can be seen at 15 weeks. The smooth muscle of the urethral sphincter is also present at this time.

Urethra

The urethra is derived from endoderm, as are the prostate gland and vagina (both outgrowths of the lower urogenital sinus), and the other small glandular structures that develop around the caudal body orifices.

In the male, the prostatic urethra proximal to the orifice of the prostatic utricle is derived from the vesicourethral part of the cloaca and the incorporated caudal ends of the mesonephric ducts. The remainder of the prostatic part, the membranous part, and probably the part within the bulb, are all derived from the urogenital sinus. The anterior urethra, as far as the glans, is formed by canalisation of the urethral plate (see below). Secondary ingrowth of mesenchyme fuses the genital folds over the urethra (Fig. 78.20). The short section within the glans may be formed from ectoderm, which invaginates into the glans.

In the female, the urethra is derived entirely from the vesicourethral region of the cloaca, including the dorsal region derived from the mesonephric ducts. It is homologous with the part of the prostatic urethra proximal to the orifices of the prostatic utricle and the ejaculatory ducts. The region of the early urethra remains open to form the vestibule into which the definitive urethra and vagina open (Fig. 78.20). It is believed that these regions are invaded by ectoderm because they are innervated by somatic nerves.

Urethral defects caused by anomalous development are not uncommon in the male. In epispadias the urethra opens on the dorsal aspect of the penis at its junction with the anterior abdominal wall. This anomaly is considered to be a less severe form of exstrophy of the bladder. In the simplest form of hypospadias related to incomplete canalisation of the urethral plate, the urethra may open on the ventral (perineal) aspect of the penis at the base of the glans, and the part of the urethra that is normally within the glans is absent. In more severe cases the genital folds fail to fuse, and the urethra opens on the ventral aspect of a malformed penis just in front of the scrotum. A still greater degree of this malformation is accompanied by failure of the genital swellings to unite with each other. In these cases the scrotum is divided and, since the testes are also frequently undescended, the resemblance to the labia majora is very striking, leading to genital ambiguity. In such cases it is important to determine at the earliest time not only the chromosomal status of the infant but also the internal anatomy and state of development of the internal genital tract. Sex assignment and rearing will depend on these factors.

The urethral sphincter first forms as a mesenchymal condensation around the urethra in 12–15 mm (stage 18) embryos, after division of the cloaca. The mesenchyme proliferates and becomes defined at the bladder neck in 31 mm embryos, and along the anterior part of the urethra by 69 mm. The muscle fibres differentiate after 15 weeks’ development, at which time both smooth and striated fibres are present. In females there is continuity between the smooth muscle of the urethral wall and of the bladder. In males the muscle fibres are less abundant because of the local development of the prostate. Striated muscle fibres form around the smooth muscle initially in the anterior wall of the urethra and later encircle the smooth muscle layer. The origin of the striated muscle is not known: it could be derived from the myogenic cells that give rise to puborectalis. The smooth and striated components of the urethral sphincter are closely related, but there is no mixing of fibres as occurs in the anorectal sphincter.

Prostate gland

The prostate gland arises during the third month from interactions between the urogenital sinus mesenchyme and the endoderm of the proximal part of the urethra. Early outgrowths, some 14 to 20 in number, arise from the endoderm around the whole circumference of the tube, but mainly on its lateral aspects and excluding the dorsal wall above the utricular plate. They give rise to the outer glandular zone of the prostate. Later outgrowths from the dorsal wall above the mesonephric ducts arise from the epithelium of mixed urogenital, mesonephric and possibly paramesonephric, origin that covers the cranial end of the sinus tubercle. They produce the internal zone of glandular tissue. The outgrowths, which are at first solid, branch, become tubular and invade the surrounding mesenchyme. The latter differentiates into smooth muscle, associated blood and lymphatic vessels and connective tissue and is invaded by autonomic nerves.

Similar outgrowths occur in the female but remain rudimentary in the absence of androgenic stimulation. The urethral glands correspond to the mucosal glands around the upper part of the prostatic urethra, and the paraurethral glands correspond to the true prostatic glands of the external zone.

The bulbourethral glands in the male, and the greater vestibular glands in the female, arise as diverticula from the epithelial lining of the urogenital sinus.

External genitalia

Patterning of the external genitalia may be achieved by mechanisms similar to those that pattern the face and limb. In the cranial region neural crest mesenchyme makes an important contribution to the organization of the pharyngeal arches and the regions around the upper sphincters. Neural crest also arises from the tail-bud region, specifically from a population of cells termed the caudoneural hinge, which share the same molecular markers as the primitive node. The neural tube at this level is derived from a mesenchymal/epithelial transformation of caudoneural-hinge cells, which form a cylinder. Neural crest cells delaminate from the dorsal surface of the cylinder in a rostrocaudal direction. It is not known whether neuronal neural crest arising from secondary neurulation processes contributes to the caudal interface between endoderm and ectoderm.

The external genitalia, like the gonads, pass through an indifferent state before distinguishing sexual characters appear (Fig. 78.20). From stage 13, primordia of the external genitalia, composed of underlying proliferating mesenchyme covered with ectoderm, arise around the cloacal membrane, between the primitive umbilical cord and the caudal limit of the embryo. During stage 15 the cloacal membrane is divided by the urorectal septum into a cranial urogenital membrane and a caudal anal membrane (Figs 78.4, 78.14). Local ectodermal/mesenchymal interactions give rise to the anal sphincter, which will develop even without the presence of the anal canal. A surface elevation, the genital tubercle, appears at the cranial end of the urogenital membrane and two lateral ridges, the genital or urethral folds, form each side of the membrane (Fig. 78.20). The genital tubercle forms a distinct primordium, which will become the glans of either the penis or the clitoris. Elongation of the genital folds and urogenital membrane produces a primitive phallus. As this structure grows it is described as having a cranial surface analogous to the dorsum of the penis, and a caudal surface analogous to the perineal surface of both sexes. The urogenital sinus, contiguous with the internal aspect of the urogenital membrane, becomes attenuated within the elongating phallus forming the primitive urethra. The urogenital membrane breaks down at about stage 19, allowing communication of ectoderm and endoderm at the edges of the disrupted membrane and continuity of the urogenital sinus with the amniotic cavity. Urine can escape from the urinary tract from this time. The endodermal layer of the attenuated distal portion of the urogenital sinus, which is now displayed on the caudal aspect of the phallus, is termed the urethral plate. As mesenchyme proliferates within the genital folds, the urethral plate sinks into the body of the phallus forming a primary urethral groove. The genital folds meet proximally in a transverse ridge immediately ventral to the anal membrane.

While these changes are in progress two labioscrotal (genital) swellings appear, one on each side of the base of the phallus, and extend caudally, separated from the genital folds by distinct grooves (Figs 78.20, 78.21).

The genital folds are not fused. **C**, A human male embryo at 12 weeks. Fusion of the genital folds has occurred.

(Photographs by P Collins.)

As a general rule, epithelium, which can be touched easily and has a somatic innervation, is derived from ectoderm. In the buccal cavity and pharynx the ectoderm/endoderm zone is towards the posterior third of the tongue – touch here usually elicits the gag reflex. In the anal canal the outer portion, distal to the anal valves, is derived from ectoderm and has a somatic innervation, whereas the epithelium proximal to the valves is derived from endoderm and has an autonomic innervation.

Homologies of the parts of the urogenital system are shown in Table 78.1.

Male genitalia

The growth of male external characteristics is stimulated by androgens regardless of the genetic sex. The male phallus enlarges to form the penis. The genital swellings meet each other ventral to the anus and unite to form the scrotum (Fig. 78.20). The genital folds fuse with each other from behind forwards, enclosing the phallic part of the urogenital sinus behind to form the bulb of the urethra and closing the definitive urethral groove in front to form the greater part of the spongiose urethra. Fusion of the folds results in the formation of a median raphe and occurs in such a way that the lining of the postglandular urethra is mainly, perhaps wholly, endodermal in origin, formed by canalisation of the urethral plate. Thus, as the phallus lengthens, the urogenital orifice is carried onwards until it reaches the base of the glans at the apex of the penis. From the tip of the phallus an ingrowth of surface ectoderm occurs within the glans to meet and fuse with the penile urethra. Subsequent canalisation of the ectoderm permits a continuation of the urethra within the glans.

The glans and shaft of the penis are recognizable by the third month. The prepuce also begins to develop in the third month, when the primary external orifice of the urethra is still at the base of the glans. A ridge consisting of a mesenchymal core covered by epithelium appears proximal to the neck of the penis and extends forwards over the glans. A solid lamella of epithelium deep to this ridge extends backwards to the base of the glans. The ventral extremities of the ridge curve backwards to become continuous with the genital folds at the margins of the urethral orifice. As the urethral folds meet to form the terminal part of the urethra, the ventral horns of the ridge fuse to form the frenulum. The epithelial lamella breaks down over the dorsum and sides of the glans to form the preputial sac, and thus free the prepuce from the surface of the glans. Thereafter the prepuce grows as a free fold of skin, which covers the terminal part of the glans. Although the prepuce and glans begin to separate from the fifth month *in utero*, they may still be joined at birth. The preputial sac may not be complete until 6–12 months or more after birth and, even then, the presence of some connecting strands may still interfere with the retractability of the prepuce.

The mesenchymal core of the phallus is comparatively undifferentiated in the first two months, but the blastemata of the corpora cavernosa become defined during the third month. Nerves are present in the differentiating mesenchyme from the seventh week. Despite containing less smooth muscle and elastic tissue than the adult, the neonatal penis is capable of erection.

The scrotum is formed by proliferation of the genital swellings. The genital swellings fuse across the midline covering the base of the penis. The testes descend into the scrotum prior to birth. The gelatinous matrix of the gubernaculum is then resorbed and the tunica vaginalis becomes adherent to the connective tissue of the scrotum. In the neonate the penis and scrotum are relatively large. The scrotum has a broad base which does not narrow until after the first year. Both the septum (i.e. the mesenchyme remaining between the tunica vaginalis on each side) and the walls of the scrotum are relatively thicker than in adults.

Female genitalia

The female phallus, which exceeds the male in length in the early stages, becomes the clitoris. The genital swellings remain separate as the labia majora and the genital folds also remain separate, forming the labia minora (Fig. 78.20). The perineal orifice of the urogenital sinus is retained as the cleft between the labia minora, above which the urethra and vagina open. The prepuce of the clitoris develops in the same way as its male homologue. By the fourth month the female external genitalia can no longer be masculinized by androgens.

At birth neonatal females have relatively enlarged labia minora, clitoris and labia majora. The labia majora are united by a posterior labial commissure. The distal end of the round ligament of the uterus, the gubernaculum ovarii, ends just outside the external inguinal ring.

There is evidence that in certain tissues, e.g. urogenital sinus and genital swellings, testosterone is converted into 5α-dihydrotestosterone. In XY individuals with a genetic deficiency of the enzyme responsible for this conversion, not only functioning testes but also female external genitalia with an enlarged clitoris and a small vaginal pouch, are present, suggesting that external genital development is under the control of 5α-dihydrotestosterone. Such individuals are often raised as girls, however, at puberty the external genitalia become responsive to testosterone, which causes masculinization at this time.

Maturation of the reproductive organs at puberty

Until the adolescent growth spurt the reproductive organs grow very slowly. Generally the changes occur over a time period termed puberty. The sequence of these events is much less variable than the age at which they take place. The sequence of puberty in girls and boys is shown in Fig. 78.22.

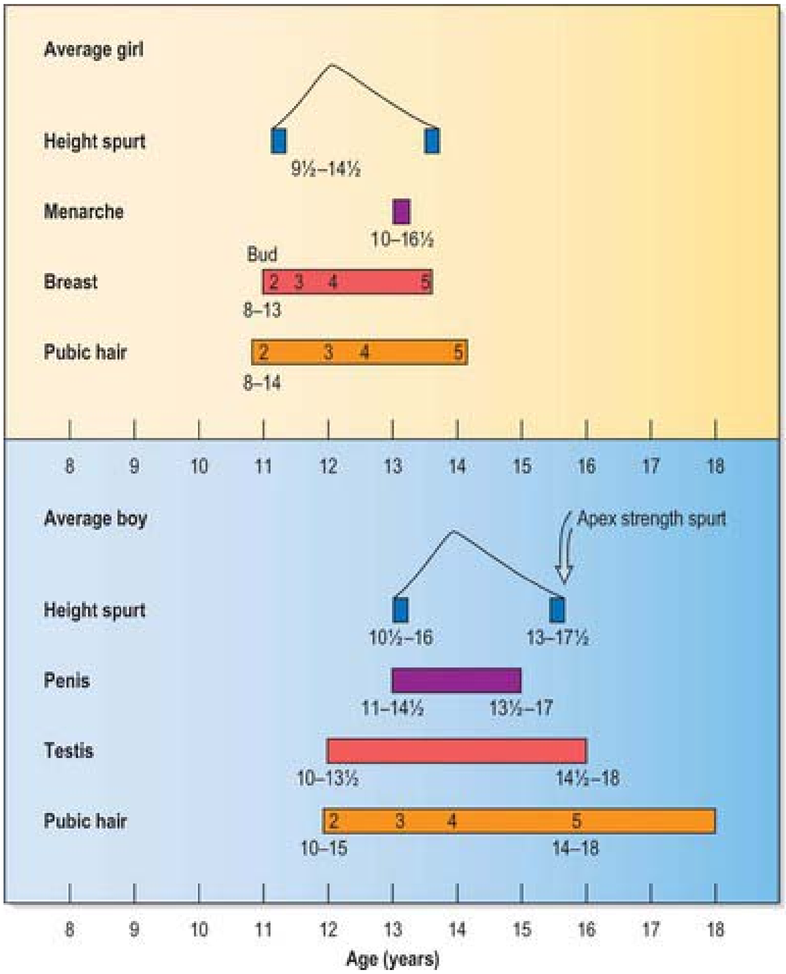

Fig. 78.22 Average ages at which maturation events occur in adolescent girls and boys. The figures beneath the bars indicate the range of ages within which each event may begin and end. Figures within the bars indicate the developmental stage.

(Adapted with permission from Tanner JM 1962 Growth at Adolescence, 2nd edn. Oxford: Blackwell Publishing.)

In girls the appearance of the breast bud is usually the first sign of puberty. The uterus and vagina develop simultaneously with the breast. Menarche occurs after the peak of the height spurt – onset is more closely related to radiological than to chronological age. It has been suggested that the menarche occurs as a critical weight of 50 kg is attained, and certainly sports and excessive restriction of diet, which may reduce weight below this level, can cause amenorrhoea in women who were previously menstruating normally. Tall girls reach sexual maturity earlier than short ones, but girls with a late adolescent growth spurt and later puberty are ultimately taller on the average than those who pass through the menarche early, for they have longer to grow. A girl who has begun to menstruate can be predicted to grow a further 7.5 cm at most. Menarche marks a definitive stage of uterine development but does not mean attainment of full reproductive function. Many of the early menstrual cycles may not involve ovulation.

The earliest sign of puberty in boys is the growth of the testes and scrotum. The volume of the testes may be estimated: the average adult volume is 20 ml, and a volume of 6 ml indicates that puberty has started. Later the penis, prostate and seminal vesicles begin to enlarge. Increased testosterone levels produced by the Leydig cells of the testes promote changes in the larynx, skin and distribution of bodily hair.

Section 9

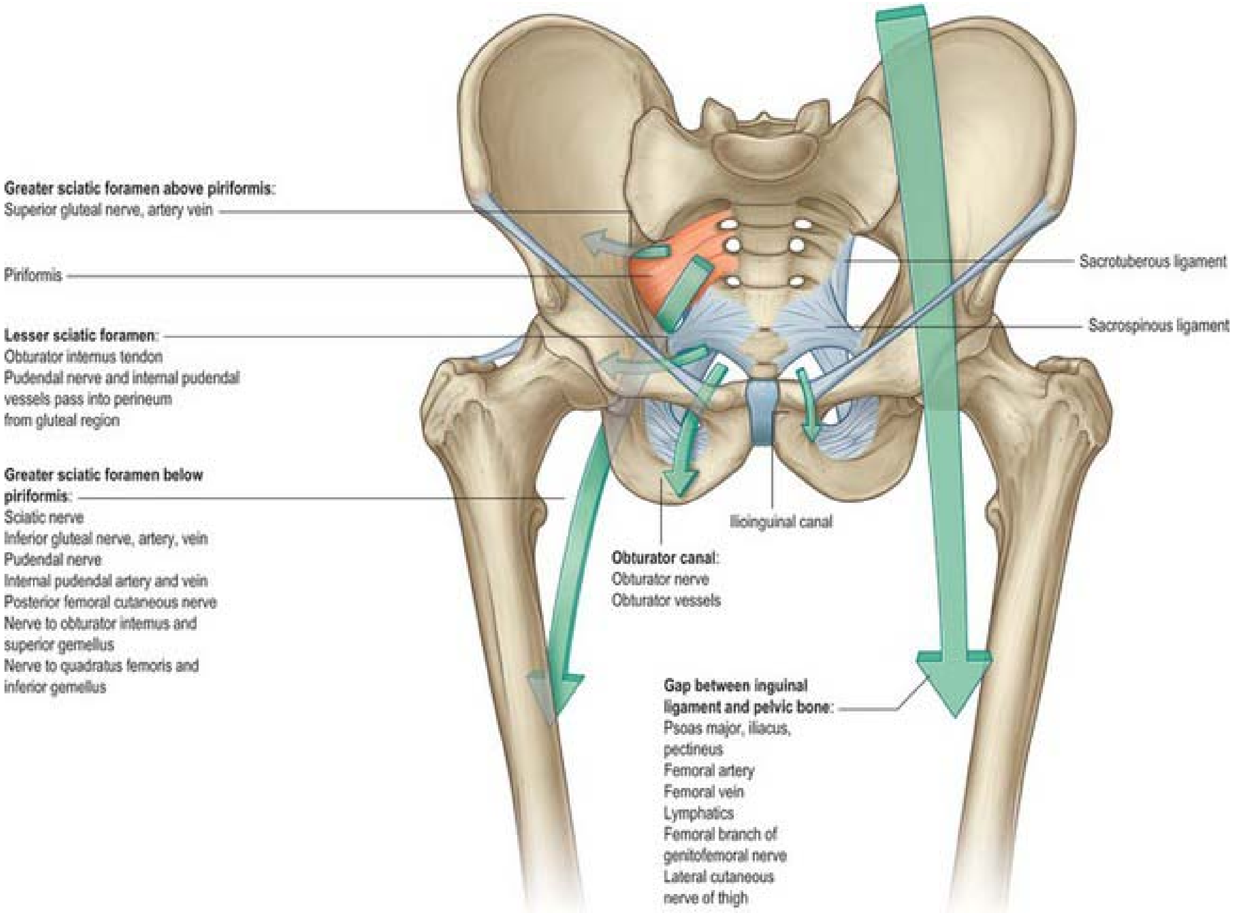
PELVIC GIRDLE AND LOWER LIMB

CHAPTER 79

Pelvic girdle and lower limb: overview and surface anatomy

This chapter is made up of two sections. The first is an overview of the general organization of the lower limb, with particular emphasis on the fascial skeleton, distribution of the major blood vessels and lymphatic channels, and the branches of the lumbar and sacral plexuses: it is intended to complement the detailed regional anatomy described in Chapters 80 to 84 Chapter 81 Chapter 82 Chapter 83 Chapter 84. The second section describes the surface anatomy of the lower limb.

The structure of the lower limb is determined by its adaptations for weightbearing, locomotion and the maintenance of equilibrium (stability). Indeed, the adaptations for weightbearing and for stability, and the differing developmental histories of the limbs account for the major structural and functional differences between the upper and lower limbs. The inguinal (pelvicrural) and gluteal (buttock) regions are important anatomical junctional zones between the trunk and the lower limb through which longitudinally running nerves and vessels may pass in either direction. The inguinal region includes the junctional zones between the limb and abdominal cavity via the myopectineal orifice (the gap between the inguinal ligament and hip bone), and between the limb and pelvic cavity via the obturator foramen. The gluteal region includes the junctional zones between the limb and the abdominopelvic cavity via the greater sciatic foramen, and between the limb and the perineum via the lesser sciatic foramen (Fig. 79.1).



Greater sciatic foramen above piriformis:

SKIN, FASCIA AND SOFT TISSUES

In the young adult the skin of the lower limb is generally stronger and thicker than that of the upper limb: weightbearing skin, e.g. of the sole of the foot, is particularly thickened. The skin of the buttocks and posterior thigh bears weight in the sitting position, and consequently is relatively thick. The skin over the anteromedial aspect of the lower leg is particularly fragile and vulnerable in the elderly. Body hair is usually well developed in all areas except the sole and posterior ankle.

Fascial skeleton

The ‘fascial skeleton’ (deep fascia) of the lower limb is well-defined and forms a tough circumferential ‘stocking-like’ structure that constrains the musculature (Fig. 79.2). Septa pass from the deep surface of this fascial sheath to the bones within, confining the functional muscle groups within osteofascial compartments. The tough fascia gives additional areas of attachment to the muscles and ensures that they work to maximal effect. Thickenings in the ensheathing layer may act as additional tendons (e.g. iliotibial tract). Elsewhere, thickenings in the fascial skeleton form fibrous retinacula where tendons cross joints. Although they are particularly prominent in the embalmed cadaver, these fascial layers are also readily demonstrable in the living, and are of considerable functional significance. The pattern of soft-tissue organization has a bearing on the physiological effects of the muscles and is crucial for efficient venous return from the limb. The fascial planes also control and direct the spread of pathological fluids (blood, pus) within the limb and play an important part in determining the degree and direction of displacement seen in long bone fractures.

Fasciocutaneous system

The fascial septa dictate the pathways of cutaneous arteries, which subsequently perforate and ramify on the fascial ‘stocking’ before supplying the skin.

Osteofascial compartments in the lower limb

The muscles of the thigh may be grouped into three compartments according to their function, namely anterior (extensor), posterior (flexor) and medial (adductor): only the anterior and posterior compartments possess distinct fascial boundaries. A very definite fascial separation into anterior (extensor), posterior (flexor) and lateral (evertor) compartments exists in the leg, and compartment syndrome is most common in this region (see below). Osteofascial compartments in the foot are described in Chapter 84.

Vessels and nerves run through all the osteofascial compartments and supply the muscles contained within them. The muscles acting within these closed compartments assist in maintaining the anti-gravity flow of venous blood.

Compartment syndrome

The fascial boundaries that limit the osteofascial compartments are largely inelastic, which means that any condition that leads to an increase in the volume of the compartmental contents, e.g. muscle swelling caused by trauma or unaccustomed overuse, haemorrhage and local infection, is likely to cause an increase in intracompartmental pressure. If unrelieved, this increased pressure will lead to compressive occlusion of the vessels in the compartment and consequent ischaemic damage to the nerves and muscles of the compartment, a phenomenon known as compartment syndrome.

BONES AND JOINTS

The bones of the lower limb are the three fused components of the pelvic girdle; the femur and patella (thigh); the tibia and fibula (leg); the tarsus, metatarsus and phalanges (foot) (Fig. 79.3). The hip bones (especially the ilium and ischium), femur, tibia and bones of the hindfoot are strong and their external (cortical) and internal (trabecular) structure is adapted for weightbearing.

Fig. 79.3 Overview of bones of the lower limb. **A**, posterior aspect. **B**, anterior aspect.

The pelvic girdle connects the lower limb to the axial skeleton via the sacroiliac joint, a synovial joint in which mobility has been sacrificed for stability and strength, to allow for effective weight transmission from the trunk to the lower limb. Anteriorly, the pelvic girdle articulates with the contralateral girdle at the pubic symphysis, a secondary cartilaginous joint that may display a slight degree of mobility during hip and sacroiliac movement and during childbirth. The hip joint, a synovial ball-and-socket joint, exhibits a very effective compromise between mobility and stability that allows movement in all three orthogonal planes. The more distal joints have gained mobility at the expense of stability. The knee joint includes the patellofemoral articulation, which allows the patella to glide over the distal femur. However, the main component of the knee joint is a bicompartmental synovial articulation between the femur and the tibia that allows flexion, extension and some medial and lateral rotation of the leg. It is not a true hinge joint because its axes of flexion and extension are variable and there is coupled rotation. The tibia and fibula articulate with each other at the superior and inferior tibiofibular joints. The superior joint, a plane synovial joint, allows slight gliding movement only. The inferior joint, a fibrous joint, lies just above the ankle and allows a degree of fibular rotation linked to ankle motion. The ankle (talocrural) joint is formed by the distal ends of the tibia and fibula ‘gripping’ the talus, and allows dorsiflexion and plantarflexion. There are multiple joints in the foot that may be classified topographically on the basis of whether they are in the hindfoot, midfoot or forefoot. Collectively, these joints allow the complex movements required as the foot fulfils its functional roles as a platform for standing and for shock absorption and propulsion in gait.

Both knee and ankle are commonly subject to closed injuries, and the relatively superficial location of the knee renders it susceptible to open injury and infection. Although the ankle is frequently injured and is a major loadbearing joint, the incidence of clinically significant degenerative arthritis is surprisingly low when compared with that found in the hip and knee.

MUSCLES

The effects of extension and medial rotation of the limb that occur during fetal development are manifest in the relative positions of the muscle groups in the thigh and the leg, and in the adult pattern of segmental innervation (dermatomes). In broad outline, the anterior aspect of the adult limb is the extensor aspect, while the flexors lie posteriorly; the reverse is true at the hip.

The role of the muscles of the lower limb in the maintenance of equilibrium during locomotion and in stance is rarely emphasized sufficiently. Many of the muscles act frequently or predominantly from their distal attachments. During both stance and locomotion, the distal attachment is often fixed and the proximal attachment is mobile, e.g. the predominant action of gluteus medius is as a pelvic stabilizer rather than as a hip abductor. (In contrast, in the upper limb the proximal muscle attachments are usually fixed and the distal attachments are mobile, an arrangement that is consistent with the prehensile function of the hand.) The lower limb contains many muscles that act upon more than one joint, and it is unusual for any joint of the lower limb to move in isolation.

Muscles of the lower limb may be subdivided into muscles of the iliac and gluteal regions, and of the thigh, leg and foot. (Note that in anatomical nomenclature, ‘leg’ refers to that part of the lower limb between the knee and ankle.) The main muscles of the iliac region are psoas major and iliacus, the major flexors of the hip that run from the lumbar spine and inner surface of the ilium respectively to the lesser trochanter of the femur. The much less important psoas minor (when present) runs from the lumbar spine to the pubis. The muscles of the gluteal region include the three named gluteal muscles and the deeper short lateral rotators of the hip joint. Gluteus maximus lies most superficially, running from the posterior pelvis to the proximal femur and fascia lata. It is a powerful extensor of the hip joint, acting more often to extend the trunk on the femur than to extend the limb on the trunk. Gluteus medius and minimus, attaching proximally to the outer iliac surface and distally to the greater trochanter of the femur, are abductors of the hip; their most important action is to stabilize the pelvis on the femur during locomotion, and they are helped in this function by tensor fasciae latae, a more anteriorly placed muscle that arises from the anterolateral ilium and inserts into the fascia lata. Two of the short lateral rotators of the hip, piriformis and obturator internus, arise from within the pelvic walls, while the others, obturator externus, the gemelli and quadratus femoris, are attached externally: all of these muscles are attached distally to the proximal femur.

The muscles of the thigh lie in three functional compartments. The anterior or extensor compartment includes sartorius and the quadriceps group. Sartorius and rectus femoris are attached proximally to the pelvis and can thus act on the hip joint as well as on the knee, whereas the vasti are attached proximally to the femoral shaft, and, acting as a unit, are powerful knee extensors. The medial or adductor compartment contains the named adductor muscles and gracilis; pectineus may also be included. These muscles are attached proximally to the anterior aspect of the pelvis, and distally to the femur; gracilis has no femoral attachment, being attached distally to the proximal tibia, while a part of adductor magnus has a proximal attachment to the ischial tuberosity. The posterior (‘hamstring’) compartment includes semitendinosus, semimembranosus and biceps femoris. These muscles are attached proximally to the ischial tuberosity and act both to extend the trunk on the femur and to flex and rotate the knee. Adductor magnus, as may be inferred from the extent of its proximal attachment and its dual innervation, shares the first of these functions with the hamstrings. Biceps femoris is the only muscle of the thigh that is attached distally to the fibula, and has no tibial attachment.

In the leg the anterior or extensor compartment includes the extensors (dorsiflexors) of the ankle and the long extensors of the toes. Tibialis anterior, the main ankle dorsiflexor, also inverts the foot at the subtalar joint, while the smallest muscle of the compartment, fibularis (peroneus) tertius, is a dorsiflexor that everts the foot. The posterior or flexor (plantarflexor) compartment has superficial and deep components. The superficial component contains gastrocnemius and soleus, powerful plantar flexors of the ankle, and the slender plantaris. Gastrocnemius and soleus are attached distally via the calcaneal (Achilles) tendon. The deep component of the flexor compartment contains popliteus, a rotator of the knee, the long flexors of the toes and tibialis posterior, the main invertor of the foot. The lateral compartment contains the main evertors of the foot, fibularis (peroneus) longus and brevis; both muscles are also plantar flexors at the ankle.

Gastrocnemius, plantaris and popliteus are the only muscles of the leg that are attached proximally to the femur and they can therefore act on the knee as well as at the ankle. The remaining leg muscles are attached proximally to the tibia, fibula or both, and to the interosseous membrane. The intrinsic muscles of the sole of the foot are arranged in layers. They facilitate the actions of the long flexors of the toes, and by effecting subtle changes in the shape of the foot they help control foot posture in stance and locomotion.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIAL SUPPLY

The femoral artery (the continuation of the external iliac artery) provides the principal arterial supply to the lower limb distal to the inguinal ligament and the gluteal fold (Figs 79.4, 79.5). The femoral artery courses within the anteromedial aspect of the thigh, becoming the popliteal artery on entering the posterior compartment of the thigh and dividing into its terminal branches in the posterior compartment of the leg. The obturator and inferior gluteal vessels also contribute to the supply of the proximal part of the limb. In the embryo the inferior gluteal artery supplied the main axial artery of the limb, which is represented in the adult by the arteria comitans nervi ischiadici (artery to the sciatic nerve).

Fig. 79.5 The anatomical territories served by the cutaneous blood supply to the lower limb.

The bones of the lower limb receive their arterial supply from nutrient vessels, metaphysial arterial branches of the peri-articular anastomoses, and the arteries supplying the muscles that attach to their periosteum. The pattern of arterial supply is particularly relevant to fracture healing, the spread of infection and malignancy, and to the planning of reconstructive surgical procedures. For further details consult Cormack & Lamberty (1994), Taylor & Razaboni (1994) and Crock (1996).

Arterial perforators of the lower limb

Achieving adequate and aesthetically satisfactory skin and soft tissue cover for large, superficial tissue defects is a perennial challenge in the field of plastic and reconstructive surgery, and accounts for a substantial part of the plastic surgeon’s workload. Generally, split-thickness and full-thickness skin grafts are suitable only for very superficial defects. To achieve tissue cover for deeper and larger tissue defects, the plastic surgeon employs one of a variety of autologous tissue flaps. The viability of a flap transplanted from one part of the body to another is crucially dependent on the blood supply of the flap. An appreciation of the angiosome concept (see Ch. 6), coupled with technological advances in reconstructive microsurgery, has stimulated the development and use of perforator (or perforator-based) flaps. These are flaps of skin or subcutaneous tissue supplied by one or more fascial ‘perforators’, i.e. arteries which reach the suprafascial plexus either directly from a source vessel, or indirectly from some other neighbouring tissue (Fig. 79.6). Perforator-based flaps are typically harvested with sparing of underlying muscle tissue and minimal trauma: their use is said to reduce postoperative pain, donor site morbidity and functional loss.

Fig. 79.6 Types of arterial perforators.

The lower limb is the largest donor site in the body for perforator-based flaps. Commonly used flaps are antero-lateral thigh flaps which provide a large amount of skin; superior and inferior gluteal artery perforator flaps used in breast reconstruction; vascularized fibula flaps for reconstruction of deficient bone; vascularized tensor fasciae latae flaps for tendon reconstruction; vascularized sural nerve flaps for nerve reconstruction; and the gracilis muscle flap, used in reanimation of paralysed muscle.

In the context of perforator flap surgery, the lower limb may be considered in terms of four anatomic regions: gluteal; anterior hip and thigh; knee and leg; ankle and foot. Each lower limb accounts for approximately 23% of the total body surface area (thigh 10.5%, leg 6.5%, buttock 2.5% and foot 3.5%) and contains an average of 90 arterial perforators (Fig. 79.7).

VENOUS DRAINAGE

The veins of the lower limb can be subdivided, like those of the upper limb, into superficial and deep groups (Figs 79.8, 79.9). The superficial veins are subcutaneous and lie in the superficial fascia; the deep veins (beneath the deep fascia) accompany the major arteries. Valves are present in both groups, but are more numerous in the deep veins. (Valves are more numerous in the veins of the lower limb than in the veins of the upper limb.) Venous plexuses occur within and between some of the lower limb muscles. The principal named superficial veins are the long and short saphenous veins; their numerous tributaries are mostly unnamed. For details and variations consult Kosinski (1926).

Deep veins of the lower limbs accompany the arteries and their branches. Plantar digital veins arise from plexuses in the plantar regions of the toes, connect with dorsal digital veins and unite to form four plantar metatarsal veins. These run in the intermetatarsal spaces and connect with dorsal veins by means of perforating veins. They then connect with each other to constitute a deep plantar venous arch adjacent to the plantar arterial arch. From this arch, medial and lateral plantar veins run near the corresponding arteries: they communicate with the long and short saphenous veins before forming the posterior tibial veins behind the medial malleolus. The posterior tibial veins accompany the posterior tibial artery. They receive veins from the calf muscles, especially the venous plexus in soleus, and connect with superficial veins and with the fibular veins. The latter, running with their artery, receive tributaries from soleus and from superficial veins.

The anterior tibial veins are continuations of the venae comitantes of the dorsalis pedis artery. They leave the extensor region between the tibia and fibula, pass through the proximal end of the interosseous membrane, and unite with the posterior tibial veins, at the distal border of popliteus, to form the popliteal vein.

Venous (muscle) pumps

In a standing position, venous return from the lower limb depends largely on muscular activity, especially contraction of the calf and foot muscles, known as the ‘muscle pump’, whose efficiency is aided by the tight sleeve of deep fascia. ‘Perforating’ veins connect the long saphenous vein with the deep veins, particularly near the ankle, distal calf and knee. Their valves are arranged so as to prevent flow of blood from the deep to the superficial veins. At rest, pressure in a superficial vein is equal to the height of the column of blood extending from that vein to the heart. When calf muscles contract, blood is pumped proximally in the deep veins and is normally prevented from flowing into the superficial veins by the valves in the perforating veins. During muscular relaxation, blood is drawn into the deep veins from the superficial veins. If the valves in the perforating veins become incompetent, these veins become sites of ‘high pressure leaks’ during muscular contraction, and the superficial veins become dilated and varicose. Similar perforating connections occur in the anterolateral region, where varicosities may also occur. Valvar incompetence in the connecting veins between the long saphenous vein and femoral vein in the adductor canal may predispose to superficial varicosities in the medial aspect of the thigh (Dodd & Cockett 1976).

Venous plexuses

Venous plexuses may be intramuscular (soleus) or intermuscular (in the foot and gluteal region). The plexuses communicate with the axially running deep veins and are components of the ‘muscle pump’ mechanism.

LYMPHATIC DRAINAGE

Most lymph from the lower limb traverses a large intermediary inguinal group of nodes (Fig. 79.10). Peripheral nodes are few and all are deeply sited. Except for an inconsistent node lying proximally on the interosseous membrane near the anterior tibial vessels, they occur only in the popliteal fossa. Enlarged popliteal nodes may be palpated along the line of the popliteal vessels while the passively supported knee is gradually moved from extension to semi-flexion. Inguinal nodes are found superficial and deep to the deep fascia. The deep nodes are few and lie alongside the medial aspect of the femoral vein. The superficial nodes may be divided into a lower vertical group that clothe the proximal part of the long saphenous vein, and an upper group that lie parallel to, but below, the inguinal ligament and which are related to the superficial circumflex iliac and superficial external pudendal vessels. Lymph from the lower limb passes from the inguinal nodes to the external and common iliac nodes, and ultimately drains to the lateral aortic group. Deep gluteal lymph reaches the same group through the internal and common iliac chains.

Superficial inguinal nodes
Popliteal group of nodes
Superficial lymphatics
Deep lymphatics
Direction of lymph flow

Fig. 79.10 Overview of lymphatics of the lower limb.

Superficial tissues

The superficial lymph vessels begin in subcutaneous plexuses. Collecting vessels leave the foot medially, along the long saphenous vein, or laterally with the short saphenous vein. Medial vessels are larger and more numerous; they start on the tibial side of the dorsum of the foot, ascend anterior or posterior to the medial malleolus and accompany the long saphenous vein. They drain to the distal superficial inguinal nodes. Lateral vessels begin on the fibular side of the dorsum of the foot; some cross anteriomedially in the leg to join the medial vessels and so pass to the distal superficial inguinal lymph nodes, others accompany the short saphenous vein and drain to the popliteal nodes. Superficial lymph vessels from the gluteal region run anteriorly to the proximal superficial inguinal nodes.

Deeper tissues

The deep lymph vessels accompany the anterior and posterior tibial, fibular, popliteal and femoral vessels. The deep vessels from the foot and leg are interrupted by popliteal nodes; those from the thigh pass to the deep inguinal nodes. The deep vessels of the gluteal and ischial regions follow their corresponding blood vessels. Those accompanying the superior gluteal vessels end in a node near the intrapelvic part of the superior gluteal artery, adjacent to the superior border of the greater sciatic foramen, while those which follow the inferior gluteal vessels traverse one or two of the small nodes below piriformis and pass to the internal iliac nodes.

INNERVATION

OVERVIEW OF THE LUMBAR AND SACRAL PLEXUSES

Nerves derived from the lumbar and sacral plexuses innervate the lower limb (Figs 79.11). The lumbar plexus lies deep within psoas major, anterior to the transverse processes of the first three lumbar vertebrae. The sacral plexus lies in the pelvis on the anterior surface of piriformis, external to the pelvic fascia, which separates it from the inferior gluteal and pudendal vessels. The lumbosacral trunk (L4 and L5) emerges medial to psoas major on the posterior abdominal wall and lies on the ala of the sacrum before crossing the pelvic brim to join the ventral ramus of S1.

Lesions of the lumbar and sacral plexuses

The deep and protected situation of the plexuses means that lesions are not common. The lumbar plexus may be involved in retroperitoneal pathology, and the sacral plexus may be invaded by spreading pelvic malignancy. Both may be involved in the reticuloses, affected by plexiform neuromas, or damaged in fractures of the lumbar spine and pelvis or in other conditions that cause severe retroperitoneal and pelvic haemorrhage. Temporary lesions may occur after pregnancy and childbirth, e.g. after difficult forceps delivery of a large baby. Pain, which may be diffuse, is the most common feature, and there is often clinical involvement of several roots.

OVERVIEW OF THE PRINCIPAL NERVES OF THE LOWER LIMB

Femoral nerve (L2–4)

The femoral nerve is the nerve of the anterior compartment of the thigh. It arises from the posterior divisions of the second to fourth lumbar ventral rami, descends through psoas major and emerges on its lateral border to pass between psoas and iliacus. It enters the thigh behind the inguinal ligament and lateral to the femoral sheath. Its terminal branches form in the femoral triangle about 2 cm distal to the inguinal ligament. In the abdomen the nerve supplies small branches to iliacus and a branch to the proximal part of the femoral artery. It subsequently supplies a large cutaneous area on the anterior and medial thigh, medial leg and foot, and gives articular branches to the hip and knee. The femoral nerve is described in detail on page 1383.

Obturator nerve (L2–4)

The obturator nerve is the nerve of the medial compartment of the thigh. It arises from the anterior divisions of the second to fourth lumbar ventral rami, descends through psoas major and emerges from its medial border at the pelvic brim. It crosses the sacroiliac joint behind the common iliac artery and lateral to the internal iliac vessels, runs along the lateral pelvic wall medial to obturator internus, and enters the thigh through the upper part of the obturator foramen. Near the foramen it divides into anterior and posterior branches which are separated at first by part of obturator externus and more distally by adductor brevis. It gives articular branches to the hip and knee, and may supply skin on the medial thigh and leg. The obturator nerve is described in detail on page 1383.

Sciatic nerve (L4, L5, S1–3)

The sciatic nerve is the nerve of the posterior compartment of the thigh and, via its major branches, of all the compartments of the leg and foot. Formed in the pelvis from the ventral rami of the fourth lumbar to third sacral spinal nerves, it is typically 2 cm wide at its origin and is the thickest nerve in the body. It enters the lower limb via the greater sciatic foramen below piriformis and descends between the greater trochanter and ischial tuberosity. The nerve passes along the back of the thigh, where it is crossed by the long head of biceps femoris, and divides into the tibial and common fibular (peroneal) nerves proximal to the knee: the level of bifurcation is variable. The tibial and common fibular nerves are structurally separate and only loosely held together within the sciatic nerve. The tibial nerve is derived from the anterior divisions of the sacral plexus and the common fibular nerve is made up of the posterior divisions of the plexus. The sciatic nerve gives off articular branches that supply the hip joint through its posterior capsule (these are sometimes derived directly from the sacral plexus) and the knee joint. All the hamstring muscles, including the ischial part of adductor magnus, but not the short head of biceps femoris, are supplied by the medial (tibial) component of the sciatic nerve. The short head of biceps is supplied by the lateral (common fibular) component. The sciatic nerve is described in detail on page 1384.

Tibial nerve (L4, L5, S1–3)

The tibial nerve is derived from the anterior divisions of the sacral plexus. It descends along the back of the thigh and popliteal fossa to the distal border of popliteus, then passes anterior to the arch of soleus with the popliteal artery and continues into the leg. In the popliteal fossa it lies lateral to the popliteal vessels, becomes superficial to them at the knee and crosses to the medial side of the artery. In the leg it is the nerve of the posterior compartment and descends with the posterior tibial vessels to lie between the heel and the medial malleolus. It ends beneath the flexor retinaculum by dividing into the medial and lateral plantar nerves. The tibial nerve supplies articular branches to the knee and ankle. Its cutaneous area of supply, including its terminal branches, includes the back of the calf, the whole of the sole, the lateral border of the foot and the medial and lateral sides of the heel. The tibial nerve is described in detail on page 1427.

Common fibular nerve (L4, L5, S1, S2)

The common fibular nerve (common peroneal nerve) is derived from the posterior divisions of the sacral plexus. In the leg it is the nerve of the anterior and lateral compartments. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, lying between the tendon of biceps femoris and the lateral head of gastrocnemius, then curves lateral to the neck of the fibula lying on the bone deep to fibularis longus and divides into superficial and deep fibular (peroneal) nerves. Before it divides, it gives off articular branches to the knee and the superior tibiofibular joints, and cutaneous branches. The cutaneous area supplied by the common fibular nerve and its terminal branches includes the anterolateral and lateral surfaces of the leg and most of the dorsum of the foot. The common fibular nerve is described in detail on page 1427.

Gluteal nerves

The gluteal nerves arise from the posterior divisions of the sacral plexus. The superior gluteal nerve (L4, L5, S1) leaves the pelvis through the greater sciatic notch above piriformis and supplies gluteus medius, gluteus minimus, tensor fasciae latae and the hip joint. The inferior gluteal nerve (L5, S1, S2) passes through the greater sciatic notch below piriformis and supplies gluteus maximus. The gluteal nerves are described in detail on page 1384.

AUTONOMIC INNERVATION

The autonomic supply to the limbs is exclusively sympathetic. The preganglionic sympathetic inflow to the lower limb is derived from neurones in the lateral horn of the lower thoracic (T10, T11 and T12) and upper lumbar (L1, L2) spinal cord segments. Fibres pass in white rami communicantes to the sympathetic chain and synapse in the lumbar and sacral ganglia. Postganglionic fibres pass in grey rami communicantes to enter the lumbar and sacral plexuses, and many are distributed via the cutaneous branches of the nerves derived from these plexuses. The blood vessels to the lower limb receive their sympathetic supply via adjacent peripheral nerves. Postganglionic fibres accompanying the iliac arteries are destined mainly for the pelvis but may supply vessels in the upper thigh.

Surgical or chemical lumbar sympathectomy may be indicated in arterial disease and in the management of plantar hyperhidrosis, and may be used to treat rest pain or other troublesome sensory symptoms in arterial disease or in causalgia. The segment of the chain including the second and third lumbar ganglia is removed: preservation of the first lumbar ganglion is said to lessen the risk of ejaculatory problems.

MOVEMENTS, MUSCLES AND SEGMENTAL INNERVATION

Most limb muscles are innervated by neurones which are derived from more than one segment of the spinal cord. The predominant segmental origin of the nerve supply for each of the muscles of the lower limb and for the movements which take place at the joints of the lower limb is summarized in Tables 79.1-79.4. Red has been used in Table 79.3 to highlight those muscles or movements which have diagnostic value (see below): damage to these segments or to their motor roots results in maximum paralysis. Data are based chiefly on clinical evidence (Sharrad 1995). The following caveats should be borne in mind when consulting these tables.

Table 79.1 Segmental innervation of the muscles of the lower limb

L1	Psoas major, psoas minor

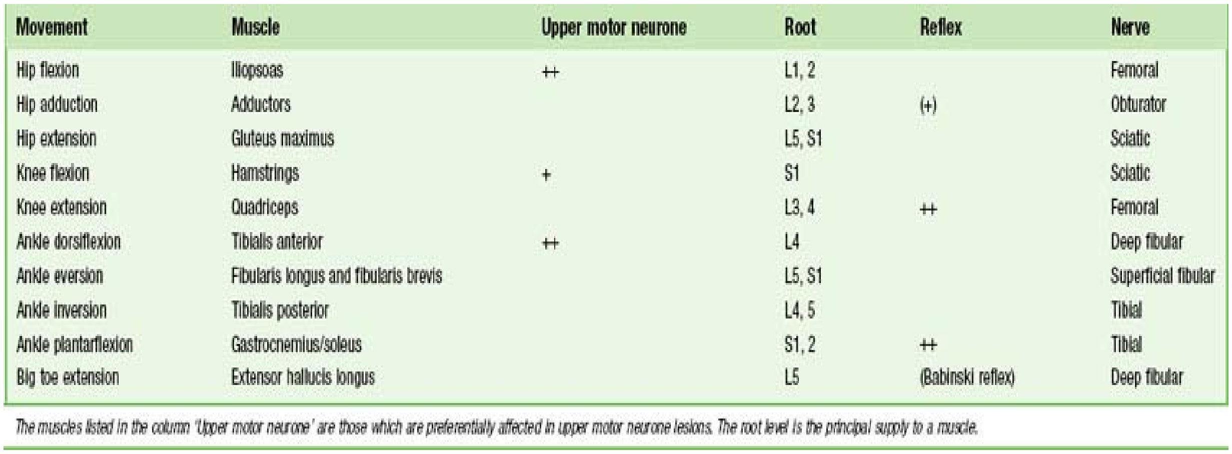
Royal blue shading denotes nerve roots from which there is a known dominant contribution. Turquoise shading denotes nerve roots from which the contribution is of similar degree.

Table 79.4 The movements and muscles tested to determine the location of a lesion in the lower limb



Movement	Muscle	Upper motor neurone	Root	Reflex	Nerve
Hip flexion	Iliopsoas	++	L1, 2		Femoral
Hip adduction	Adductors		L2, 3	(+)	Obturator
Hip extension	Gluteus maximus		L5, S1		Sciatic
Knee flexion	Hamstrings	+	S1		Sciatic
Knee extension	Quadriceps		L3, 4	++	Femoral
Ankle dorsiflexion	Tibialis anterior	++	L4		Deep fibular
Ankle eversion	Fibularis longus and fibularis brevis		L5, S1		Superficial fibular
Ankle inversion	Tibialis posterior		L4, 5		Tibial
Ankle plantarflexion	Gastrocnemius/soleus		S1, 2	++	Tibial
Big toe extension	Extensor hallucis longus		L5	(Babinski reflex)	Deep fibular

The muscles listed in the column 'Upper motor neurone' are those which are preferentially affected in upper motor neurone lesions. The root level is the principal supply to a muscle.

Movements

At the central nervous level of control, muscles are not recognized as individual actuators but as components of movement, and may therefore contribute to several types of movement, acting variously as prime movers, antagonists, fixators or synergists. Some muscles have been included in more than one place in Table 79.3, on the basis that a muscle which acts across one joint can produce a combination of movements (e.g. flexion with medial rotation, or extension with adduction) and a muscle which crosses two joints can produce more than one movement. It must also be remembered that these listings are not exhaustive.

Nerve roots

There is no universal consensus concerning the contribution that individual spinal roots make to the innervation of individual muscles: the most positive identifications, which are limited, have been obtained by electrically stimulating spinal roots and recording the evoked electromyographic activity in the muscles. Much of the information in Tables 79.1-79.4 is therefore based on neurological experience gained in examining the effects of lesions, and some of it is far from new. Spinal roots have been given turquoise shading when they innervate a muscle to a similar extent, or when differences in their contribution have not been described. Royal blue has been used to indicate roots from which there is known to be a dominant contribution. Minor contributions have been retained in the table in order to increase its utility in other contexts, such as electromyography and comparative anatomy.

Neurological localization of a lesion

In clinical practice it is only necessary to test a relatively small number of muscles in order to determine the location of a lesion. Any muscle to be tested must satisfy a number of criteria. It should be visible, so that wasting or fasciculation can be observed, and the muscle consistency with contraction can be felt. It should have an isolated action, so that its function can be tested separately. It should help to differentiate between lesions at different levels in the neuraxis and in the peripheral nerve, or between peripheral nerves. It should be tested in such a way that normal can be differentiated from abnormal, so that slight weakness can be detected early with reliability. Some preference should be given to muscles with an easily elicited reflex. Table 79.4 gives a list of movements and muscles chosen according to these criteria: in practice, these tests would be combined with tests of sensory function. Knowledge of the sequence in which motor branches leave a peripheral nerve to innervate specific muscles is very helpful in localizing the level of a lesion.

SURFACE ANATOMY

SKELETAL LANDMARKS

Pelvis

An oblique skin crease, the fold of the groin, marks the junction of the front of the thigh with the anterior abdominal wall, and lies distal to the inguinal ligament (Fig. 79.12). The anterior superior iliac spine lies above the lateral end of the fold and can always be palpated. At its medial end, the fold reaches the pubic tubercle. From the anterior superior iliac spine, the iliac crest is easily palpable along its entire length. It terminates posteriorly as the posterior superior iliac spine, which may be felt in the depression seen just above the buttock. This depression lies at the level of the second sacral segment, at the level of the middle of the sacroiliac joint and the termination of the spinal dural sac. The ischial tuberosity may be palpated in the lower part of the buttock. It is covered by gluteus maximus when the hip joint is extended, but can be identified without difficulty when the hip is flexed, e.g. in the sitting position, when the tuberosity emerges from under cover of the lower border of gluteus maximus and becomes subcutaneous, separated from the skin only by a pad of fat and the ischial bursa. In this position, the weight of the body is supported by the ischial tuberosities.

(With permission from Lumley JSP, 2002, Surface Anatomy, The Anatomical Basis of Clinical Examination, 3rd edn. Edinburgh: Churchill Livingstone.)

Femur

The greater trochanter of the femur, which is the only palpable part of the proximal portion of the femur, lies the breadth of the subject's hand below the midpoint of the iliac crest. It can be both seen and felt as a prominence in front of the hollow on the side of the gluteal region. The lower end of the femur is less deeply placed. When the knee is flexed passively, the medial surface of the medial condyle and the lateral surface of the lateral condyle of the femur may both be palpated, and portions of the femoral articular surface can be examined on each side of the lower part of the patella.

Patella

The patella can be readily identified. When the quadriceps is relaxed in the fully extended knee, the patella can be tilted and moved on the lower end of the femur. The lower limit of the patella lies more than 1–2 cm above the line of the knee joint (Figs 73.13 and 73.14).

Knee

The patella and the medial and lateral condyles of the femur have been described above. The tibial condyles form visible and palpable landmarks at the medial and lateral sides of the patellar tendon (Fig. 79.13). The latter may be traced downwards from the apex of the patella to the tibial tubercle, which is easily seen as well as felt. When the knee is flexed, the anterior margins of the tibial condyles can be felt: each forms the lower boundary of a depression at the side of the patellar tendon. The lateral condyle is the more prominent of the two. The joint line of the tibiofemoral joint corresponds to the upper margins of the tibial condyles and can be represented by a line drawn round the limb at this level. The anterior horns of the menisci lie in the angles between this line and the edges of the patellar tendon. The iliotibial tract is attached to a prominence, Gerdy’s tubercle, on the anterior aspect of the lateral condyle that is usually 1 cm below the joint line and 2 cm lateral to the tibial tubercle.

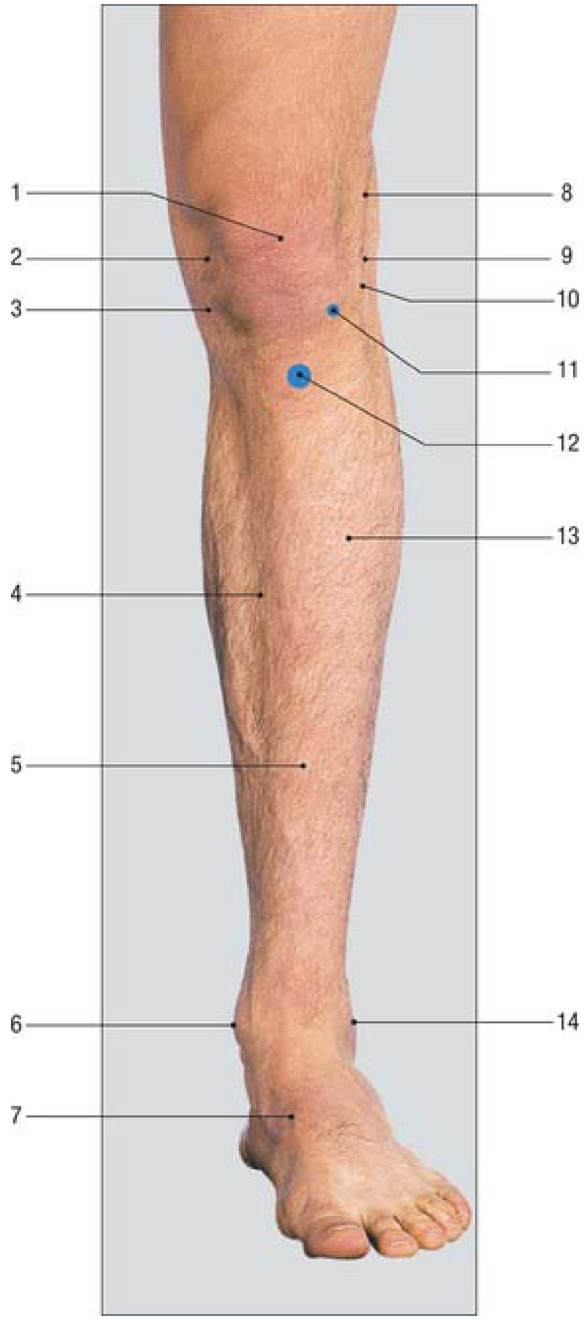

Fig. 79.13 Anterior aspect of the knee and leg. **1**. Patella. **2**. Medial femoral condyle. **3**. Medial tibial condyle. **4**. Medial surface of tibial shaft. **5**. Gerdy's tubercle on anterior aspect of lateral tibial condyle. **12**. Tibial tubercle. **13**. Anterior compartment of leg. **14**. Lateral malleolus.

(With permission from Lumley JSP, 2002, Surface Anatomy, The Anatomical Basis of Clinical Examination, 3rd edn. Edinburgh: Churchill Livingstone.)

The head of the fibula forms a slight surface elevation on the upper part of the posterolateral aspect of the leg. It lies vertically below the posterior part of the lateral condyle of the femur, not less than 1 cm below the level of the knee joint.

Leg and ankle

The subcutaneous medial surface of the tibia corresponds to the flat anteromedial aspect of the leg. Above, this surface merges with the medial condyle of the tibia, and below it is continuous with the visible prominence of the medial malleolus of the tibia (Fig. 79.14A). The sinuous anterior border of the tibia can be felt distinctly throughout most of its extent, but inferiorly it is somewhat masked by the tendon of tibialis anterior, which lies to its lateral side. The lateral malleolus of the fibula forms a conspicuous projection on the lateral side of the ankle: it descends to a more distal level than the medial malleolus and is placed on a more posterior plane (Fig. 79.14B). The lateral aspect of the lateral malleolus is continuous above with an elongated, subcutaneous, triangular area of the lower shaft of the fibula. The lateral part of the anterior margin of the lower end of the tibia can be detected immediately in front of the base of the lateral malleolus; the line of the ankle joint can be gauged from it.

*(**A** and **B** with permission from Lumley JSP, 2002, Surface Anatomy, The Anatomical Basis of Clinical Examination, 3rd edn. Edinburgh: Churchill Livingstone.)*

Foot

The anterior part of the upper surface of the calcaneus can be identified a little in front of the lateral malleolus on the dorsum of the foot. When the foot is passively inverted, the upper and lateral part of the head of the talus can be both seen and felt 3 cm anterior to the distal end of the tibia; it is obscured by the extensor tendons when the toes are dorsiflexed.

The dorsal aspects of the bodies of the metatarsal bones can be felt more or less distinctly, although they tend to be obscured by the extensor tendons of the toes. The tuberosity on the base of the fifth metatarsal bone forms a distinct projection, which can be both seen and felt, half-way along the lateral border of the foot.

The flat lateral surface of the calcaneus can be palpated on the lateral aspect of the heel and can be traced forwards below the lateral malleolus, where it is hidden by the tendons of fibularis longus and brevis. The peroneal tubercle (fibular tubercle), when sufficiently large, can be felt 2 cm below the tip of the lateral malleolus. A palpable depression just anterior to the lateral malleolus leads to the lateral end of the sinus tarsi.

On the medial side of the foot, the sustentaculum tali of the calcaneus can be felt 2 cm vertically below the medial malleolus. The medial aspect of the calcaneus can be felt (indistinctly) below and behind the sustentaculum tali. The most conspicuous bony landmark on the medial side of the foot is the tuberosity of the navicular bone, which is usually visible and can always be felt 2.5 cm anterior to the sustentaculum tali. Anterior to this, the medial cuneiform bone can be identified by tracing the tendon of tibialis anterior into it. The upper and medial parts of the joint between the medial cuneiform and the first metatarsal can be felt as a narrow groove.

When the foot is placed on the ground, it rests on the posterior part of the inferior surface of the calcaneus, the heads of the metatarsal bones and, to a lesser extent, on its lateral border. The instep, which corresponds to the medial longitudinal arch of the foot, is elevated from the ground. The medial and lateral tubercles of the calcaneus can be identified on the posterior part of the inferior surface of the calcaneus, but they are obscured by the tough fibro-fatty pad that covers them. The heads of the metatarsal bones are similarly covered by a thick pad, which forms the ball of the foot. The foot is at its widest at this level, reflecting the slight splay of the metatarsal bones as they pass anteriorly.

The calcaneocuboid joint lies 2 cm behind the tubercle on the base of the fifth metatarsal bone and is practically in line with the talonavicular joint, whose position may be gauged from the position of the head of the talus. The tarsometatarsal joints lie on a line joining the tubercle of the fifth metatarsal bone to the tarsometatarsal joint of the great toe. When the latter joint cannot be felt on the medial border of the foot, its position may be indicated 2.5 cm in front of the tuberosity of the navicular bone. The joint between the second metatarsal and the intermediate cuneiform lies some 2–3 mm behind the line of the other tarsometatarsal joints. The metatarsophalangeal joints lie 2.5 cm behind the webs of the toes.

MUSCULOTENDINOUS AND LIGAMENTOUS LANDMARKS

Buttock and hip

The bulky prominence of the buttock is caused by the forward tilt of the pelvis (which throws the ischium backwards), the size of gluteus maximus, and the large amount of subcutaneous fat.

The horizontal gluteal fold marks the upper limit of the posterior aspect of the thigh. It does not correspond to the lower border of gluteus maximus but is caused by fibrous connections between the skin and the deep fascia. The natal cleft, which separates the buttocks inferiorly, starts above at the third or fourth sacral spine. The upper border of gluteus maximus begins on the iliac crest some 3 cm lateral to the posterior superior iliac spine and runs downwards and laterally to the apex of the greater trochanter. Its lower border corresponds to a line drawn from the ischial tuberosity, through the midpoint of the gluteal fold, to a point about 9 cm below the greater trochanter (Fig. 79.15). Although gluteus maximus overlaps the ischial tuberosity in the standing position, on sitting it slides superiorly posterior to the tuberosity, leaving it free to bear weight. The muscle can be felt to contract when the hip is extended against resistance.

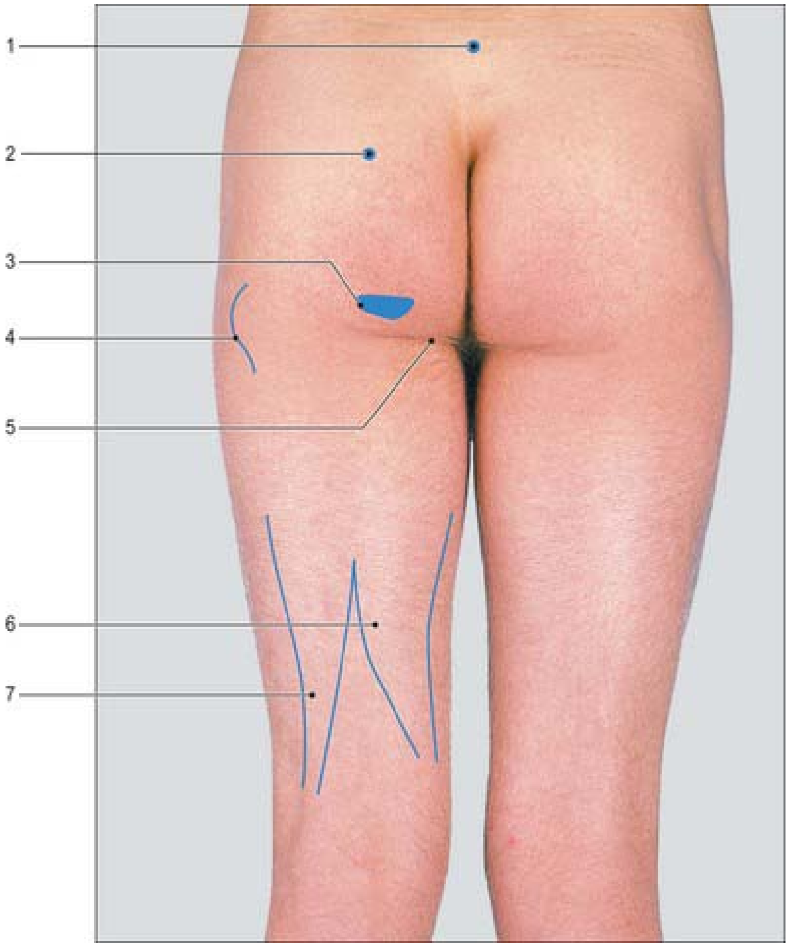

Fig. 79.15 Gluteal region and posterior aspect of the thigh. **1**. 4th lumbar spinous process. **2**. Posterior superior iliac spine. **3**. Ischial tuberosity. **4**. Greater trochanter. **5**. Gluteal crease. **6**. Semitendinosus and semimembranosus. **7**. Biceps femoris.

(With permission from Lumley JSP, 2002, Surface Anatomy, The Anatomical Basis of Clinical Examination, 3rd edn. Edinburgh: Churchill Livingstone.)

Gluteus medius completely covers the underlying gluteus minimus. Both muscles lie in a slight depression superolateral to gluteus maximus and inferior to the anterior portion of the iliac crest. They constitute the major abductors of the hip and are demonstrated by asking the subject to stand on one limb. The ipsilateral muscles contract and tilt the pelvis in order to stabilize the centre of gravity, and the contralateral gluteal fold will rise. If the hip abductors are paralysed, e.g. in congenital dislocation of the hip or in a long-standing fracture of the neck of the femur, this mechanism is disturbed and the normal tilting of the pelvis does not occur. Indeed, when the patient stands on the affected hip, the pelvis tilts downwards on the contralateral side (Trendelenburg’s sign).

Thigh

The inguinal ligament can be felt running between the anterior superior iliac spine and the pubic tubercle when the thigh is abducted and externally rotated. Just distal to the inguinal ligament, but running horizontally, is the hip flexure line (Holden’s line), where the deep layer of superficial fascia of the abdominal wall meets the fascia lata of the thigh.

The shallow depression lying immediately below the fold of the groin corresponds to the femoral triangle. It is bounded on its lateral side by the strap-like sartorius which can be both seen and felt in a reasonably thin and muscular subject when the hip is flexed in the sitting position, while keeping the knee extended, especially when the thigh is slightly abducted and rotated laterally. Sartorius can be traced downwards and medially from the anterior superior iliac spine to approximately half-way down the medial side of the thigh; distally, it may be identified as a soft longitudinal ridge passing towards the posterior part of the medial femoral condyle. The adductor group of muscles forms the bulky, fleshy mass at the upper part of the medial side of the thigh. The medial border of adductor longus forms the medial boundary of the femoral triangle and can be felt as a distinct ridge when the thigh is adducted against resistance. At its upper end, its tendon of origin immediately below the pubic tubercle can be identified and felt between the finger and thumb, which is a useful guide to this bony landmark.

The forward convexity of the front of the thigh is caused by the curvature of the femur covered by the fleshy mass of quadriceps femoris. Rectus femoris appears as a ridge passing down the anterior aspect of the thigh when the sitting subject flexes the hip with the knee extended. Vastus medialis constitutes the bulge above and medial to the patella. Vastus lateralis forms the elevation above and lateral to the patella, more proximal and less pronounced than that of vastus medialis. Vastus intermedius is hidden by the other three muscles.

The flattened appearance of the lateral aspect of the thigh is produced by the iliotibial tract, which is a thickened portion of the deep fascia of the thigh (fascia lata). It stands out as a strong, visible ridge on the lateral aspect of the knee when the knee is either extended against gravity or when the opposite limb is lifted from the floor while standing.

Knee

The large depression that can be seen at the back of the knee when the joint is actively flexed against resistance corresponds to the popliteal fossa (Fig. 79.16). The transverse skin crease of the popliteal fossa is 2–3 cm above the tibiofemoral joint line. The fossa is bounded on the lateral side by the prominent tendon of biceps femoris, which can be felt between the finger and thumb and can be traced downwards to the head of the fibula. Three tendons can be felt on the medial side of the fossa. Semitendinosus is the most lateral and posterior, and gracilis is the most medial and anterior. These two tendons stand out sharply and can be seen when the knee is flexed against resistance and the limb actively adducted. The third tendon is that of semimembranosus: it is more deeply situated and can be felt in the interval between the tendons of semitendinosus and gracilis. It is much thicker than the other two tendons and broadens rapidly as it is traced upwards. Distally, in thin individuals, the upper border of the pes anserinus can be palpated. The upper borders of the two heads of gastrocnemius form the medial and lateral inferior boundaries of the popliteal fossa.

(With permission from Lumley JSP, 2002, Surface Anatomy, The Anatomical Basis of Clinical Examination, 3rd edn. Edinburgh: Churchill Livingstone.)

The lateral collateral ligament may be felt passing from the tip of the fibular head to the lateral epicondyle of the femur when the knee is flexed and laterally directed pressure is applied to the medial side of the knee. The medial patellofemoral ligament may be felt overlying the medial femoral condyle in the flexed knee, running between the midpoint of the medial patella and medial femoral epicondyle.

Leg

The muscles in the anterior osteofascial compartment of the leg form a gentle prominence over the upper two-thirds of its anterolateral aspect: this prominence is accentuated when the foot is actively dorsiflexed. In the lower third of the leg these muscles are replaced by their tendons. The tendon of tibialis anterior can be seen just lateral to the anterior border of the tibia and traced downwards and medially across the front of the ankle (Fig. 79.14A). The other tendons cannot be examined satisfactorily above the ankle. Immediately above the medial malleolus and close to the medial border of the tibia, the tendons of tibialis posterior and flexor digitorum longus can be felt (rather indistinctly) when the foot is actively inverted and plantar flexed.

On the lateral aspect of the leg, fibularis longus can be seen as a narrow ridge during active eversion and plantarflexion of the foot. It covers and hides fibularis brevis. Both muscles cover the lateral aspect of the fibula, which means that the shaft of the fibula can only be palpated indistinctly between its neck and its lower subcutaneous triangular area.

The bulky prominence of the calf of the leg is formed by gastrocnemius and soleus, both of which can be identified either when the foot is plantar flexed against resistance, or when the heel is raised from the ground by standing on tiptoes. The two heads of gastrocnemius unite to form the inferior angle of the popliteal fossa. The medial head of gastrocnemius descends to a lower level than the lateral head. Soleus lies deep to gastrocnemius; when tensed, it bulges from under gastrocnemius, particularly on the lateral side, and its fleshy belly extends to a more distal level. Both muscles end below in the conspicuous calcaneal tendon which can be gripped between the finger and thumb and followed downwards to its insertion into the posterior aspect of the calcaneus (Fig. 79.16).

Foot

When the toes are actively dorsiflexed, the belly of extensor digitorum brevis forms a small elevation on the dorsum of the foot, a little in front of the lateral malleolus. It is the only intrinsic muscle of the foot to arise from the dorsum of the foot. The tendon of tibialis anterior stands out conspicuously on the medial side when active dorsiflexion of the toes is combined with inversion: it can be traced downwards and medially to the medial cuneiform bone. Also in dorsiflexion, the tendon of extensor hallucis longus can be identified lateral to tibialis anterior. Still more laterally, and immediately in front of the lateral part of the inferior end of the tibia, the tendons of extensor digitorum longus and fibularis tertius are crowded together as they pass through the fibrous loop of the inferior extensor retinaculum. More distally, these tendons diverge to their insertions.

The tendon of tibialis posterior winds posterior to the medial malleolus and then curves forwards in the interval between this bony landmark and the sustentaculum tali to reach the tuberosity of the navicular bone. The tendon is thrown into relief when the foot is forcibly plantar flexed and inverted. The tendon of flexor digitorum longus lies midway between the medial margin of the calcaneal tendon and the margin of the medial malleolus. It curves forwards below tibialis posterior and lies on the medial aspect of the sustentaculum tali. From there, it passes forwards and laterally to the centre of the sole of the foot, where it breaks up into tendons for the lateral four toes. The tendon of flexor hallucis longus lies inferior to, and grooves, the sustentaculum tali. As it passes forward to the great toe, it crosses the line of the flexor digitorum longus opposite the interval between the sustentaculum tali and the tuberosity of the navicular bone. Abductor hallucis may be seen in some subjects as a fleshy mass across the instep of the foot, passing from the medial calcaneal tubercle to the ball of the great toe.

The plantar fascia is most easily palpated along its medial border, in the sole of the foot when the toes are maximally dorsiflexed. Its precise origin is difficult to palpate because of the thickness of the heel pad, but it is easily palpated just distal to the heel pad as far as the ball of the foot.

VESSELS, PULSES AND NERVES

Arteries

The femoral artery enters the thigh at a point midway between the anterior superior iliac spine and the pubic symphysis, directly anterior to the hip joint. Its course can be represented by the upper two-thirds of a line joining that point to the adductor tubercle when the flexed thigh is abducted slightly and rotated laterally.

The popliteal artery may be represented approximately by a line extending from the junction of the middle and lower thirds of the thigh, 2.5 cm medial to its posterior midline, to the midpoint between the femoral condyles, and continuing inferolaterally to the level of the tibial tuberosity, medial to the fibular neck. The artery bifurcates into the anterior and posterior tibial arteries at the lower border of popliteus.

The anterior tibial artery may be represented by a line extending from a point half-way between the tibial tuberosity and fibular head to a point midway between the anterior borders of the two malleoli.

The posterior tibial artery corresponds to a line drawn from a mid-axial point on the calf at the level of the neck of the fibula to a point a third of the way between the posterior border of the medial malleolus and the calcaneal tendon. The same line represents the course of the tibial nerve. At first the nerve lies lateral to the popliteal artery, then gradually crosses the vessel to gain its medial side. The trunk of the medial plantar artery begins midway between the medial malleolus and heel (medial calcaneal tubercle) and extends towards the first interdigital cleft as far as the navicular bone.

Pulses

Femoral artery

The pulsations of the femoral artery can be felt at its origin, where the vessel can be compressed against the superior ramus of the pubis or the head of the femur. Like the carotid pulse, the femoral pulse is of value in assessing whether there is any significant cardiac output in cases of circulatory collapse. It is a common site for radiological catheter insertion and for arterial puncture for blood gas analysis.

Popliteal artery

The pulse of the popliteal artery is the most difficult of the peripheral pulses to feel because the artery lies deep in the popliteal fossa. It is best examined with the subject lying supine or prone, with the knee flexed, in order to relax the tense popliteal fascia that roofs the popliteal fossa. The popliteal pulse is then felt by deep pressure over the midline of the fossa against the popliteal surface of the femur.

Posterior tibial artery

The pulse of the posterior tibial artery can be felt by gentle palpation behind the medial malleolus as the artery lies between the tendons of flexor hallucis longus and flexor digitorum longus.

Dorsalis pedis arterial

The dorsalis pedis arterial pulse is found by palpation against the underlying tarsal bones immediately lateral to the tendon of extensor hallucis longus.

Veins

The surface marking for the femoral vein is immediately medial to the femoral pulse. The long saphenous vein usually terminates 2 cm inferior to the femoral pulse. Its course may be marked out in the thigh by a line passing from this point downwards and backwards to a point the breadth of the subject’s hand behind the medial border of the patella.

The long saphenous vein can often be seen as it runs upwards and backwards across the medial surface of the tibia a little above and in front of the medial malleolus: this is a useful site for obtaining surgical venous access or for harvesting vein for cardiac bypass surgery. The vein is accompanied in this region by the saphenous nerve, which is usually anterolateral, but may be posterior, to the vein. The vein and nerve then run proximally and posteriorly along the medial border of the tibia to reach a point the breadth of the subject’s hand posterior to the medial border of the patella. The short saphenous vein may be represented by a line that runs from the posterior surface of the lateral malleolus up the midline of the calf to the popliteal fossa; together with the sural nerve, it is the key anatomical guide to surgical dissection of the popliteal fossa.

The dorsal venous arch is often a conspicuous feature on the dorsum of the foot and curves, convex forwards, across the metatarsus. The long saphenous vein arises from its medial end and runs upwards and backwards immediately in front of the medial malleolus. The short saphenous vein arises from the lateral end of the arch and passes backwards and inferior to, and then upwards and posterior to, the lateral malleolus.

Femoral venous cannulation

While femoral venous puncture is relatively easy and supplies ready access to the right atrium, the use of this approach is relatively unpopular for long-term cannulation because of a higher incidence of thrombosis and sepsis. However, it is a useful site for venous sampling in a patient with collapsed veins. For femoral venous cannulation the skin puncture site is approximately 1 cm medial to the femoral artery and just below the inguinal ligament. After skin puncture the needle is advanced with the syringe at an angle of 30° to the skin, aiming cephalad.

Nerves

The areas of distribution and spinal segments of origin of the cutaneous nerves of the lower limb are shown in Figure 79.17.

Fig. 79.17 The cutaneous nerves of the lower limb: areas of distribution and spinal segments of origin. **A**, Anterior aspect; **B**, posterior aspect; **C**, sole of foot; **D**, dorsum of foot.

The surface marking for the femoral nerve in the inguinal region is immediately lateral to the femoral pulse. The surface marking for the course of the saphenous nerve is described with the course of the long saphenous vein (see above).

The course of the sciatic nerve can be represented by a line that starts at a point midway between the posterior superior iliac spine and ischial tuberosity, curves outwards and downwards through a point midway between the greater trochanter and the ischial tuberosity (Fig. 79.18), and then continues vertically downwards in the midline of the posterior aspect of the thigh to the upper angle of the popliteal fossa, where it divides into the tibial and common fibular nerves (if it has not already done so at a higher level).

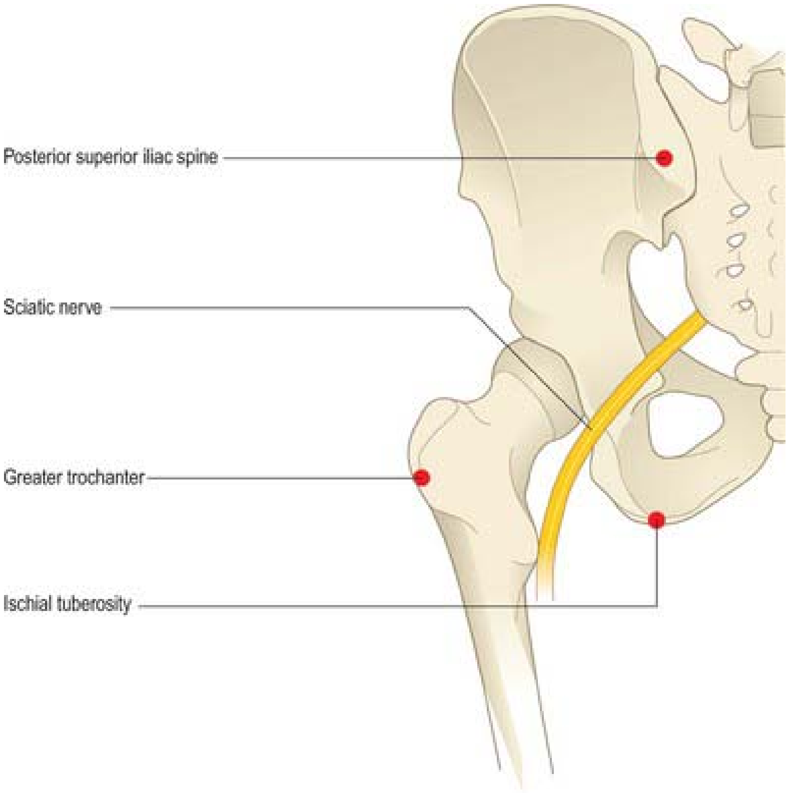

Fig. 79.18 Surface marking of the sciatic nerve. The line of the nerve joins the midpoint between the ischial tuberosity and the posterior superior iliac spine with the midpoint between the ischial tuberosity and the greater trochanter and then continues vertically down the back of the thigh.

The course of the common fibular nerve can be indicated by a line that runs from the upper angle of the popliteal fossa, along the medial side of the tendon of biceps femoris and then curves downwards and forwards around the neck of the fibula. The nerve is palpable medial and, more distally to the tendon of biceps and over the neck of the fibula, although here it is less distinct as it passes deep to the origin of fibularis longus. At the neck of the fibula the nerve is at particular risk of damage either from a tightly applied plaster cast or from a fracture.

The deep fibular nerve starts on the lateral aspect of the neck of the fibula, passes downwards and medially, and rapidly becomes associated with the anterior tibial artery, which it accompanies to the ankle. The superficial fibular nerve also begins on the lateral aspect of the neck of the fibula. It descends to a point on the anterior border of fibularis longus, at the junction of the middle and lower thirds of the leg, where it pierces the deep fascia and divides into medial and lateral branches. The latter gradually diverge as they descend to reach the dorsum of the foot and may be seen if the foot is pulled into maximal plantarflexion and adduction.

With one exception, the cutaneous nerves of the foot are not normally visible. The superficial fibular nerve is frequently seen and palpated over the dorsolateral aspect of the ankle and midfoot when the ankle is plantar flexed and the fourth toe passively flexed. This is particularly true in individuals with little subcutaneous fat. While the lateral branch is often seen, the medial branch is rarely visible. These superficial nerves are at risk from surgery in the anterior ankle region (especially during arthroscopy): they can be identified reliably by passive plantarflexion and inversion of the foot whilst running the blunt end of a ballpoint pen across the anterior ankle. An easily palpable click will localize the nerves, even in patients who are not thin.

Dermatomes

Our knowledge of the extent of individual dermatomes, especially in the limbs, is largely based on clinical evidence. The dermatomes of the lower limb arise from spinal nerves T12 to S3 (Fig 79.19 and 79.20).

Fig. 79.19 Dermatomes of the lower limb. There is considerable variation and overlap between dermatomes, but the overlap across axial lines (heavy black) is minimal.

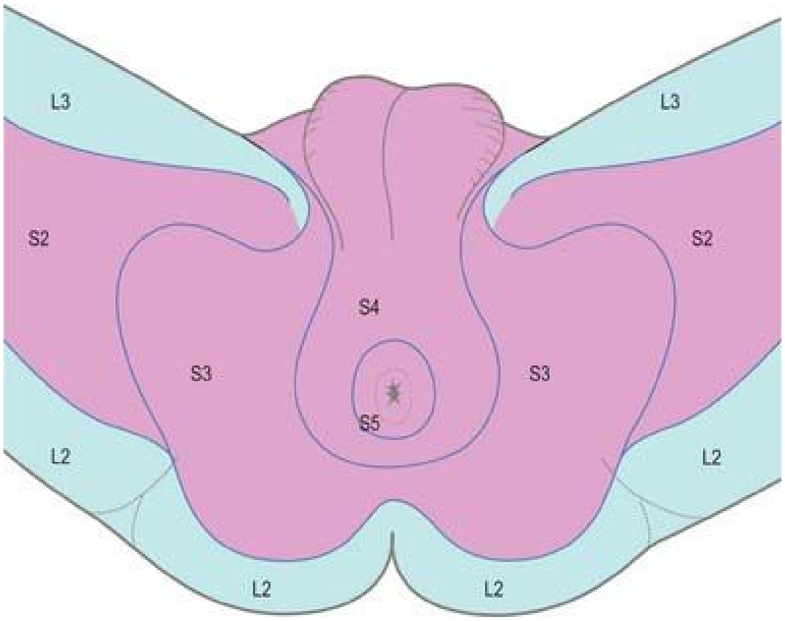

Fig. 79.20 Dermatomes of the perineum.

The preaxial border starts near the midpoint of the thigh and descends to the knee. It then curves medially, descending to the medial malleolus and the medial side of the foot and hallux. The postaxial border starts in the gluteal region and descends to the centre of the popliteal fossa, then deviates laterally to the lateral malleolus and the lateral side of the foot. The ventral and dorsal axial lines exhibit corresponding obliquity. The ventral starts proximally at the medial end of the inguinal ligament and descends along the posteromedial aspect of the thigh and leg to end proximal to the heel. The dorsal axial line begins in the lateral gluteal region and descends posterolaterally in the thigh to the knee; it inclines medially and ends proximal to the ankle. Considerable overlap exists between adjacent dermatomes innervated by nerves derived from consecutive spinal cord segments.

Myotomes

The predominant segmental origin of the nerve supply for each of the muscles of the lower limb and for the movements which take place at the joints of the lower limb are summarized in Tables 79.1-79.4.

Reflexes

Knee jerk (L2–4)

With the patient supine and the knee supported and partially flexed, the patellar tendon is struck at its midpoint: this should elicit contraction of the quadriceps, which extends the knee.

Ankle jerk (S1, 2)

With the patient supine and the lower limb externally rotated and partially flexed at hip and knee, the foot is passively dorsiflexed to stretch the calcaneal tendon, which is then struck with a percussion hammer. Contraction of the calf muscles plantar flexes the ankle. The reflex can also be examined with the patient kneeling on a chair.

Plantar reflex

The plantar reflex is a superficial reflex whose elicitation forms an important part of the clinical examination of the central nervous system. With the foot relaxed and warm, the outer edge of the sole is stroked longitudinally with a hard object (traditionally the examiner’s nail or a key). This should elicit flexion of the toes, although the normal adult response varies with the strength of the stimulus. In adults with upper motor neurone lesions, the response includes extension of the great toe (Babinski’s sign).

Nerve blocks

Nerves can be effectively blocked with local anaesthetic injection for surgical or post-injury pain relief. The useful blocks in the lower limb are around the hip, for thigh and knee pain, and around the ankle, for foot surgery. For the deeper nerves around the hip, the use of a nerve stimulator needle is very helpful to localize the nerve precisely before infiltration of local anaesthetic. For example, blockade of the sciatic nerve in the buttock, femoral nerve in the anterior groin, and obturator nerve in the medial groin may be undertaken to provide pain relief for total knee replacement; the tibial nerve at the posteromedial ankle, the sural nerve at the posterolateral ankle and the superficial fibular nerves at the anterior ankle may all be blocked at the ankle to allow ‘awake foot surgery’.

CLINICAL PROCEDURES

Intramuscular injection

Intramuscular injections into the buttock should be avoided to prevent iatrogenic damage to the sciatic nerve. If the buttock is to be used, the safe area is the true upper and outer quadrant, which is identified with the whole buttock exposed. The injection is then given mainly into gluteus medius rather than into gluteus maximus, provided a sufficiently long needle is used: most so-called ‘intramuscular’ injections given into the buttock are actually given into the fat. A safe alternative is to inject into the lateral aspect of the thigh (vastus lateralis).

Joint injection and aspiration

Careful aseptic technique is essential for all joint aspirations and injections.

Hip

With the patient lying supine, and after the positions of the femoral artery and the anterior superior iliac spine have been marked out, the needle is introduced anteriorly approximately 5 cm distal to the anterior superior iliac spine and 4 cm lateral to the femoral pulse, and passed posteriorly, a little proximally (cephalad), and medially.

Knee

The lateral retropatellar approach is used. With the patient supine and the knee extended, the needle is introduced at the level of the superior border of the patella and guided towards the suprapatellar pouch.

Ankle

The anterior approach entails introducing the needle between the tendons of tibialis anterior and extensor hallucis longus with the ankle partially plantar flexed, keeping the needle tangential to the curve of the talus.

Arthroscopy portals

The placement of portals for arthroscopy is critical, partly to maximize surgical access for visualization and for surgical instruments, but to also avoid damage to structures such as nerves and blood vessels.

Hip

Hip arthroscopy is not yet a common procedure but is increasingly being used. A variety of entry portals have been described. The anterolateral portal is sited on the skin approximately 4 cm lateral to the femoral pulse and 4 cm inferior to the inguinal ligament. A needle traversing the skin 30–45° cephalad is passed under X-ray control into the joint. Once the synovial cavity is entered the ‘vacuum’ is lost and the joint can be distracted. Other more lateral portals can be used: the lateral cutaneous nerve of the thigh and the sciatic nerve are potentially at risk.

Knee

The knee is the joint most frequently examined in this way. The standard portals are anterior. When the knee is flexed at a right angle, ‘soft triangles’ bordered by the patellar tendon, the femoral condyles and the tibia and anterior horns of the menisci are palpable on either side of the superior third of the patellar tendon. Small ‘stab’ incisions can be made in the apices of these triangular areas at about the level of the inferior pole of the patella for the anterolateral portal, and slightly lower for the anteromedial portal. These portals will allow passage of an arthroscope and instruments, with good access to most of the joint. The fat pad is close by and passage through it will hamper the view and subsequent surgery. The patellar tendon and the infrapatellar branch of the saphenous nerve are at risk from the incisions. The nerve is less vulnerable than the tendon: its position is variable but it usually lies below the appropriate portal sites. However, in the days of open meniscal surgery, the nerve was usually divided and painful neuroma formation was not uncommon.

Posteromedial and posterolateral portals are useful when better access to the posterior knee is required. The saphenous and common fibular nerves respectively are at risk with these approaches, and anatomical knowledge is vital to safe portal placement. Laterally the incision should be anterior to the tendon of biceps, which can easily be palpated. Medially the situation is more difficult because the saphenous nerve and vein run over the medial epicondylar region of the knee, a hand’s breadth posterior to the medial border of the patella. It is essential that sharp incision includes the skin only, and that dissection down to the joint capsule is undertaken bluntly. If the medial meniscus is sutured, the capsule must be exposed before tying off sutures to avoid ensnaring the nerve. In lateral meniscal repair a useful guide to avoid injury to the common fibular nerve is never to allow needles or sutures to pass medial to the tendon of popliteus whilst viewing arthroscopically.

Ankle

The use of ankle arthroscopy is well established, especially in treating sports-related injuries. Anterior portals are standard. The anteromedial portal can be placed to pass just medial to the tendon of tibialis anterior, in the palpable soft spot. However, this comes close to the long saphenous vein and nerve, and limiting the sharp incision to the skin, followed by blunt deeper dissection, reduces the risk. Alternatively the anteromedial portal can be chosen to pass between the lateral edge of tibialis anterior and extensor hallucis longus. The anterolateral portal is placed with the help of the arthroscope in the joint to check the position of a preliminary needle passed into the joint. The portal should pass lateral to fibularis tertius and extensor digitorum longus. The intermediate dorsal cutaneous branch of the superficial fibular nerve is at risk as it crosses the ankle anterior to the lateral malleolus, and therefore it is wise to ink in the nerves and blood vessels before making any incision. The nerves can be felt at the front of the ankle even in obese patients. They are often seen if the ankle is maximally pulled into plantarflexion and are seen to flick as the barrel of a pen is pulled across the front of the ankle. Posterior ankle arthroscopy is controversial: there is a view that the proximity of the neurovascular bundle (medially) and the sural nerve (laterally) renders it too hazardous. Keeping lateral to the tendon of flexor hallucis will safeguard the medial neurovascular bundle.

Surgical incisions

Hip

Hip joint surgery is usually undertaken for paediatric problems, trauma, or arthroplasty in arthritis. Anterior and anterolateral approaches, often used in children, put the lateral cutaneous nerve of the thigh at considerable risk. Even in more lateral approaches, the lateral cutaneous nerve of the thigh and the femoral and sciatic nerves are all at risk through traction. A popular anterolateral approach to the hip joint involves splitting and separating forwards the anterior part of gluteus medius and vastus lateralis as a single sheet of tissue for subsequent reattachment to the greater trochanter. This technique relies on the anatomical continuity of the tissue. If the splitting of gluteus medius is more than a few centimetres superior to the tip of the greater trochanter then the superior gluteal nerve and vessels are at risk, and weakness of hip abduction and a limp may result. In the posterior approach to the hip joint, gluteus maximus is incised in the line of its fibres. This is followed by division of the tendons of the short lateral rotators (piriformis, obturator internus and gemelli) near their trochanteric attachments to reveal the joint capsule. The sciatic nerve is protected by reflecting medially the cut ends of the divided short lateral rotators.

Knee

Most open knee surgery can be undertaken through an anterior midline longitudinal incision, which gives good access and means that any future surgery can usually be undertaken via the same wound. New incisions run the risk of skin necrosis and poor wound healing as a consequence of interfering with the cutaneous blood supply. Inevitable interruption of the cutaneous nerves, including the infrapatellar branch of the saphenous nerve, means that there is always numbness lateral to a longitudinal incision.

The extensile approach to the posterior knee is extensive. The key is to expose the sural nerve and short saphenous vein and to trace them proximally. This will lead the surgeon into the popliteal fossa and, after opening the deep fascia, safely to the neurovascular bundle. The wound crosses a flexure crease. A scar perpendicular to the crease might induce a fixed flexion contracture of the joint and therefore, as at the anterior elbow, an S-shaped incision is employed where the transverse segment runs in the line of the flexure crease.

Ankle and foot

Incisions around the foot and ankle frequently put cutaneous nerves at risk and such an injury can cause a distressing painful neuroma. The sural nerve at the ankle has a notorious tendency to form neuromas, often after repair of a ruptured calcaneal tendon. Bunion surgery is also problematic and can be undertaken through an internervous plane with a dorsomedial incision over the first metatarsophalangeal joint, rather than the traditional dorsal approach.

CHAPTER 80

Pelvic girdle, gluteal region and thigh

The pelvic girdle consists of the paired hip bones (each consisting of the ilium, ischium and pubis) and a single sacrum. The two pubic bones articulate anteriorly at the pubic symphysis and the sacrum articulates posteriorly with the two iliac bones: however, the bones are virtually incapable of independent movement except in the female during parturition. The pelvic girdle is massively constructed and serves as a weightbearing and protective structure, as an attachment for trunk and limb muscles, and as the skeletal framework of a birth canal capable of accommodating a large-headed fetus.

The gluteal region or buttock is an area demarcated by the gluteal fold inferiorly, a line joining the greater trochanter and the anterior superior iliac spine laterally, the iliac crest superiorly and the midline medially. It contains a large bulk of skeletal muscle that covers several vulnerable neurovascular structures, and incorporates junctional zones between the lower limb, pelvis and perineum at the sciatic foramina. Direct and indirect musculoskeletal injuries in this region may damage the sciatic nerve and gluteal vessels.

The thigh consists of a cylinder of compact bone, the femoral shaft, surrounded by muscle groups traversed by important neurovascular structures. The muscles are grouped according to function and lie within osteofascial compartments that are defined by fascial septa running between the femur and an enveloping tube of tough fascia, the fascia lata. The femoral artery gives off its major branch, the profunda femoris, in the anterior compartment, and the sciatic nerve usually divides into its main branches, the tibial and common fibular nerves, as it passes through the posterior compartment. The femoral nerve divides soon after entering the anterior compartment beneath the inguinal ligament; the obturator nerve enters the region proximally and medially from the pelvis and divides into its main branches which run anterior and posterior to adductor brevis.

SKIN AND SOFT TISSUES

SKIN

See also Chapter 79.

Vascular supply and lymphatic drainage

Buttock

Most of the skin of the buttock is supplied by musculocutaneous perforating vessels from the superior and inferior gluteal arteries. There are also small peripheral contributions from similar branches of the internal pudendal, iliolumbar and sacral arteries.

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is to the superficial inguinal nodes.

Thigh

The skin of the thigh distal to the inguinal ligament and gluteal fold is supplied mainly by branches of the femoral and profunda femoris arteries. There is some contribution from the obturator, inferior gluteal and popliteal arteries and from direct cutaneous, musculocutaneous and fasciocutaneous vessels. For further details consult Cormack & Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is to the superficial inguinal nodes, mainly via collecting trunks accompanying the long saphenous vein.

Innervation

See page 1346 and Figs 79.17B, 79.19.

SOFT TISSUE

Fascia

Superficial fascia

The superficial fascia of the buttock is continuous superiorly with that over the low back, and contains a variable quantity of coarse fat. The superficial fascia of the thigh consists, as elsewhere in the limbs, of loose areolar tissue containing fat. In some regions, particularly near the inguinal ligament, it splits into recognizable layers, between which may be found the branches of superficial vessels and nerves. It is thick in the inguinal region, where its two layers enclose the superficial inguinal lymph nodes, long saphenous vein and other smaller vessels. Here the superficial layer is continuous with that of the abdominal fascia. The deep layer, a thin fibroelastic stratum, is most marked medial to the long saphenous vein and inferior to the inguinal ligament, and is interposed between the subcutaneous vessels and nerves and the deep fascia, fusing with the latter a little below the ligament. (The line of fusion lies in the floor of the ventral flexure line, otherwise known as the groove associated with the hip joint.) This membranous layer of superficial fascia overlies the saphenous opening, blending with its circumference and with the femoral sheath. Over the opening it is perforated by the long (great) saphenous vein, by the superficial branches of the femoral artery other than the superficial circumflex iliac (which perforates the fascia lata separately), and lymphatic vessels, hence the term cribriform fascia (Latin *cribrum* = a sieve).

Deep fascia

The deep fascia covering the gluteal muscles varies in thickness. Over the maximus it is thin, but over the anterior two-thirds of the medius it forms the thick, strong gluteal aponeurosis. This is attached to the lateral border of the iliac crest superiorly, and splits anteriorly to enclose tensor fasciae latae and posteriorly to enclose gluteus maximus.

Fascia lata

The fascia lata, the wide deep fascia of the thigh, is thicker in the proximal and lateral parts of the thigh where tensor fasciae latae and an expansion from gluteus maximus are attached to it. It is thin posteriorly and over the adductor muscles, but thicker around the knee, where it is strengthened by expansions from the tendon of biceps femoris laterally, sartorius medially, and quadriceps femoris anteriorly. The fascia lata is attached superiorly and posteriorly to the back of the sacrum and coccyx, laterally to the outer margin of the iliac crest, anteriorly to the inguinal ligament and superior ramus of the pubis, and medially to the inferior ramus of the pubis, the ramus and tuberosity of the ischium, and the lower border of the sacrotuberous ligament. From the iliac crest it descends as a dense layer over gluteus medius to the upper border of gluteus maximus, where it splits into two layers, one passing superficial and the other deep to the muscle, the layers reuniting at the lower border of the muscle.

Iliotibial tract

Over the flattened lateral surface of the thigh, the fascia lata thickens to form a strong band, the iliotibial tract. The upper end of the tract splits into two layers, where it encloses and anchors tensor fasciae latae and receives, posteriorly, most of the tendon of gluteus maximus. The superficial layer ascends lateral to tensor fasciae latae to the iliac crest; the deeper layer passes up and medially, deep to the muscle, and blends with the lateral part of the capsule of the hip joint. Distally, the iliotibial tract is attached to a smooth, triangular facet (Gerdy’s tubercle) on the anterolateral aspect of the lateral condyle of the tibia where it is superficial to, and blends with, an aponeurotic expansion from vastus lateralis. When the knee is extended against resistance it stands out as a strong, visible ridge on the anterolateral aspect of the thigh and knee.

Distally, the fascia lata is attached to all exposed bony points around the knee joint, such as the condyles of the femur and tibia, and the head of the fibula. On each side of the patella the deep fascia is reinforced by transverse fibres, which receive contributions from the lateral and medial vasti. The stronger lateral fibres are continuous with the iliotibial tract.

Intermuscular septa

The deep surface of the fascia lata yields two intermuscular septa, which are attached to the whole of the linea aspera and to its proximal and distal prolongations. The lateral septum, thicker and stronger than the medial one, extends from the attachment of gluteus maximus to the lateral femoral condyle, and lies between vastus lateralis in front and the short head of biceps femoris behind and provides partial attachment for them. The medial, thinner and weaker septum lies between vastus medialis and the adductors and pectineus. Numerous smaller septa, such as that separating the thigh adductors and flexors, pass between the individual muscles, ensheathing them and sometimes providing partial attachment for their fibres.

Saphenous opening

The saphenous opening is an aperture in the deep fascia, inferolateral to the medial end of the inguinal ligament, which allows passage to the long saphenous vein and other smaller vessels (Fig. 80.1). The cribriform fascia, which is pierced by these structures, fills in the aperture and must be removed to reveal it. Adjacent subsidiary openings may exist to transmit venous tributaries. In the adult the approximate centre of the opening is 3 cm lateral to a point just distal to the pubic tubercle. The length and width of the opening vary considerably. The fascia lata in this part of the thigh displays superficial and deep strata (not to be confused with the superficial and deep layers of the superficial fascia described above). They lie, respectively, anterior and posterior to the femoral sheath; with the saphenous opening situated where the two layers are in continuity. This serves to explain the somewhat oblique and spiral configuration of the saphenous opening.

The superficial stratum, lateral and superior to the saphenous opening, is attached, in continuity, to the crest and anterior superior spine of the ilium, to the whole length of the inguinal ligament, and to the pecten pubis and lacunar ligament. It is reflected inferolaterally from the pubic tubercle as the arched falciform margin, which forms the superior, lateral and inferior boundaries of the saphenous opening: this margin adheres to the anterior layer of the femoral sheath, and the cribriform fascia is attached to it. The falciform margin is considered to have superior and inferior cornua. The inferior cornu is well defined, and is continuous behind the long saphenous vein with the deep stratum of the fascia lata.

The deep stratum is medial to the saphenous opening and is continuous with the superficial stratum at its lower margin. Traced upwards, it covers pectineus, adductor longus and gracilis, passes behind the femoral sheath, with which it is blends, and continues to the pecten pubis.

Fascial compartments

There are three functional groups of muscle in the thigh, namely, anterior (extensor), posterior (flexor) and medial (adductor). The anterior and posterior groups occupy separate osteofascial compartments that are limited peripherally by the fascia lata and separated from each other by the femur and the medial and lateral intermuscular septa (Fig. 80.2). The adductor muscles, though distinct in terms of function and innervation, do not possess a separate compartment limited by fascial planes. Nevertheless it is customary to speak of three compartments: anterior, posterior and medial. The muscles of the three compartments are described below. Adductor magnus, adductor longus and pectineus could each be considered to be constituents of two compartments, i.e. adductor magnus in the posterior and the medial compartments, and adductor longus and pectineus in the anterior and the medial compartments.

The nerve supply to the compartments of the thigh mainly follows the ‘one compartment – one nerve’ principle. Thus the femoral nerve supplies the anterior compartment muscles, the obturator nerve supplies the medial compartment muscles, and the sciatic nerve supplies those in the posterior compartment. The dual functional and compartmental attribution of adductor magnus and adductor longus and pectineus are reflected in their dual nerve supplies.

In contrast to the motor innervation, the arterial supply to the compartmental muscle groups does not exhibit such a direct relationship. All groups receive a supply from the femoral system, particularly from the profunda femoris and its branches. The adductors receive a contribution from the obturator artery, and the hamstrings receive a proximal supply from the inferior gluteal artery. Further details are given in the descriptions of the individual muscles.

Femoral sheath

The femoral sheath is a funnel-shaped distal prolongation of extraperitoneal fascia, formed of transversalis fascia anterior to the femoral vessels, and of the iliac fascia posteriorly (Fig. 80.3). It is wider proximally and its tapered distal end fuses with the vascular adventitia 3 or 4 cm distal to the inguinal ligament. At birth the sheath is shorter; it elongates when extension at the hips becomes habitual. The femoral branch of the genitofemoral nerve perforates its lateral wall. The medial wall slopes laterally and is pierced by the long (great) saphenous vein and lymphatic vessels. Like the carotid sheath, the femoral sheath encloses a mass of connective tissue in which the vessels are embedded. Three compartments are described: a lateral one containing the femoral artery, an intermediate one for the femoral vein, and a medial compartment, the femoral canal, which contains lymph vessels and an occasional lymph node embedded in areolar tissue. The presence of this canal allows the femoral vein to distend. The canal is conical and approximately 1.25 cm in length. Its proximal (wider) end, termed the femoral ring, is bounded in front by the inguinal ligament, behind by pectineus and its fascia and the pectineal ligament, medially by the crescentic, lateral edge of the lacunar ligament and laterally by the femoral vein. The spermatic cord, or the round ligament of the uterus, is just above its anterior margin, while the inferior epigastric vessels are near its anterolateral rim. It is larger in women than in men: this is due partly to the relatively greater width of the female pelvis and partly to the smaller size of the femoral vessels in women. The ring is filled by condensed extraperitoneal tissue, the femoral septum, which is covered on its proximal aspect by the parietal peritoneum. The femoral septum is traversed by numerous lymph vessels that connect the deep inguinal to the external iliac lymph nodes.

Iliac fascia

The iliac fascia covers psoas and iliacus. It is thin above, but thickens progressively towards the inguinal ligament. The part covering psoas is thickened above as the medial arcuate ligament. Medially, the fascia over psoas is attached by a series of fibrous arches to the intervertebral discs, the margins of vertebral bodies, and the upper part of the sacrum. Laterally, it blends with the fascia anterior to quadratus lumborum above the iliac crest, and with the fascia covering iliacus below the crest.

The iliac part is connected laterally to the whole of the inner lip of the iliac crest and medially to the pelvic brim, where it blends with the periosteum. It is attached to the iliopubic ramus, where it receives a slip from the tendon of psoas minor, when that muscle is present. The external iliac vessels are anterior to the fascia but the branches of the lumbar plexus are posterior. The fascia is separated from the peritoneum by loose extraperitoneal tissue. Lateral to the femoral vessels, the iliac fascia is continuous with the posterior margin of the inguinal ligament and the transversalis fascia. Medially it passes behind the femoral vessels to become the pectineal fascia, attached to the pecten pubis. At the junction of its lateral and medial parts it is attached to the iliopubic ramus and the capsule of the hip joint. It thus forms a septum between the inguinal ligament and the hip bone, dividing the space here into a lateral part, the muscular space, containing psoas major, iliacus and the femoral nerve, and a medial part, the vascular space, transmitting the femoral vessels (Fig. 80.3). The iliac fascia continues downward to form the posterior wall of the femoral sheath.

Obturator membrane

The obturator membrane (Fig. 80.4) is a thin aponeurosis that closes (obturates) most of the obturator foramen, leaving a superolateral aperture, the obturator canal, through which the obturator vessels and nerve leave the pelvis and enter the thigh. The membrane is attached to the sharp margin of the obturator foramen except at its inferolateral angle, where it is fixed to the pelvic surface of the ischial ramus, i.e. internal to the foramen. Its fibres are arranged mainly transversely in interlacing bundles; the uppermost bundle, which is attached to the obturator tubercles, completes the obturator canal. The outer and inner surfaces of the obturator membrane provide attachment for the obturator externus and internus respectively. Some fibres of the pubofemoral ligament of the hip joint are attached to the outer surface.

BONE

The pelvic girdle is an entity consisting of the two hip bones and the sacrum (strictly speaking, the sacrum is part of the vertebral column). These bones are virtually incapable of independent movement except in the female during parturition. The pelvic girdle is massively constructed and serves as a weightbearing and protective structure, an attachment for trunk and limb muscles, and as the skeletal framework of the birth canal.

HIP BONE

The hip bone is large, irregular, constricted centrally and expanded above and below (Fig. 80.5A,B). Its lateral surface has a deep, cup-shaped acetabulum, articulating with the femoral head, anteroinferior to which is the large, oval or triangular obturator foramen. Above the acetabulum the bone widens into an undulant plate surmounted by a sinuously curved iliac crest.

(From Sobotta 2006.)

The bone articulates in front with its fellow and posteriorly with the side of the sacrum to form the pelvic girdle. Each hip bone has three parts, ilium, ischium and pubis, connected to each other by cartilage in youth but united as one bone in adults. The principal union is in the acetabulum. The ilium includes the upper acetabulum and expanded area above it; the ischium includes the lower acetabulum and bone posteroinferior to it; the pubis forms the anterior acetabulum, separating the ilium from ischium, and the anterior median region where the pubes meet.

Acetabulum

The acetabulum (Fig. 80.5A,C) is an approximately hemispherical cavity situated about the centre of the lateral aspect of the hip bone. It faces anteroinferiorly and is circumscribed by an irregular margin deficient inferiorly at the acetabular notch. The acetabular fossa forms the central floor and is rough and non-articular. The articular lunate surface is widest above (the ‘dome’), where weight is transmitted to the femur. Consequently, fractures through this region tend to be associated with unsatisfactory outcomes. All three components of the hip bone contribute to the acetabulum, although unequally. The pubis forms the anterosuperior fifth of the articular surface, the ischium forms the floor of the fossa and rather more than the posteroinferior two-fifths of the articular surface, and the ilium forms the remainder. Occasionally a linear defect may be seen to cross the acetabular surface from the superior border to the acetabular fossa This does not correspond to any junction between the main morphological parts of the hip bone.

Obturator foramen

The obturator foramen lies below and slightly anterior to the acetabulum, between the pubis and ischium. It is bordered above by the grooved obturator surface of the superior pubic ramus, medially by the pubic body and its inferior ramus, below by the ischial ramus, and laterally by the anterior border of the ischial body, including the margin of the acetabulum. The foramen is almost closed by the obturator membrane (see above), which is attached to its margins, except superolaterally, where a communication remains between the pelvis and thigh. This free edge of the membrane is attached to an anterior obturator tubercle at the anterior end of the inferior border of the superior pubic ramus, and a posterior obturator tubercle on the anterior border of the acetabular notch; these tubercles are sometimes indistinct. Since the tubercles lie in different planes and the obturator groove crosses the upper border of the foramen, the acetabular rim is in fact a spiral. The foramen is large and oval in males, but smaller and nearly triangular in females.

Structure

The thicker parts of the hip bone are trabecular, encased by two layers of compact bone, while the thinner parts, as in the acetabulum and central iliac fossa, are often translucent and consist of a single lamina of compact bone. In the upper acetabulum and along the arcuate line, i.e. the route of weight transmission from the sacrum to the femur, the amount of compact bone is increased and the subjacent trabecular bone displays two sets of pressure lamellae. These start together near the upper auricular surface and diverge to meet two strong buttresses of compact bone, from which two similar sets of lamellar arches start and converge on the acetabulum. The anterior part of the iliac crest has been much studied with regard to distribution of cortical and trabecular bone. For a survey of these studies consult Whitehouse (1977). Additionally, Whitehouse's observations, based on scanning electron micrography, indicate that the cortical bone is very porous, being only 75% bone, decreasing to 35% near the anterior superior iliac spine. Denser cortical bone starts at the margins of the crest and thickens rapidly below it on both aspects of the iliac blade.

Studies of the internal stresses within the hip bone have revealed a pattern of trabeculae that corresponds well with the theoretically expected patterns of stress trajectories (Holm 1980). These patterns are considerably more complex than in any other major bone. Stresses are higher in the acetabular than in the iliac region. In the ilium, the pelvic surface is subjected to considerably less stress than is the gluteal surface.

Muscle attachments

See individual bones.

Vascular supply

In the infant, nutrient arteries are clearly demonstrable for each component of the hip bone. Each nutrient artery branches in fan-like fashion within its bone of supply (Crock 1996). Later, a periosteal arterial network develops, with contributions from numerous local arteries (see under individual bones).

Innervation

Periosteal innervation is by a network of nerves derived from branches of local nerves. These nerves also supply muscles attaching to the periosteum and the joints involving the hip bone. Autonomic nerves accompany nutrient arteries and branch within the bone.

Ossification

Ossification (Figs 80.6, 80.7) is by three primary centres, one each for the ilium, ischium and pubis. The iliac centre appears above the greater sciatic notch prenatally at about the ninth week; the ischial centre in its body in the fourth month, and the pubic centre in its superior ramus between the fourth and fifth months. At birth the whole iliac crest, the acetabular floor and inferior margin are cartilaginous. Gradual ossification of the three components of the acetabulum results in a triradiate cartilaginous stem extending medially to the pelvic surface as a Y-shaped epiphysial plate between the ilium, ischium and pubis, and including the anterior inferior iliac spine. Cartilage along the inferior margin also covers the ischial tuberosity, forms conjoined ischial and pubic rami, and continues to the pubic symphysial surface and along the pubic crest to its tubercle.

Cartilaginous growth plates. **5**. Ossifying greater trochanter. **6**. Ischium. **7**. Pubis. **8**. Cartilage between pubic and ischial rami.

The ossifying ischium and pubis fuse to form a continuous ischiopubic ramus at the seventh or eighth year. Secondary centres, other than for the acetabulum, appear about puberty and fuse between the 15th and 25th years. There are usually two for the iliac crest (which fuse early), and single centres for the ischial tuberosity (in cartilage close to the inferior acetabular margin and spreading forwards), anterior inferior iliac spine (although it may ossify from the triradiate cartilage), and symphysial surface of the pubis (the pubic tubercle and crest may have separate centres). Progression of ossification of the iliac crest in girls is an index of skeletal maturity and is useful in determining the optimal timing of surgery for spinal deformity.

Between the ages of 8 and 9 years three major centres of ossification appear in the acetabular cartilage. The largest appears in the anterior wall of the acetabulum and fuses with the pubis, the second in the iliac acetabular cartilage superiorly, fusing with the ilium, and the third in the ischial acetabular cartilage posteriorly, fusing with the ischium. At puberty these epiphyses expand towards the periphery of the acetabulum and contribute to its depth (Ponseti 1978). Fusion between the three bones within the acetabulum occurs between the 16th and 18th years. Delaere et al (1992) have suggested that ossification of the ilium is similar to that of a long bone, possessing three cartilaginous epiphyses and one cartilaginous process, although it tends to undergo osteoclastic resorption comparable with that of cranial bones. During development the acetabulum increases in breadth at a faster rate than it does in depth.

Avulsion fractures of pelvic apophyses may occur from excessive pull on tendons, usually in athletic adolescents. The most frequent examples of such injuries are those to the ischial tuberosity (hamstrings) and anterior inferior iliac spine (rectus femoris).

Pubis

Topography

The pubis (Figs 80.5, 80.6) is the ventral part of the hip bone and forms a median cartilaginous pubic symphysis with its fellow. The body of the pubis occupies the anteromedial part of the bone, and from the body a superior ramus passes up and back to the acetabulum and an inferior ramus passes back, down and laterally to join the ischial ramus inferomedial to the obturator foramen.

Body

The body, anteroposteriorly compressed, has anterior, posterior and symphysial (medial) surfaces and an upper border, the pubic crest. The anterior surface also faces inferolaterally; it is rough superomedially and smooth elsewhere, giving attachment to medial femoral muscles. The smooth posterior surface faces upwards and backwards as the oblique anterior wall of the lesser pelvis and is related to the urinary bladder. The symphysial surface is elongated and oval, united by cartilage to its fellow at the pubic symphysis. Denuded of cartilage it has an irregular surface of small ridges and furrows or nodular elevations, varying considerably with age, features which are of forensic interest. The pubic crest is the rounded upper border of the body which overhangs the anterior surface; its lateral end is the rounded pubic tubercle. Both crest and tubercle are palpable, the latter partly obscured in males by the spermatic cord that crosses above it from the scrotum to the abdomen. The pubic rami diverge posterolaterally from the superolateral corners of the body.

The anterior surface of the pubic body faces the femoral adductor region. The anterior pubic ligament attaches to its medial part along a rough strip, which is wider in females. The posterior surface is separated from the urinary bladder by retropubic fat. The puboprostatic ligaments are attached to this surface medial to levator ani.

Superior pubic ramus

The superior pubic ramus passes upwards, backwards and laterally from the body, superolateral to the obturator foramen, to reach the acetabulum. It is triangular in section and has three surfaces and borders. Its anterior, pectineal surface, tilted slightly up, is triangular in outline and extends from the pubic tubercle to the iliopubic ramus. It is bounded in front by the rounded obturator crest and behind by the sharp pecten pubis (pectineal line) which, with the crest, is the pubic part of the linea terminalis (i.e. anterior part of the pelvic brim). The posterosuperior, pelvic surface, medially inclined, is smooth and narrows into the posterior surface of the body, which is bounded above by the pecten pubis and below by a sharp inferior border. The obturator surface, directed down and back, is crossed by the obturator groove sloping down and forwards. Its anterior limit is the obturator crest and its posterior limit is the inferior border.

Inferior pubic ramus

The inferior pubic ramus, an inferolateral process of the body, descends inferolaterally to join the ischial ramus medial to, and below, the obturator foramen. The union may be locally thickened, but not obviously so in adults. The ramus has two surfaces and borders. The anterolateral surface, continuous above with that of the pubic body, faces the thigh and is marked by muscles. It is limited laterally by the margin of the obturator foramen and, medially, by the rough anterior border. The posteromedial surface is continuous above with that of the body and is transversely convex: its medial part is often everted in males and gives attachment to the crus of the penis. This surface faces the perineum medially, its smooth lateral part tilted up towards the pelvic cavity.

The internal surface is indistinctly divided into medial, intermediate and lateral areas. The medial area faces inferomedially in direct contact with the crus of the penis or clitoris and is limited above and behind by an indistinct ridge for attachment of the fascia overlying the superficial perineal muscles. The medial margin of the ramus, strongly everted in males, provides attachment for the fascia lata and the membranous layer of the superficial perineal fascia.

Pubic tubercle

The pubic tubercle provides attachment to the medial end of the inguinal ligament. It forms part of the floor of the superficial inguinal ring and is crossed by the spermatic cord.

Pecten pubis

The pecten pubis is the sharp, superior edge of the pectineal surface. The conjoint tendon and lacunar ligament are attached at its medial end and a strong, fibrous, pectineal ligament is attached along the rest of its surface. The smooth pelvic surface is separated from parietal peritoneum only by areolar tissue, in which the lateral umbilical ligament descends forwards across the ramus and, laterally, the vas deferens passes backwards. The obturator groove, which is converted to a canal by the upper borders of the obturator membrane and obturator muscles, transmits the obturator vessels and nerve from the pelvis to the thigh. Some fibres of the pubofemoral ligament are attached to the lateral end of the obturator crest.

Muscle attachments

The tendon of adductor longus is attached on the anterior (external) surface of the body, below the pubic crest. Below adductor longus, gracilis is attached to a line near the lower margin extending down onto the inferior ramus. Above gracilis, adductor brevis is attached to the body and inferior ramus. Above again, obturator externus is attached to the anterior surface, spreading onto inferior pubic and ischial rami. Adductor magnus usually extends from the ischial ramus on to the lower part of the inferior pubic ramus between adductor brevis and obturator externus. Pectineus is attached to the pectineal surface of the superior ramus along its upper part. Ascending loops of cremaster are attached to the pubic tubercle. The lateral part of rectus abdominis and, inferiorly, pyramidalis, are attached lateral to the tubercle, on the pubic crest. Medially the crest is crossed by the medial part of rectus abdominis, ascending from ligamentous fibres that interlace in front of the pubic symphysis. Anterior fibres of levator ani are attached on the posterior (internal) surface of the body near its centre. More laterally, obturator internus is attached on this surface, extending onto both rami. Psoas minor, when present, is attached near the centre of the pecten pubis.

Vascular supply

The pubis is supplied by a periosteal anastomosis of branches from the obturator, inferior epigastric and medial circumflex femoral arteries. The superficial and deep external pudendal arteries may also contribute. Multiple vascular foramina are present, mainly at the lateral (acetabular) end of the bone, but there is no consistently placed nutrient foramen.

Innervation

The periosteum of the pubis is innervated by branches of nerves that supply muscles attached to the bone, the hip joint and the symphysis pubis.

Ossification

Ossification of the pubis is described on page 1354.

Ilium

Topography

The ilium has upper and lower parts and three surfaces (Figs 80.5, 80.6). The smaller, lower part forms a little less than the upper two-fifths of the acetabulum. The upper part is much expanded, and has gluteal, sacropelvic and iliac (internal) surfaces. The posterolateral gluteal surface is an extensive rough area; the anteromedial iliac fossa is smooth and concave; the sacropelvic surface is medial and posteroinferior to the fossa, from which it is separated by the medial border.

Iliac crest

The iliac crest is the superior border of the ilium. It is convex upwards but sinuous from side to side, being internally concave in front, and convex behind. Its ends project as anterior and posterior superior iliac spines. The anterior superior iliac spine is palpable at the lateral end of the inguinal fold; the lateral end of the inguinal ligament is attached to the anterior superior iliac spine. The posterior superior iliac spine is not palpable but is often indicated by a dimple, approximately 4 cm lateral to the second sacral spinous process, above the medial gluteal region (buttock).

The crest has ventral and dorsal segments. The ventral occupies slightly more than the anterior two-thirds of the crest and its prominence is associated with changes in iliac form as a result of the emergence of the upright posture; the dorsal segment, which occupies approximately the posterior third in man, is a feature of all land vertebrates. The ventral segment of the crest has internal and external lips and the rough intermediate zone is narrowest centrally. The tubercle of the crest projects outwards from the outer lip approximately 5 cm posterosuperior to the anterior superior spine. The dorsal segment has two sloping surfaces separated by a longitudinal ridge ending at the posterior superior spine. The summit of the crest, a little behind its midpoint, is level with the fourth lumbar vertebral body. The interosseous and posterior sacroiliac ligaments arise from the medial margin of the dorsal segment.

Anterior border

The anterior border descends to the acetabulum from the anterior superior spine. Superiorly it is concave forwards. Inferiorly, immediately above the acetabulum, is a rough anterior inferior iliac spine, which is divided indistinctly into an upper area for the straight part of rectus femoris and a lower area extending laterally along the upper acetabular margin to form a triangular impression for the proximal end of the iliofemoral ligament.

Posterior border

The posterior border is irregularly curved and descends from the posterior superior spine, at first forwards, with a posterior concavity forming a small notch. At the lower end of the notch is a wide, low projection, the posterior inferior iliac spine. Here the border turns almost horizontally forwards for approximately 3 cm, then down and back to join the posterior ischial border. Together these borders form a deep notch, the greater sciatic notch, that is bounded above by the ilium and below by the ilium and ischium. The upper fibres of the sacrotuberous ligament are attached to the upper part of the posterior border. The superior rim of the notch is related to the superior gluteal vessels and nerve. The lower margin of the greater sciatic notch is covered by piriformis and related to the sciatic nerve.

Medial border

The medial border separates the iliac fossa and the sacropelvic surface. It is indistinct near the crest, rough in its upper part, then sharp where it bounds an articular surface for the sacrum, and finally rounded. The latter part is the arcuate line, which inferiorly reaches the posterior part of the iliopubic ramus, marking the union of the ilium and pubis.

Gluteal surface

The gluteal surface, facing inferiorly in its posterior part and laterally and slightly downwards in front, is bounded above by the iliac crest, below by the upper acetabular border and by the anterior and posterior borders. It is rough and curved, convex in front, concave behind, and marked by three gluteal lines. The posterior gluteal line is shortest, descending from the external lip of the crest approximately 5 cm in front of its posterior limit and ending in front of the posterior inferior iliac spine. Above, it is usually distinct, but inferiorly it is ill-defined and frequently absent. The anterior gluteal line, the longest, begins near the midpoint of the superior margin of the greater sciatic notch and ascends forwards into the outer lip of the crest, a little anterior to its tubercle. The inferior gluteal line, seldom well-marked, begins posterosuperior to the anterior inferior iliac spine, curving posteroinferiorly to end near the apex of the greater sciatic notch. Between the inferior gluteal line and the acetabular margin is a rough, shallow groove. Behind the acetabulum the lower gluteal surface is continuous with the posterior ischial surface, the conjunction marked by a low elevation.

The articular capsule is attached to an area adjoining the acetabular rim, most of which is covered by gluteus minimus. Posteroinferiorly, near the union of the ilium and ischium, the bone is related to piriformis.

Iliac fossa

The iliac fossa, the internal concavity of the ilium, faces anterosuperiorly. It is limited above by the iliac crest, in front by the anterior border and behind by the medial border, separating it from the sacropelvic surface. It forms the smooth and gently concave posterolateral wall of the greater pelvis. Below it is continuous with a wide shallow groove which is bounded laterally by the anterior inferior iliac spine and medially by the iliopubic ramus.

The wide groove between the anterior inferior iliac spine and the iliopubic ramus is occupied by the converging fibres of iliacus laterally and the tendon of psoas major medially: the tendon is separated from the underlying bone by a bursa. The right iliac fossa contains the caecum, and often the vermiform appendix and terminal ileum. The left iliac fossa houses the terminal part of the descending colon and the proximal sigmoid colon.

Sacropelvic surface

The sacropelvic surface, the posteroinferior part of the medial iliac surface, is bounded posteroinferiorly by the posterior border, anterosuperiorly by the medial border, posterosuperiorly by the iliac crest and anteroinferiorly by the line of fusion of the ilium and ischium. It is divided into iliac tuberosity, auricular and pelvic surfaces. The iliac tuberosity, a large, rough area below the dorsal segment of the iliac crest, shows cranial and caudal areas separated by an oblique ridge and connected to the sacrum by the interosseous sacroiliac ligament. The sacropelvic surface gives attachment to the posterior sacroiliac ligaments and, behind the auricular surface, to the interosseous sacroiliac ligament. The iliolumbar ligament is attached to its anterior part. The auricular surface, immediately anteroinferior to the tuberosity, articulates with the lateral sacral mass. Shaped like an ear, its widest part is anterosuperior, its ‘lobule’ posteroinferior and on the medial aspect of the posterior inferior spine. Its edges are well defined, but the surface, though articular, is rough and irregular. It articulates with the sacrum and is reciprocally shaped. The anterior sacroiliac ligament is attached to its sharp anterior and inferior borders. The narrow part of the pelvic surface, between the auricular surface and the upper rim of the greater sciatic notch, often shows a rough preauricular sulcus (that is usually better defined in females) for the lower fibres of the anterior sacroiliac ligament. For the reliability of this feature as a sex discriminant, refer to Finnegan (1978) and Brothwell & Pollard (2001). The pelvic surface is anteroinferior to the acutely recurved part of the auricular surface, and contributes to the lateral wall of the lesser pelvis. Its upper part, facing down, is between the auricular surface and the upper limb of the greater sciatic notch. Its lower part faces medially and is separated from the iliac fossa by the arcuate line. Anteroinferiorly it extends to the line of union between the ilium and ischium. Though usually obliterated, it passes from the depth of the acetabulum to approximately the middle of the inferior limb of the greater sciatic notch.

Muscle attachments

The attachment of sartorius extends down the anterior border below the anterior superior iliac spine. The iliac crest gives attachment to the anterolateral and dorsal abdominal muscles, and to the fasciae and muscles of the lower limb. The fascia lata and iliotibial tract are attached to the outer lip and tubercle of its ventral segment. Tensor fasciae latae is attached anterior to the tubercle. The lower fibres of external oblique and, just behind the summit of the crest, the lowest fibres of latissimus dorsi are attached to its anterior two-thirds. A variable interval exists between the most posterior attachment of external oblique and the most anterior attachment of latissimus dorsi, and here the crest forms the base of the lumbar triangle. Internal oblique is attached to the intermediate area of the crest. Transversus abdominis is attached to the anterior two-thirds of the inner lip of the crest, and behind this to the thoracolumbar fascia and quadratus lumborum. The highest fibres of gluteus maximus are attached to the dorsal segment of the crest on its lateral slope. Erector spinae arises from the medial slope of the dorsal segment. The straight part of rectus femoris is attached to the upper area of the anterior inferior spine. Some fibres of piriformis are attached in front of the posterior inferior spine on the upper border of the greater sciatic notch.

The gluteal surface is divided by three gluteal lines into four areas. Behind the posterior line, the upper rough part gives attachment to the upper fibres of gluteus maximus and the lower, smooth region to part of the sacrotuberous ligament and iliac head of piriformis. Gluteus medius is attached between the posterior and anterior lines, below the iliac crest, and gluteus minimus is attached between the anterior and inferior lines. The fourth area, below the inferior line, contains vascular foramina.

The reflected head of rectus femoris attaches to a curved groove above the acetabulum. Iliacus is attached to the upper two-thirds of the iliac fossa and is related to its lower third. The medial part of quadratus lumborum is attached to the anterior part of the sacropelvic surface, above the iliolumbar ligament. Piriformis is sometimes partly attached lateral to the preauricular sulcus, and part of obturator internus is attached to the more extensive remainder of the pelvic surface.

Vascular supply

Branches of the iliolumbar artery run between iliacus and bone; one or more enter large nutrient foramina lying posteroinferiorly in the iliac fossa. The superior gluteal, obturator and superficial circumflex iliac arteries contribute to the periosteal supply. The obturator artery may supply a nutrient branch. Vascular foramina on the iliac gluteal aspect may lead into large vascular canals in the bone.

Innervation

The periosteum is innervated by branches of nerves that supply muscles attached to the bone, the hip joint and the sacroiliac joint.

Ossification

Ossification of the ilium is described on page 1354.

Ischium

Topography

The ischium, the inferoposterior part of the hip bone, has a body and ramus. The body has upper and lower ends and femoral, posterior and pelvic surfaces (Figs 80.5, 80.6). Above, it forms the posteroinferior part of the acetabulum; below, its ramus ascends anteromedially at an acute angle to meet the inferior pubic ramus, thereby completing the boundary of the obturator foramen. The ischiofemoral ligament is attached to the lateral border below the acetabulum.

The femoral surface faces downwards, forwards and laterally towards the thigh. It is bounded in front by the margin of the obturator foramen. The lateral border, indistinct above but well defined below, forms the lateral limit of the ischial tuberosity. At a higher level the femoral surface is covered by piriformis, from which it is partially separated by the sciatic nerve and the nerve to quadratus femoris. The posterior surface, facing superolaterally, is continuous above with the iliac gluteal surface, and here a low convexity follows the acetabular curvature. Inferiorly, this surface forms the upper part of the ischial tuberosity, above which is a wide, shallow groove on its lateral and medial aspects. Above the ischial tuberosity the posterior surface is crossed by the tendon of obturator internus and the gemelli. The nerve to quadratus femoris lies between these structures and the bone. The ischial tuberosity is a large, rough area on the lower posterior surface and inferior extremity of the ischium. Though obscured by gluteus maximus in hip extension, it is palpable in flexion. It is 5 cm from the midline and about the same distance above the gluteal fold. It is elongated, widest above, and tapers inferiorly. The ischial posterior aspect lies between the lateral and posterior borders. The posterior border blends above with that of the ilium, helping to complete the inferior rim of the greater sciatic notch, the posterior end of which has a conspicuous ischial spine. Below this, the rounded border forms the floor of the lesser sciatic notch, between the ischial spine and tuberosity. The pelvic surface is smooth and faces the pelvic cavity; inferiorly it forms part of the lateral wall of the ischio-anal fossa.

Ischial ramus

The ischial ramus has anteroinferior and posterior surfaces continuous with the corresponding surfaces of the inferior pubic ramus: the anteroinferior surface is roughened by the attachment of the medial femoral muscles. The smooth posterior surface is partly divided into perineal and pelvic areas, like the inferior pubic ramus. The upper border completes the obturator foramen; the rough lower border, together with the medial border of the inferior pubic ramus, contributes to the pubic arch. The fascia overlying the superficial perineal muscles is attached below the ridge between the perineal and pelvic areas of the posterior surface of the ischial ramus. Above the ridge areas give attachment to the crus of the penis or clitoris and the sphincter urethrae. The lower border of the ramus provides an attachment for the fascia lata and a membranous layer of the superficial perineal fascia.

Ischial tuberosity

The ischial tuberosity is divided nearly transversely into upper and lower areas. The upper area is subdivided by an oblique line into a superolateral and an inferomedial part. The lower area, narrowing as it curves onto the inferior ischial aspect, is subdivided by an irregular vertical ridge into lateral and medial areas. The medial is covered by fibroadipose tissue that usually contains the ischial bursa of gluteus maximus, which supports the body in sitting. Medially the tuberosity is limited by a curved ridge that passes on to the ramus and which gives attachment to the sacrotuberous ligament and its falciform process.

Ischial spine

The ischial spine projects downwards and a little medially (Fig. 80.8). The sacrospinous ligament is attached to its margins, separating the greater from the lesser sciatic foramen. The ligament is crossed posteriorly by the internal pudendal vessels, pudendal nerve and the nerve to obturator internus.

Muscle attachments

Part of obturator externus is attached to the lower femoral surface of the ischial body. Part of obturator externus, the anterior fibres of adductor magnus and, near the lower border, gracilis, are all attached to the anterior surface of the ischial ramus. Between adductor magnus and gracilis the attachment of adductor brevis may descend from the inferior pubic ramus. The posterior surface is divided into pelvic and perineal areas. The pelvic area, facing back, has part of obturator internus attached to it. The perineal area faces medially; its upper part is related to the crus of the penis or clitoris, and its lower part gives attachment to sphincter urethrae, ischiocavernosus and the transverse superficial perineal muscle.

The ischial tuberosity gives attachment to the posterior femoral muscles. Quadratus femoris is attached along the upper part of its lateral border. The upper area of the tuberosity is subdivided by an oblique line into a superolateral part for semimembranosus and an inferomedial part for the long head of biceps femoris and semitendinosus. The lower area is subdivided by an irregular vertical ridge into lateral and medial areas. The larger lateral area is for part of adductor magnus. Superomedial to the tuberosity the posterior surface has a wide, shallow groove, usually covered by hyaline cartilage, with a bursa between it and the tendon of obturator internus. Gemellus inferior is attached to the lower margin of the groove, near the tuberosity. Gemellus superior is attached to the upper margin, near the ischial spine.

The pelvic surface of the ischial spine gives attachment to coccygeus (coextensive with the sacrospinous ligament) and to the most posterior fibres of levator ani. Obturator internus is attached to the upper part of the smooth pelvic ischial surface and converges on the lesser sciatic notch, covering the rest of this surface other than the pelvic aspect of the ischial spine: the muscle and its fascia separate the bone from the ischiorectal fossa.

Vascular supply

There are multiple vascular foramina at the acetabular margins, and a few are usually present on the pelvic surface. The bone is supplied by branches of the obturator, medial circumflex femoral and inferior gluteal arteries.

Innervation

The periosteum is innervated by branches of nerves that supply the hip joint and muscles attached to the bone.

Ossification

Ossification of the ischium is described on page 1354.

SACRUM

See page 724.

COCCYX

See page 728.

SKELETAL PELVIS AS A WHOLE

The term pelvis (‘basin’) is applied variously to the skeletal ring formed by the hip bones and the sacrum, the cavity therein, and even the entire region where the trunk and lower limbs meet. It is used here in the skeletal sense, to describe the irregular osseous girdle between the femoral heads and fifth lumbar vertebra. It is large because its primary function is to withstand the forces of body weight and musculature. In this section, its obstetric, forensic and anthropological significance will be considered.

The pelvis can be regarded as having greater and lesser segments, the true and false pelves. The segments are arbitrarily divided by an oblique plane passing through the sacral promontory posteriorly and the lineae terminales elsewhere. Each linea terminalis includes the iliac arcuate line, pectineal line (pecten), and pubic crest. The segments are continuous, and the parts of the body cavity that they enclose are also continuous through the pelvic inlet (pelvic inlet).

Greater pelvis

The greater pelvis consists of the ilium and pubis above the lineae terminales and the sacral base. This junctional zone is structurally massive and forms powerful arches from the acetabular fossae to the vertebral column around the visceral cavity, which is part of the abdomen. It has little anterior wall because of the pelvic inclination.

Pelvic inlet (superior pelvic aperture)

The pelvic inlet or brim may be round or oval, and is indented posteriorly by the sacral promontory. The pelvic brim is obstetrically important and has also long been measured for anthropological reasons, as has the pelvic cavity.

By convention, the pelvic inlet is described in three dimensions. The anteroposterior diameter (true conjugate) is measured between the midpoints of the sacral promontory and upper border of the symphysis pubis and on average is 10 cm in the adult male and 11.2 cm in the adult female. The transverse diameter is the maximum distance between similar points (assessed by eye) on opposite sides of the pelvic brim and is on average 12.5 cm in the male and 13.1 cm in the adult female. The oblique diameter is measured from the iliopubic ramus to the opposite sacroiliac joint and is on average 12 cm in the adult male and 12.5 cm in the adult female. These measurements vary with the individual and racial group.

Articulated bony pelvis

The lesser pelvis encloses a true basin when soft tissues of the pelvic floor are in place. Skeletally it is a narrower continuation of the greater pelvis, with irregular but more complete walls around its cavity. Of obstetric importance, it has a curved median axis, and superior and inferior openings. The superior opening is occupied by viscera. The pelvic floor, viscera and subjacent perineal sphincters close the inferior opening.

Cavity of the lesser pelvis

The cavity of the lesser pelvis is short, curved, and markedly longer in its posterior wall. Anteroinferiorly it is bounded by pubic bones, their rami and symphysis. Posteriorly it is bounded by the concave anterior sacral surface and coccyx. Laterally on each side its margins are the smooth quadrangular pelvic aspect of the fused ilium and ischium. The region so enclosed is the pelvic cavity proper, through which pass the rectum, bladder and parts of the reproductive organs. The cavity in females must also permit passage of the fetal head.

The pelvic cavity diameters are measured at approximately the mid level. The anteroposterior diameter is measured between the midpoints of the third sacral segment and posterior surface of the symphysis pubis and is about 10.5 cm in the male and 13 cm in the adult female. The transverse diameter is the widest transverse distance between the side walls of the cavity, and often the greatest transverse dimension in the whole cavity. It measures about 12 cm in the adult male and 12.5 cm in the adult female. The oblique diameter is the distance from the lowest point of one sacroiliac joint to the midpoint of the contralateral obturator membrane and measures about 11 cm in the male and 13.1 cm in the adult female. All measurements vary with the individual and racial group.

Pelvic outlet (inferior pelvic aperture)

Less regular in outline than the pelvic inlet, the pelvic outlet is indented behind by the coccyx and sacrum and bilaterally by the ischial tuberosities. Its perimeter thus consists of three wide arcs. Anteriorly is the pubic arch, between the converging ischiopubic rami. Posteriorly and laterally on both sides are the sciatic notches between the sacrum and ischial tuberosities. These are divided by the sacrotuberous and sacrospinous ligaments into greater and lesser sciatic foramina.

With ligaments included, the pelvic outlet is rhomboidal. Its anterior limbs are the ischiopubic rami (joined by the inferior pubic ligament) and its posterior margins are the sacrotuberous ligaments, with the coccyx in the midline. The outlet is thus not rigid in its posterior half, being limited by ligaments and the coccyx, all slightly yielding. Even with the sacrum taken as the posterior midline limit (more reliable for measurement), there may be slight mobility at the sacroiliac joints. Note also that a plane of the pelvic outlet is merely conceptual. The anterior, ischiopubic part has a plane which is inclined down and back to a transverse line between the lower limits of the ischial tuberosities, and the posterior half has a plane approximating to the sacrotuberous ligaments, sloping down and forwards to the same line.

Three measurements are made for the pelvic outlet. The anteroposterior diameter is usually measured from the coccygeal apex to the midpoint of the lower rim of the symphysis. The lowest sacral point may also be used (on average male 8 cm, female 12.5 cm). The transverse (bituberous) diameter is measured between the ischial tuberosities at the lower borders of their medial surfaces (on average male 8.5 cm, female 11.8 cm). The oblique diameter extends from the midpoint of the sacrotuberous ligament on one side to the contralateral ischiopubic junction (on average male 10 cm, female 11.8 cm). All measurements vary with the individual and racial group.

Other measurements

Apart from these main measurements, by consensus the basis of pelvic osteometry, other planes and measurements are used in obstetric practice. The plane of greatest pelvic dimensions is an obstetric concept. It represents the most capacious pelvic level, between the pelvic brim and midlevel plane, and corresponds with the latter anteriorly at the middle part of the symphysis pubis and posteriorly at the level of the second and third sacral segments.

The plane of least dimensions is said to be at about midpelvic level. Its transverse diameter is between the apices of the ischial spines. This measurement is about 9.5 cm in an adult female and is just wide enough to allow passage of the biparietal diameter of a fetal head (about 9 cm). Not surprisingly, most difficulty in parturition occurs here.

The above measurements are sometimes made in clinical practice using X-ray or MRI pelvimetry. Precise measurement is not possible without radiological techniques, and even these do not take into account the soft tissues. In the past, measurements were made at physical and vaginal examination. However, these manual measurements have proved to be of little clinical value and are now obsolete.

Morphological classification of pelves

Interest in the dimensions described above is primarily obstetric and, less frequently, forensic. All pelvic measurements display individual variation and the values quoted are means from limited surveys. Sexual and racial differences also occur. These measurements have been analysed by many anatomists, anthropologists, obstetricians and radiologists in attempts to classify human pelves, especially female. The four most common terms used today are gynaecoid, anthropoid, platypelloid and android. The gynaecoid pelvis is the traditional Western female pelvis with a heart-shaped brim and the range of measurements quoted above. An anthropoid pelvis has a larger midcavity and a wide anteroposterior inlet which is oval in shape: it is more common in women of African origin and may be associated with a ‘high assimilation’ pelvis where there is an additional lumbar vertebra. A platypelloid pelvis is flat and oval from side to side at the brim: it is a contracted pelvis that is rarely seen nowadays, having previously been associated with rickets. An android pelvis has a triangular brim and is the shape of a male pelvis.

Pelvic axes and inclination

The axis of the superior pelvic aperture traverses its centre at right angles to its plane, directed down and backwards (Fig. 80.9). When prolonged (projected) it passes through the umbilicus and midcoccyx. An axis is similarly established for the inferior aperture: projected upwards it impinges on the sacral promontory. Axes can likewise be constructed for any plane, and one for the whole cavity is a concatenation of an infinite series of such lines (Fig. 80.9). The fetal head, however, descends in the axis of the inlet as far as the level of the ischial spines; it is then directed forwards into the axis of the vagina at right angles to that axis. The form of this pelvic axis and the disparity in depth between the anterior and posterior contours of the cavity are prime factors in the mechanism of fetal transit in the pelvic canal.

Horizontal plane

Fig. 80.9 Median sagittal section through the female pelvis, showing the planes of the inlet and outlet and the axis of the pelvic cavity.

In the standing position the pelvic canal curves obliquely backwards relative to the trunk and abdominal cavity. The whole pelvis is tilted forwards, the plane of the pelvic brim making an angle of 50–60° with the horizontal. The plane of the pelvic outlet is tilted to about 15°. Strictly, the pelvic outlet has two planes, an anterior passing backwards from the pubic symphysis and a posterior passing forwards from the coccyx, both descending to meet at the intertuberous line. In standing, the pelvic aspect of the symphysis pubis faces nearly as much upwards as backwards and the sacral concavity is directed anteroinferiorly. The front of the symphysis and anterior superior iliac spines are in the same vertical plane. In sitting, body weight is transmitted through inferomedial parts of the ischial tuberosities, with variable soft tissues intervening. The anterior superior iliac spines are in a vertical plane through the acetabular centres, and the whole pelvis is tilted back with the lumbosacral angle somewhat diminished at the sacral promontory.

Pelvic mechanism

The skeletal pelvis supports and protects the contained viscera, but is primarily part of the lower limbs, affording wide attachment for leg and trunk muscles. It constitutes the major mechanism for transmitting the weight of the head, trunk and upper limbs to the lower limbs. It may be considered as two arches divided by a coronal transacetabular plane. The posterior arch, chiefly concerned in transmitting weight, consists of the upper three sacral vertebrae and strong pillars of bone from the sacroiliac joints to the acetabular fossae. The anterior arch, formed by the pubic bones and their superior rami, connects these lateral pillars as a tie beam to prevent separation; it also acts as a compression strut against medial femoral thrust. The sacrum, as the summit of the posterior arch, is loaded at the lumbosacral joint. Theoretically this force has two components, one thrusting the sacrum downwards and backwards between the iliac bones, the other thrusting its upper end downwards and forwards. Sacral movements are regulated by osseous shape and massive ligaments. The first component therefore acts against the wedge, its tendency to separate iliac bones resisted by the sacroiliac and iliolumbar ligaments and symphysis pubis.

Vertical coronal sections through the sacroiliac joints suggest division of the (synovial) articular region of the sacrum into three segments. In the anterosuperior segment, involving the first sacral vertebra, the articular surfaces are slightly sinuous and almost parallel. In the middle segment the posterior width between the articular markings is greater than the anterior, and centrally a sacral concavity fits a corresponding iliac convexity, an interlocking mechanism relieving the strain on the ligaments produced by body weight. In the posteroinferior segment the anterior sacral width is greater than the posterior and here its sacral surfaces are slightly concave. Anteroinferior sacral dislocation by the second component (of force) is prevented, therefore, mainly by the middle segment, owing to its cuneiform shape and interlocking mechanism. However, some rotation occurs, in which the anterosuperior segment tilts down and the posteroinferior segment up. ‘Superior’ segmental movement is limited to a small degree by wedging but primarily by tension in the sacrotuberous and sacrospinous ligaments. In all movements the sacroiliac and iliolumbar ligaments and symphysis pubis resist separation of the iliac bones.

SEXUAL DIFFERENCES IN THE PELVIS

The pelvis provides the most marked skeletal differences between male and female. Distinction can be made even during fetal life, particularly in the subpubic arch. In infancy, dimensions of the whole pelvis are greater in males than in females, but the size of the pelvic cavity is usually greater in females. This distinction prevails in childhood, but the difference is maximal at about 22 months. Sexual differences in adults are divisible into metrical and non-metrical features: the range of most features overlaps between the sexes.

Differences are inevitably linked to function. While the primary pelvic function in both sexes is locomotor, the pelvis, particularly the lesser pelvis, is adapted to parturition in females, and these changes variably affect the proportions and dimensions of the greater pelvis. Since males are distinctly more muscular and therefore more heavily built, overall pelvic dimensions, such as the intercristal measurement (distance between the iliac crests), are greater, markings for muscles and ligaments more pronounced, and general architecture heavier. The male iliac crest is more rugged and more medially inclined at its anterior end; in females the crests are less curved in all parts. The iliac alae are more vertical in females, but do not ascend so far; the iliac fossae are therefore shallower and each iliopectineal line more vertical. These iliac peculiarities probably account for the greater prominence of female hips.

The male is relatively and absolutely more heavily built above the pelvis, with consequent differences at the lumbosacral and hip joints. The sacral basal articular facet for the fifth lumbar vertebra and intervening disc is more than a third of the total sacral basal width in males but less than a third in females, in whom the sacrum is also relatively broader, accentuating this difference. The female has relatively broader sacral alae. The male acetabulum is absolutely larger, and its diameter is approximately equal to the distance between its anterior rim and symphysis pubis. In females, acetabular diameter is usually less than this distance, not only because it is absolutely smaller but also because the anterolateral wall of the cavity is comparatively and often absolutely wider. The height of the female symphysis and adjoining parts of the pubis and ischium, which form the anterior pelvic wall, are also absolutely less, producing a somewhat triangular obturator foramen, which is more ovoid in males. Differing pubic growth is also expressed in the subpubic arch below the symphysis and between the inferior pubic rami. It is more angular in males, being 50–60°; in females it is rounded, less easy to measure and usually 80–85°. A greater separation of the pubic tubercles in females contributes to the pubic width. The ischiopubic rami are also much more lightly built and narrowed near the symphysis; in males they bear a distinctly rough, everted area for attachment of the penile crura, the corresponding attachment for the clitoris being poorly developed. Ischial spines are closer in males and are more inturned. The greater sciatic notch is usually wider in females: mean values for males and females are 50.4° and 74.4°, respectively. The greater female values for angle and width are associated with increased backward sacral tilt and greater anteroposterior pelvic diameter, especially at lower levels.

The sacrum also displays metrical sexual differences. Female sacra are less curved, the curvature being most marked between the first and second segments and the third and fifth, with an intervening flatter region. Male sacra are more evenly curved, relatively long and narrow and more often exceeding five segments (by addition of a lumbar or coccygeal vertebra). The sacral index compares sacral breadth (between the most anterior points on the auricular surfaces) with length (between midpoints on the anterior margins of the promontory and apex): average values for males and females are 105% and 115%. Auricular surfaces are relatively smaller and more oblique in females, but extend onto the upper three sacral vertebrae in both sexes. The dorsal auricular border is more concave in females. Many differences may be summarized in the generalization that the pelvic cavity is longer and more conical in males, shorter and more cylindrical in females; the axis is curved in both. Differences are greater at the inferior aperture than at the brim, where in absolute measurements males are not as different from females as sometimes stated. The superior aperture is more likely to be anthropoid or android in males and gynaecoid or android in females.

In forensic practice, identification of human skeletal remains (which are sometimes fragmentary) usually involves determination of sex, and this is most reliably established from an examination of the pelvis. Even fragments of the pelvis may be useful in this respect. Several studies of metrical characteristics in various pelvic regions have been made, leading to the establishment of various indices. The ilium has received particular attention, e.g. one index compares the pelvic and sacroiliac parts of the bone. A line is extended back from the iliopubic ramus to the nearest point on the anterior auricular margin and thence to the iliac crest. The auricular point divides this chilotic line into anterior (pelvic) and posterior (sacral) segments, each expressed as a percentage of the other. Chilotic indices display reciprocal values in the sexes: the pelvic part of the chilotic line is predominant in females, and the sacral part in males. Detailed metrical studies of the ilium have indicated its limited reliability in ‘sexing’ pelves. However, the higher incidence and definition of the female preauricular sulcus is recognized. The desirability of correlating all available metrical data is to be emphasized; when a range of pelvic data can be combined, especially if they are metrical, 95% accuracy should be achieved. Complete accuracy has been claimed when the rest of the skeleton is available. Assessment of sex from isolated and often incomplete human remains is less reliable. For further details, consult Mays (1998) and Brothwell & Pollard (2001).

FEMUR

Topography

The femur is the longest and strongest bone in the human body (Figs 80.10, 80.11). Its length is associated with a striding gait, its strength with the weight and muscular forces it is required to withstand. Its shaft, almost cylindrical along most of its length, is bowed forward. It has a proximal rounded, articular head projecting medially from its short neck, which, in turn, is a medial extension of the proximal shaft. The distal extremity is wider and more substantial, and presents a double condyle that articulates with the tibia. In standing, the femoral shafts show an inclination upwards and outwards from their tibial articulations, with the femoral heads being separated by the pelvic width. Since the tibia and fibula descend vertically from the knees, the ankles are also in the line of body weight in standing or walking. The degree of femoral obliquity varies between individuals, but is generally greater in women, reflecting the relatively greater pelvic breadth and shorter femora. Proximally the femur consists of a head, neck, and greater and lesser trochanters.

Femoral head

The femoral head faces anterosuperomedially to articulate with the acetabulum (Fig. 80.12). The head, often described as rather more than half a ‘sphere’, is not part of a true sphere but is spheroidal. Its smoothness is interrupted posteroinferior to its centre by a small, rough fovea. The head is intracapsular and is encircled, distal to its equator, by the acetabular labrum. Its articular margin is distinct, except anteriorly, where the articular surface extends on to the neck. The ligamentum teres is attached to the fovea. The anterior surface of the head is separated inferomedially from the femoral artery by the tendon of psoas major, the psoas bursa, and the articular capsule.

Femoral neck

The femoral neck (Fig. 80.12) is approximately 5 cm long, narrowest in its mid part and widest laterally, and connects the head to the shaft at an average angle of 135° (angle of inclination; neck–shaft angle): this facilitates movement at the hip joint, enabling the limb to swing clear of the pelvis. The neck also provides a lever for the action of the muscles acting about the hip joint, which are attached to the proximal femur. The neck–shaft angle is widest at birth and diminishes gradually until adolescence; it is smaller in females. The neck is laterally rotated with respect to the shaft (angle of anteversion) some 10–15°, although values of this angle vary between individuals and between populations (Eckhoff et al 1994). The contours of the neck are rounded: the upper surface is almost horizontal and slightly concave, the lower is straighter but oblique, directed inferolaterally and backwards to the shaft near the lesser trochanter. On all aspects the neck expands as it approaches the articular surface of the head. The anterior surface of the neck is flat and marked at the junction with the shaft by a rough intertrochanteric line. The posterior surface, facing posteriorly and superiorly, is transversely convex, and concave in its long axis; its junction with the shaft is marked by a rounded intertrochanteric crest. There are numerous vascular foramina, especially anteriorly and posterosuperiorly.

The anterior surface is intracapsular, the capsule attaching laterally to the intertrochanteric line. Facets, often covered by extensions of articular cartilage, and various imprints frequently occur here. These facets may sometimes be associated with squatting. One such feature, the cervical fossa, may be a racial characteristic. On the posterior surface the capsule does not reach the intertrochanteric crest; little more than the medial half of the neck is intracapsular. The anterior surface adjoining the head and covered by cartilage is related to the iliofemoral ligament. A groove, produced by the tendon of obturator externus as it approaches the trochanteric fossa, spirals across the posterior surface of the neck in a proximolateral direction.

Greater trochanter

The greater trochanter is large and quadrangular, projecting up from the junction of the neck and shaft (Fig. 80.12). Its posterosuperior region projects superomedially to overhang the adjacent posterior surface of the neck and here its medial surface presents the rough trochanteric fossa. The proximal border of the trochanter lies approximately a hand’s breadth below the iliac tubercle, level with the centre of the femoral head. It has an anterior rough impression. Its lateral surface, continuous distally with the lateral surface of the femoral shaft, is crossed anteroinferiorly by an oblique, flat strip, which is wider above. This surface is palpable, especially when the muscles are relaxed. The trochanteric fossa occasionally presents a tubercle or exostosis.

Lesser trochanter

The lesser trochanter is a conical posteromedial projection of the shaft at the posteroinferior aspect of its junction with the neck. Its summit and anterior surface are rough, but its posterior surface, at the distal end of the intertrochanteric crest, is smooth. It is not palpable.

Intertrochanteric line

The intertrochanteric line, a prominent ridge at the junction of the anterior surfaces of the neck and shaft, descends medially from a tubercle on the upper part of the anterior aspect of the greater trochanter to a point on the lower border of the neck, anterior to the lesser trochanter, where there may also be a tubercle. This line is the lateral limit of the hip joint capsule anteriorly. The upper and lower bands of the iliofemoral ligament are attached to its proximal and distal ends and the associated tubercles. Distally it is continuous with the spiral line.

Intertrochanteric crest

The intertrochanteric crest, a smooth and prominent ridge at the junction of the posterior surface of the neck with the shaft, descends medially from the posterosuperior angle of the greater trochanter to the lesser trochanter. A little above its centre is a low, rounded quadrate tubercle. It is covered by gluteus maximus, from which it is separated, medial to the tubercle, by quadratus femoris and the upper border of adductor magnus.

Gluteal tuberosity

The gluteal tuberosity may be an elongated depression or a ridge. It may at times be prominent enough to merit the unofficial title of ‘third trochanter’.

Shaft

The shaft is surrounded by muscles and is impalpable (Figs 80.10, 80.11). The distal anterior surface, for 5–6 cm above the patellar articular surface, is covered by a suprapatellar bursa, between bone and muscle. The distal lateral surface is covered by vastus intermedius. The medial surface, devoid of attachments, is covered by vastus medialis.

The shaft is narrowest centrally, expanding a little at its proximal end, and substantially more at its distal end. Its long axis makes an angle of approximately 10° with the vertical, and diverges 5–7° from the long axis of the tibia. Its middle third has three surfaces and borders. The extensive anterior surface, smooth and gently convex, is between the lateral and medial borders, which are both round and indistinct. The posterolateral surface is bounded posteriorly by the broad, rough linea aspera, usually a crest with lateral and medial edges. Its subjacent compact bone is augmented to withstand compressive forces, which are concentrated here by the anterior curvature of the shaft. The linea aspera gives attachment to adductor longus, intermuscular septa and the short head of biceps femoris, all inseparably blended at their attachments. Perforating arteries cross the linea laterally under tendinous arches in adductor magnus and biceps femoris. Nutrient foramina, directed proximally, appear in the linea aspera, varying in number and site, one usually near its proximal end, a second usually near its distal end. The posteromedial surface, smooth like the others, is bounded in front by the indistinct medial border and behind by the linea aspera. In its proximal third the shaft has a fourth, posterior surface, bounded medially by a narrow, rough spiral line that is continuous proximally with the intertrochanteric line and distally with the medial edge of linea aspera. Laterally this surface is limited by the broad, rough, gluteal tuberosity, ascending a little laterally to the greater trochanter and descending to the lateral edge of the linea aspera. In its distal third the posterior surface of the shaft presents a further surface, the popliteal surface (see below) between the medial and lateral supracondylar lines. These lines are continuous above with the corresponding edges of the linea aspera. The lateral line is most distinct in its proximal two-thirds, where the short head of biceps femoris and lateral intermuscular septum are attached. Its distal third has a small rough area for the attachment of plantaris, often encroaching on the popliteal surface. The medial line is indistinct in its proximal two-thirds, where vastus medialis is attached. Distally, the medial line is crossed obliquely by the femoral vessels entering the popliteal fossa from the adductor canal. Further distally, the line is often sharp for 3 or 4 cm proximal to the adductor tubercle.

The popliteal surface, triangular in outline, lies between the medial and lateral supracondylar lines. In its distal medial part it is rough and slightly elevated. Forming the proximal part of the floor of the popliteal fossa, the popliteal surface is covered by a variable amount of fat that separates the popliteal artery from bone. The superior medial genicular artery, a branch of the popliteal artery, arches medially above the medial condyle. It is separated from bone by the medial head of gastrocnemius. The latter is attached a little above the condyle; further distally there may be a smooth facet underlying a bursa for the medial head of gastrocnemius. More medially, there is often an imprint proximal to the articular surface: in flexion this is close to a rough tubercle on the medial tibial condyle for the attachment of semimembranosus. The superior lateral genicular artery arches up laterally proximal to the lateral condyle but is separated from bone by the attachment of plantaris to the distal part of the lateral supracondylar line.

Distal end

The distal end of the femur is widely expanded as a bearing surface for transmission of weight to the tibia (Fig. 80.13). It bears two massive condyles, which are partly articular. Anteriorly the condyles are confluent and continue into the shaft; posteriorly they are separated by a deep intercondylar fossa and project beyond the plane of the popliteal surface. The articular surface is a broad area, like an inverted U, for the patella and the tibia. The patellar surface extends anteriorly on both condyles, especially the lateral. It is transversely concave, vertically convex and grooved for the posterior patellar surface. The tibial surface is divided by the intercondylar fossa but is anteriorly continuous with the patellar surface. Its medial part is a broad strip on the convex inferoposterior surface of the medial condyle, and is gently curved with a medial convexity. Its lateral part covers similar aspects of the lateral condyle but is broader and passes straight back. The tibial surfaces are convex in all directions. The medial and lateral tibial surfaces have dissimilar anteroposterior curvatures. However views differ as to the exact representation of these differences. One view holds that in both tibial portions of the femoral condyles the sagittal radius of curvature is ever decreasing (a ‘closing helix’). More recently it has been suggested that the medial articular surface describes arcs of two circles. The more posterior has a smaller radius. Laterally there may only be one arc of fixed curvature with a radius similar to that of the posterior arc of the medial femoral articular surface. These differences are believed to be important determinants of knee joint motion.

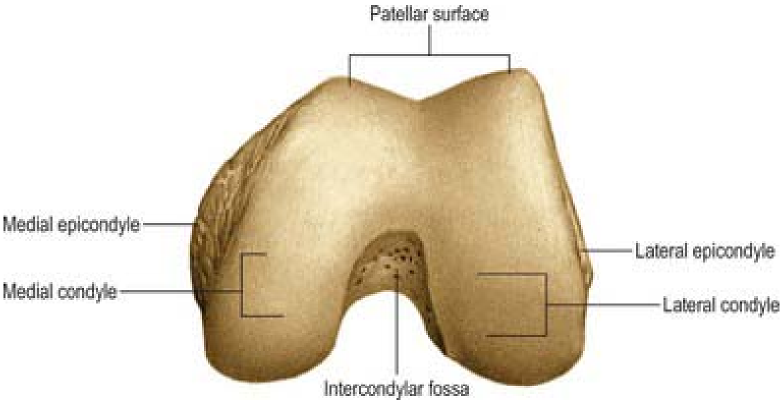

Fig. 80.13 Distal end of femur: articular surface.

(From Sobotta 2006.)

Patellar surface (trochlear groove)

The patellar surface extends more proximally on the lateral side. Its proximal border is therefore oblique and runs distally and medially, separated from the tibial surfaces by two faint grooves that cross the condyles obliquely. The lateral groove is the more distinct. It runs laterally and slightly forwards from the front of the intercondylar fossa and expands to form a faint triangular depression, resting on the anterior edge of the lateral meniscus when the knee is fully extended. The medial groove is restricted to the medial part of the medial condyle and rests on the anterior edge of the medial meniscus in full extension. Where it ceases, the patellar surface continues back to the lateral part of the medial condyle as a semilunar area adjoining the anterior region of the intercondylar fossa. This area articulates with the medial vertical facet of the patella in full flexion; its outline is indistinct in most femora. In habitual squatters articular cartilage may extend to the lateral aspect of the lateral condyle under vastus lateralis.

The trochlear groove helps to stabilize the patella. An abnormally shallow groove predisposes to instability.

Intercondylar fossa

The intercondylar fossa separates the two condyles distally and behind. In front it is limited by the distal border of the patellar surface, and behind by an intercondylar line, separating it from the popliteal surface. It is intracapsular but largely extrasynovial. Its lateral wall, the medial surface of the lateral condyle, bears a flat posterosuperior impression which spreads to the floor of the fossa near the intercondylar line for the proximal attachment of the anterior cruciate ligament. The medial wall of the fossa, i.e. the lateral surface of the medial condyle, bears a similar larger area, but far more anteriorly, for the proximal attachment of the posterior cruciate ligament. Both impressions are smooth and largely devoid of vascular foramina, whereas the rest of the fossa is rough and pitted by vascular foramina. A bursal recess between the ligaments may ascend to the fossa. The capsular ligament and, laterally, the oblique popliteal ligament, are attached to the intercondylar line. The ligamentum mucosum (infrapatellar synovial fold or plica) is attached to the anterior border of the fossa.

Lateral condyle

The lateral condyle (Figs 80.13, 80.14) is larger anteroposteriorly than the medial. Its most prominent point is the lateral epicondyle to which the lateral collateral ligament is attached. A short groove, deeper in front, separates the lateral epicondyle inferiorly from the articular margin. This groove allows the tendon of popliteus to run deep to the lateral collateral ligament and insert inferior and anterior to the ligament insertion. Adjoining the joint margin is a strip of condyle, 1 cm broad. It is intracapsular and covered by synovial membrane except for the attachment of popliteus.

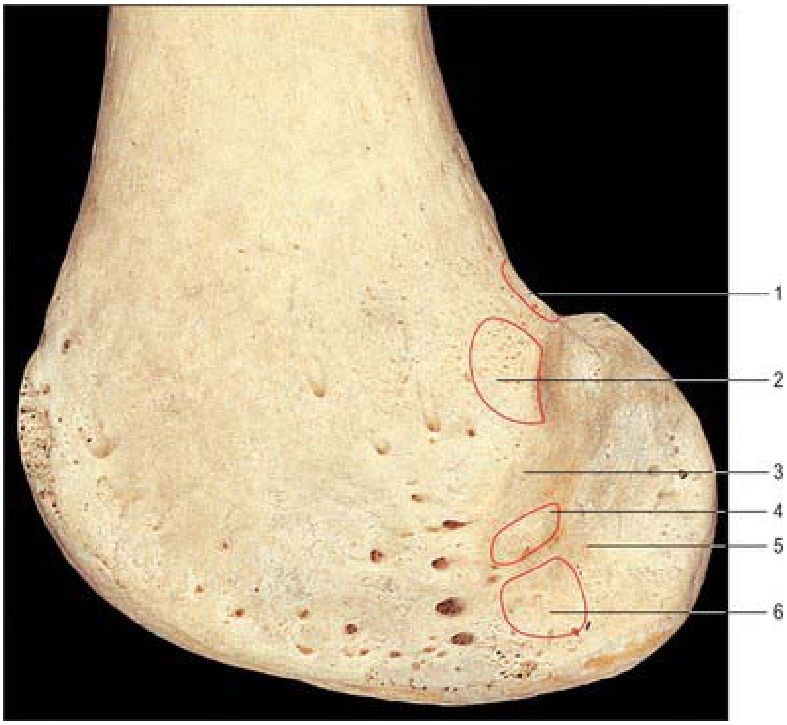

Fig. 80.14 Distal end of femur: lateral aspect. **1**. Attachment of plantaris. **2**. Attachment of lateral head of gastrocnemius. **3**. Lateral epicondyle. **4**. Attachment of lateral collateral ligament. **5**. Groove for popliteus in full flexion. **6**. Attachment of popliteus.

The medial surface is the lateral wall of the intercondylar fossa. Its lateral surface projects beyond the shaft. Part of the lateral head of gastrocnemius is attached to an impression posterosuperior to the lateral epicondyle.

Medial condyle

The medial condyle has a bulging, convex medial aspect which is easily palpable. Proximally its adductor tubercle, which may only be a facet rather than a projection, receives the tendon of adductor magnus. The medial prominence of the condyle, the medial epicondyle, is anteroinferior to the tubercle. The lateral surface of the condyle is the medial wall of the intercondylar fossa. The condyle projects distally so that, despite the obliquity of the shaft, the profile of the distal end is almost horizontal. A curved strip, 1 cm wide, adjoining the medial articular margin, is covered by synovial membrane and is inside the joint capsule. Proximal to this, the medial epicondyle receives the medial collateral ligament.

Structure

The femoral shaft is a cylinder of compact bone with a large medullary cavity. The wall is thick in its middle third, where the femur is narrowest and the medullary cavity most capacious. Proximally and distally the compact wall becomes progressively thinner, and the cavity gradually fills with trabecular bone. The extremities, especially where articular, consist of trabecular bone within a thin shell of compact bone, their trabeculae being disposed along lines of greatest stress. At the proximal end the main trabeculae form a series of plates orthogonal to the articular surface, converging to a central dense wedge, which is supported by strong trabeculae passing to the sides of the neck, especially along its upper and lower profiles (Fig. 80.15). Force applied to the femoral head is therefore transmitted to the wedge and thence to the junction of the neck and shaft. This junction is strengthened by dense trabeculae extending laterally from the lesser trochanter to the end of the superior aspect of the neck, thus resisting tensile or shearing forces applied to the neck through the head (Fig. 80.16). Tensile and compressive tests indicate that axial trabeculae of the femoral head withstand much greater stresses than peripheral trabeculae. A smaller bar across the junction of the greater trochanter with the neck and shaft resists shearing produced by muscles attached to it. These two bars are proximal layers of arches between the sides of the shaft and transmit to it forces applied to the proximal end. A thin vertical plate, the calcar femorale, ascends from the compact wall near the linea aspera into the trabeculae of the neck. Medially it joins the posterior wall of the neck; laterally it continues into the greater trochanter, where it disperses into general trabecular bone. It is thus in a plane anterior to the trochanteric crest and base of the lesser trochanter. Newell (1997), in a review of the calcar femorale, has described its three-dimensional anatomy in terms of the work of Dixon (1910), who was the first to recognize the deficiencies of the classic two-dimensional description of the architecture of the proximal femur. Dixon suggested that the trabecular framework of the proximal femur was spiral, and that the ‘arches’ were simplified sectional profiles of this spiral. At the distal end of the femur, trabeculae spring from the entire internal surface of compact bone, descending perpendicular to the articular surface. Proximal to the condyles these are strongest and most accurately perpendicular. Horizontal planes of trabecular bone, arranged like crossed girders, form a series of cubical compartments.

Muscle attachments

The greater trochanter provides attachment for gluteus minimus and medius. Gluteus minimus is attached to its rough anterior impression and gluteus medius to its lateral oblique strip. The bone is separated from the tendon of gluteus medius by a bursa. The area behind is covered by deep fibres of gluteus maximus, with part of its trochanteric bursa interposed. The tendon of piriformis is attached to the upper border of the trochanter and the common (tricipital) tendon of obturator internus and the gemelli is attached to its medial surface. The trochanteric fossa receives the tendon of obturator externus. Psoas major is attached to the summit and anteromedial surface of the lesser trochanter. Iliacus is attached to the medial or anterior surface of its base, descending a little behind the spiral line as its tendon fuses with that of psoas. Adductor magnus (upper part) passes over its posterior surface, sometimes separated by an interposed bursa.

The most proximal fibres of vastus lateralis are attached to the proximal end of the intertrochanteric line, and those of vastus medialis to the distal end. Quadratus femoris is attached to the quadrate tubercle and the immediately distal bone. Vastus intermedius is attached to the anterior and lateral surfaces of the proximal three-quarters of the femoral shaft. Slips of articularis genu are attached distal to this.

The gluteal tuberosity receives the deeper fibres of the distal half of gluteus maximus and, at its medial edge, the uppermost fibres of adductor magnus. Distal to this, adductor magnus is attached to the linea aspera and, by an aponeurosis, to the proximal part of the medial supracondylar ridge. Its remaining fibres form a large tendon attached to the adductor tubercle, with an aponeurotic expansion to the distal part of the medial supracondylar ridge.

Pectineus and adductor brevis are attached to the posterior femoral surface between the gluteal tuberosity and spiral line. The pectineal attachment is a line, sometimes slightly rough, from the base of the lesser trochanter to the linea aspera. Adductor brevis is attached lateral to pectineus and beyond this to the proximal part of the linea aspera, medial to adductor magnus. Adductor longus, intermuscular septa and the short head of biceps femoris are attached to the linea aspera. Vastus lateralis has a linear attachment from the anterior surface of the base of the greater trochanter to the proximal end of the gluteal tuberosity, and along the lateral margin of the latter to the proximal half of the lateral edge of the linea aspera. Vastus medialis is attached from the distal end of the intertrochanteric line along the spiral line to the medial edge of the linea aspera and thence to the medial supracondylar line, which also receives many fibres from the aponeurotic attachments of adductor magnus.

The medial head of gastrocnemius is attached to the posterior surface a little above the medial condyle. The short head of biceps femoris is attached to the proximal two-thirds of the lateral supracondylar line. Plantaris attaches to the line distally. Vastus medialis is attached to the proximal two-thirds of the medial supracondylar line.

Part of the lateral head of gastrocnemius is attached posterosuperiorly to the lateral epicondyle. Popliteus is attached anteriorly in the groove on the outer aspect of the lateral epicondyle. Its tendon passes deep to the lateral collateral ligament (Fig. 80.14). The tendon lies in the groove in full knee flexion; in extension it crosses the articular margin and may form an impression on it.

Vascular supply

The blood supply of the femoral head (Fig. 80.17) is derived from an arterial ring around the neck, just outside the attachment of the fibrous capsule, constituted by the medial and lateral circumflex femoral arteries with minor contributions from the superior and inferior gluteal vessels (see trochanteric anastomosis). From this ring, ascending cervical branches pierce the capsule (under its zona orbicularis) to ascend the neck beneath the reflected synovial membrane. These vessels become the retinacular arteries and form a subsynovial intracapsular anastomosis. Here the vessels are at risk with a displaced fracture of the femoral neck. Interruption of blood supply in this way can lead to avascular necrosis of the femoral head. If the fracture is intracapsular, not only is the intraosseous blood supply damaged but the retinacular vessels are also vulnerable. If the fracture is extracapsular, the retinacular vessels will remain intact and avascular necrosis of the femoral head is much less likely. The ascending cervical vessels give off metaphysial branches that enter the neck, while the intracapsular ring gives off lateral and inferior epiphysial branches. A small medial epiphysial supply, of importance in early childhood, reaches the head along the ligamentum teres by the acetabular branches of the obturator and medial circumflex femoral arteries, which anastomose with the other epiphysial vessels. During growth, the epiphysial plate separates the territories of the metaphysial and epiphysial vessels; these vessels anastomose freely after osseous union of the head and neck. Observations on developmental patterns of this supply in late fetal and early postnatal periods have revealed that although medial and lateral circumflex femoral arteries at first contribute equally, two major branches of the medial provide the final supply, both posterior to the neck. The supply from the lateral circumflex artery diminishes and the arterial ring is interrupted. As the femoral neck elongates, the extracapsular circle becomes more distant from the epiphysial part of the head.

Fig. 80.17 Collateral circulation around the hip and upper thigh, anterior aspect.

The trochanteric regions and subtrochanteric shaft are supplied by the trochanteric and cruciate arterial anastomoses. More distally in the shaft, nutrient foramina, directed proximally, are found in the linea aspera, varying in number and site: one is usually near its proximal end and a second usually near its distal end. The main nutrient artery is usually derived from the second perforating artery (see profunda femoris). If two nutrient arteries occur, they may branch from the first and third perforators. Periosteal vessels arise from the perforators and from the profunda, and run circumferentially rather than longitudinally. The distal metaphysis has many vascular foramina. Arterial supply here is from the genicular anastomosis. For further details consult Crock (1980, 1996).

The pattern of venous drainage of the head and neck corresponds in general to that of the arteries, though there may be a single large cervical vein posteroinferiorly.

Innervation

The periosteal innervation is derived proximally from nerves that supply the hip joint, distally from those supplying the knee, and in all areas from nerves that innervate muscles attached to the bone.

Ossification

The femur ossifies from five centres: in the shaft, head, greater and lesser trochanters and the distal end (Figs 80.10, 80.11, 80.18). Other than the clavicle, it is the first long bone to ossify. The process starts in the midshaft in the seventh prenatal week and extends to produce a miniature shaft that is largely ossified at birth. Secondary centres appear in the distal end (from which the condyles and epicondyles are formed) during the ninth month, in the head during the first six months after birth, in the greater trochanter during the fourth year and in the lesser between the 12th and 14th year. The centre in the cartilaginous head is restricted to it until the tenth year, so that the epiphysial line (Fig. 80.7) is horizontal and the inferomedial part of the articular surface is on the neck. The medial epiphysial margin later grows over this part of the articular surface. Thus, the mature epiphysis is a hollow cup on the summit of the neck. The epiphysial line follows the articular margin except where it is separated superiorly from the articular surface by a non-articular area where blood vessels enter the head (Trueta 1957). The epiphyses fuse independently: the lesser trochanter soon after puberty followed by the greater trochanter. The capital epiphysis fuses in the 14th year in females and 17th year in males,. The epiphysis at the distal end fuses in the 16th year in females, and 18th year in males. The distal epiphysial plate traverses the adductor tubercle.

Growth plate considerations

Trauma to any epiphysial plate can lead to bony union between epiphysis and metaphysis, and so cause premature cessation of growth. Any surgery in the hip region in children can injure the growth plate, resulting in abnormal proximal femoral development. In the case of fractures involving the epiphysis, expeditious restoration of normal bony alignment is essential in order to minimize the risk of subsequent abnormal growth.

The growth plate represents a line of weakness and predisposes to fracture from injury. Such acute injuries affecting the capital epiphysis are uncommon. However, a more chronic fracture through the capital epiphysis occurs in ‘slipped upper femoral epiphysis’. The condition affects pubescent adolescents, especially males. Endocrinological abnormality may be related.

The femoral head epiphysis displaces posteriorly off the femoral neck. If it heals in this position, lower limb deformity and restricted hip movement occur. A classic hallmark is obligatory external rotation of the femur as the hip is flexed. Treatment varies according to the time taken for the ‘slip’ to occur. Normal anatomical restoration is not attempted because of an increased incidence of avascular necrosis. The position of the femoral head may be accepted as it is and fixed with screws in this position to stop further displacement. This treatment will deliberately cause premature growth plate fusion and so prevent future ‘slippage’. Since the distal femoral growth plate accounts for most of the normal increase in longitudinal growth of the femoral shaft, an acceptable limb length difference usually results.

Infection of bone in neonates and young children tends to arise via bacteria in the blood stream which usually ‘seed’ in the metaphysial region, probably as a consequence of the vascular ‘arcade’ arrangement of arteries in this part of the bone. The proximal femoral growth plate is intra-articular. As a result infection in the proximal femoral metaphysis can spread into the joint and result in a septic arthritis that can destroy the hip joint permanently.

The distal end of the femur is the only epiphysis in which ossification consistently starts just before birth: the phenomenon therefore serves as a reliable indicator of the gestational maturity of a stillborn baby. Since the epiphysial plate is level with the adductor tubercle, the epiphysis is partly extra-articular. Operations here may damage the distal epiphysial cartilage in children and result in subsequent shortening of the leg.

JOINTS

PUBIC SYMPHYSIS

The pubic bones meet in the midline at the pubic symphysis, a secondary cartilaginous joint (Fig. 80.4).

Articulating surfaces

The articulating surfaces are the medial (symphysial) surfaces of the pubic bones, each covered by a thin layer of tightly adherent hyaline cartilage (surface growth cartilage in the young). The junction is not flat but marked by reciprocal crests and papillae. Theoretically this would resist shearing. The surfaces of hyaline cartilage are connected by fibrocartilage, varying in thickness and constituting the interpubic disc. The symphysis often contains a cavity, probably due to absorption. It rarely appears before the tenth year and is non-synovial. The cavity, which is better developed in females, is usually posterosuperior but may reach the front or even occupy most of the cartilage.

Ligaments

The interpubic disc is strengthened anteriorly by several interlacing collagenous fibrous layers, passing obliquely from bone to bone, decussating with fibres of the external oblique aponeuroses and the medial tendons of the recti abdominis. These layers constitute the anterior pubic ligament. There are less well-developed posterior fibres, sometimes named the posterior pubic ligament. The main ligaments of the joint are the superior and arcuate pubic ligaments. The superior pubic ligament connects the bones above, extending to the pubic tubercles. The arcuate pubic ligament, a thick arch of fibres, connects the lower borders of the symphysial pubic surfaces bounding the pubic arch. It blends superiorly with the interpubic disc and extends laterally attached to the inferior pubic rami. Its inferior edge is separated from the anterior border of the perineal membrane by an opening which is traversed by the deep dorsal vein of the penis or clitoris.

Vascular supply

The pubic symphysis is supplied by pubic branches of the obturator, superficial external pudendal and inferior epigastric arteries.

Innervation

The pubic symphysis is innervated by branches from the iliohypogastric, ilioinguinal and pudendal nerves.

Factors maintaining stability

The interpubic disc and the superior and arcuate ligaments are the main stabilizing factors of the pubic symphysis.

Movements

Angulation, rotation and displacement are possible but slight and are likely during movement at the sacroiliac and hip joints. Excessive movement may occur as a sports injury. Some separation occurs late in gestation and during childbirth: on occasion this is considerable.

Relations

Anteriorly the pubic symphysis is related to superficial fascia and skin. Because of the obliquity of the joint, the proximal ends of the penile or clitoral shafts lie anterior to the lower half of the joint. Inferiorly the urethra lies about 2.5 cm away in the male, and somewhat closer in the female, as it passes through the perineal membrane. Closer to the joint, the deep dorsal vein of the penis or clitoris passes between the arcuate ligament and the anterior border of the perineal membrane. Posteriorly the upper part of the joint is separated from the inferolateral surfaces of the bladder by the retropubic fat pad. Inferiorly in the male the prostatic venous plexus separates the prostate from the lower part of the joint. The region is sometimes termed the retropubic space. These relationships explain why traumatic disruption of the anterior bony pelvis may be associated with serious urogenital injury.

SACROILIAC JOINT

The sacroiliac joint is a synovial articulation between the sacral and iliac auricular surfaces. Fibrous adhesions and gradual obliteration occur in both sexes, earlier in males, and after the menopause in females. Radiological evidence of obliteration in normal subjects is occasionally seen before 50 years, but is not uncommon thereafter: in old age the joint may be completely fibrosed and occasionally even ossified.

Articulating surfaces

The surfaces are nearly flat in infants, whereas in adults they are irregular, often markedly so, and sometimes undulant. The curvatures and irregularities, greater in males, are reciprocal: they restrict movements and contribute to the considerable strength of the joint in transmitting weight from the vertebral column to the lower limbs. The sacral surface is covered by hyaline cartilage which is thicker anteriorly than posteriorly in adults. The thinner cartilage on the iliac surface is also hyaline in type, as confirmed by the presence of type II collagen.

Fibrous capsule

The capsule is attached close to both articular margins.

Ligaments

The ligaments of the sacroiliac joint are the anterior, interosseous and posterior sacroiliac, iliolumbar, sacrotuberous and sacrospinus ligaments.

Anterior sacroiliac ligament

The anterior sacroiliac ligament (Fig. 80.8), an anteroinferior capsular thickening, is particularly welldeveloped near the arcuate line and the posterior inferior iliac spine, where it connects the third sacral segment to the lateral side of the preauricular sulcus. It is thin elsewhere.

Interosseous sacroiliac ligament

The interosseous sacroiliac ligament is the major bond between the bones, filling the irregular space posterosuperior to the joint. It is covered superficially by the posterior sacroiliac ligament. Its deeper part has superior and inferior bands passing from depressions posterior to the sacral auricular surface to those on the iliac tuberosity. These bands are covered by, and blend with, a more superficial fibrous sheet connecting the posterosuperior margin of a rough area posterior to the sacral auricular surface to the corresponding margins of the iliac tuberosity. This sheet is often partially divided into superior and inferior parts, the former uniting the superior articular process and lateral crest on the first two sacral segments to the neighbouring ilium as a short posterior iliac ligament (see Fig. 42.52).

The posterior sacroiliac ligament

The posterior sacroiliac ligament (see Fig. 42.52) overlies the interosseous ligament: the dorsal rami of the sacral spinal nerves and vessels intervene. It consists of several weak fasciculi connecting the intermediate and lateral sacral crests to the posterior superior iliac spine and posterior end of the internal lip of the iliac crest. Inferior fibres, from the third and fourth sacral segments, ascend to the posterior superior iliac spine and posterior end of the internal lip of the iliac crest: they may form a separate long posterior sacroiliac ligament. This ligament is continuous laterally with part of the sacrotuberous ligament and medially with the posterior lamina of the thoracolumbar fascia.

Iliolumbar ligament

See page 735.

Sacrotuberous ligament

The sacrotuberous ligament (Fig. 80.8, see Fig. 42.52) is attached by its broad base to the posterior superior iliac spine., the posterior sacroiliac ligaments (with which it is partly blended), to the lower transverse sacral tubercles and the lateral margins of the lower sacrum and upper coccyx. Its oblique fibres descend laterally, converging to form a thick, narrow band that widens again below and is attached to the medial margin of the ischial tuberosity. It then spreads along the ischial ramus as the falciform process, whose concave edge blends with the fascial sheath of the internal pudendal vessels and pudendal nerve. The lowest fibres of gluteus maximus are attached to the posterior surface of the ligament; superficial fibres of the lower part of the ligament continue into the tendon of biceps femoris. The ligament is pierced by the coccygeal branches of the inferior gluteal artery, the perforating cutaneous nerve and filaments of the coccygeal plexus.

Sacrospinous ligament

The thin, triangular sacrospinous ligament (Fig. 80.8) extends from the ischial spine to the lateral margins of the sacrum and coccyx anterior to the sacrotuberous ligament, with which it blends in part. Its anterior surface is in fact the coccygeus muscle, i.e. muscle and ligament are coextensive. The sacrospinous ligament is often regarded as a degenerate part of coccygeus.

Sciatic foramina

The sacrotuberous and sacrospinous ligaments convert the sciatic notches into foramina (Fig. 80.8).

Greater sciatic foramen

The greater sciatic foramen is bounded anterosuperiorly by the greater sciatic notch, posteriorly by the sacrotuberous ligament and inferiorly by the sacrospinous ligament and ischial spine. It is partly filled by the emerging piriformis, above which the superior gluteal vessels and nerve leave the pelvis. Below it, the inferior gluteal vessels and nerve, internal pudendal vessels and pudendal nerve, sciatic and posterior femoral cutaneous nerves and the nerves to obturator internus and quadratus femoris all leave the pelvis.

Lesser sciatic foramen

The lesser sciatic foramen is bounded anteriorly by the ischial body, superiorly by its spine and sacrospinous ligament, and posteriorly by the sacrotuberous ligament. It transmits the tendon of obturator internus, the nerve to obturator internus, and the internal pudendal vessels and pudendal nerve.

Vascular supply

The arterial supply of the sacroiliac joint is derived from the iliolumbar, superior gluteal and superior lateral sacral arteries, with corresponding venous drainage. Lymphatic drainage follows the arteries, reaching the iliac and lumbar nodes.

Innervation

Nerve fibres ramify within the joint capsule and adjoining ligaments, but their source is uncertain. It is thought that the joint probably receives branches from the anterior and posterior rami of the first two sacral spinal nerves, and from the superior gluteal nerve, and there may also be contributions from the obturator nerve and the lumbosacral trunk: it would appear that Hilton's law is not readily applicable to this joint.

The sacro-iliac joint has been implicated as the source of pain in the lower back and buttocks in approximately 15% of the population. Diagnosing sacroiliac joint-mediated pain is difficult because the presenting complaints are similar to those of other causes of back pain. Patients with sacroiliac joint-mediated pain rarely report pain above L5; most localize their pain to the area around the posterior superior iliac spine.

Factors maintaining stability

The sacroiliac joint is one of the most stable joints in the body, and supports the weight of the trunk. The reciprocal irregularity of the joint surfaces allows very little movement. The tendency of the sacrum to be forced downwards by the trunk is resisted by the extremely strong posterior ligaments, while the iliolumbar ligaments help to resist displacement of the fifth lumbar vertebra over the sacrum. The sacrotuberous and sacrospinous ligaments oppose upward tilting of the lower part of the sacrum when downward thrust is applied at its upper end.

Movements

Primary movement of the sacroiliac joint is minimal. All muscles that cross the joint act on the lumbar spine or on the hip. Such movements as do occur are secondarily imposed on the joint as the pelvis moves. Data from living subjects are technically difficult to obtain, and those based on plain radiographs are unreliable. Studies using implanted tantalum spheres and biplanar radiography have shown mean rotational ranges of less than 2°. Even when there is recordable movement, the direction of movement is irregular. Biplanar radiography has also shown that the axes of movement of the sacroiliac joint during hip movement are oblique, and that the axes differ in flexion and extension.

During pregnancy the pelvic joints and ligaments loosen under the influence of the hormone relaxin. Movements in the joints increase. Relaxation renders the sacroiliac locking mechanism less effective, permitting greater rotation and perhaps allowing alterations in pelvic diameters at childbirth, although the effect is probably small. The impaired locking mechanism diverts the strain of weightbearing to the ligaments, with frequent sacroiliac strain after pregnancy.

Relations

The sacroiliac joints have many important anterior relations. The internal and external iliac veins join to form the common iliac veins immediately anteriorly, separating the joints from the bifurcations of the common iliac arteries and, more anteriorly, the ureters. The lumbosacral trunk and the obturator nerve cross the anterior aspect of the joint behind the vessels. Piriformis partly attaches to the anterior capsule, separating the joint from the upper part of the sacral plexus.

Variants

Accessory sacroiliac articulations are not uncommon. They develop behind the articular surface between the lateral sacral crest and posterior superior iliac spine and iliac tuberosity, and are acquired fibrocartilaginous joints resulting from the stresses of weightbearing. They have a joint capsule, are saddle-shaped, and may be single, double, unilateral or bilateral (Weisl 1954).

MUSCLES

MUSCLES OF THE ILIAC REGION

Although there is no ‘iliac region’ as such, this heading conveniently describes a group of three muscles that originate from the lumbar vertebral column (psoas major and minor) and the ilium (iliacus). Two (psoas major and iliacus) are attached together on the femur as flexors of the hip joint and are often considered as a functional unit, iliopsoas. Psoas minor only reaches the pubis, and acts on the spine and sacroiliac joint.

Psoas major

Attachments

Psoas major is a long muscle that lies on either side of the lumbar vertebral column and the pelvic brim (Fig. 80.19). Its proximal attachments are complex. They include the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae. There are five digitations, each from the bodies of two adjoining vertebrae and their intervertebral disc. The highest of these arises from the lower margin of the body of the 12th thoracic vertebra, the upper margin of the body of the first lumbar vertebra and the interposed thoracolumbar disc. The lowest arises from the adjacent margins of the bodies of the fourth and fifth lumbar vertebrae and the interposed disc. A series of tendinous arches extend across the narrow parts of the bodies of the lumbar vertebrae between the digitations already described. The lumbar arteries and veins, and filaments from the sympathetic trunk, pass medial to these arches. The upper four lumbar intervertebral foramina bear important relations to these attachments of the muscle. The foramina lie anterior to the transverse processes and posterior to the attachments to vertebral bodies, discs and tendinous arches. Thus, the roots of the lumbar plexus enter the muscle directly, the plexus is lodged within it, and its branches emerge from its borders and surfaces.

Fig. 80.19 The hip flexors and superficial muscles of the thigh.

The muscle descends along the pelvic brim, continues posterior to the inguinal ligament and anterior to the capsule of the hip joint, and converges to a tendon which, having received on its lateral side nearly all the fibres of iliacus, becomes attached to the lesser trochanter of the femur. The large subtendinous iliac bursa, which occasionally communicates with the cavity of the hip joint, separates the tendon from the pubis and the capsule of the joint.

The complex vertebral attachments of psoas major sometimes display minor numerical variations.

Relations

The upper limit of psoas major is posterior to the diaphragm in the lowest part of the posterior mediastinum. It may be in contact with the posterior extremity of the pleural sac. In the abdomen its anterolateral surface is related to the medial arcuate ligament (a linear arched thickening in the psoas fascia), extraperitoneal tissue and peritoneum, the kidney, psoas minor, renal vessels, ureter, testicular or ovarian vessels and genitofemoral nerve. Anteriorly, the right psoas is overlapped by the inferior vena cava and crossed by the terminal ileum; the left psoas is crossed by the colon. Its posterior surface is related to the transverse processes of the lumbar vertebrae and the medial edge of quadratus lumborum. The lumbar plexus is embedded posteriorly in the substance of psoas major. Medially the muscle is related to the bodies of the lumbar vertebrae and lumbar vessels. Along its anteromedial margin it is in contact with the sympathetic trunk, aortic lymph nodes and, along the pelvic brim, with the external iliac artery. This margin is covered by the inferior vena cava on the right side, and lies posterior and lateral to the abdominal aorta on the left side. In the thigh, psoas is related anteriorly to the fascia lata and the femoral artery, and posteriorly to the capsule of the hip joint from which it is separated by a bursa. At its medial border, it is related to pectineus and the medial circumflex femoral artery, and to the femoral vein, which may overlap it slightly. At its lateral border it is related to the femoral nerve and iliacus. The femoral nerve descends at first through the fibres of psoas major, and then in the furrow between it and iliacus.

Branches of the lumbar plexus diverge from the abdominal part of psoas. Emerging from the lateral border, from above downwards, are the iliohypogastric, ilioinguinal and lateral femoral cutaneous and femoral nerves. Emerging from the anterolateral surface is the genitofemoral nerve. The obturator and accessory obturator nerves and the upper root of the lumbosacral trunk all emerge from the medial border.

Vascular supply

Psoas major is supplied by a rich network of arteries derived from the lumbar, iliolumbar, obturator, external iliac and femoral arteries. In general terms, the upper part of the muscle is supplied by the lumbar arteries, the mid part by the anterior branch of the iliolumbar artery (the main artery to the muscle) with contributions from the deep circumflex and external iliac arteries, and the distal part by the femoral artery and its branches. The psoas sheath has an arterial supply independent from that of the muscle, though the same vessels contribute.

Innervation

Psoas major is innervated by the ventral rami of the lumbar spinal nerves, mainly L1 and 2 with some contribution from L3.

Actions

Psoas major acts together with iliacus; the combination is referred to as iliopsoas. See below with iliacus.

Testing

See below after iliacus.

Psoas minor

Attachments

Psoas minor (Fig. 80.19) is absent in almost 40% of subjects. When present, it lies anterior to psoas major, entirely within the abdomen. It arises from the sides of the bodies of the twelfth thoracic and first lumbar vertebrae and from the disc between them. It ends in a long, flat tendon which is attached to the pecten pubis and ilio-pubic ramus and, laterally, to the iliac fascia.

Relations

Psoas minor lies on psoas major, and its proximal anterior relations are those of the anterior or anteromedial surface of that muscle.

Vascular supply

The main arterial supply to psoas minor is from the lumbar arteries, though there may be minor contributions from other vessels of the network that supplies psoas major.

Innervation

Psoas minor is innervated by a branch from L1.

Action

Psoas minor is probably a weak flexor of the trunk.

Testing

Psoas minor cannot be tested clinically.

Iliacus

Attachments

Iliacus (Fig. 80.19) is a triangular sheet of muscle that arises from the superior two-thirds of the concavity of the iliac fossa, the inner lip of the iliac crest, the ventral sacroiliac and iliolumbar ligaments, and the upper surface of the lateral part of the sacrum (see Fig. 42.36). In front, it reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsule of the hip joint. Most of its fibres converge into the lateral side of the strong tendon of psoas major, and the muscles then insert together into the lesser trochanter, but some fibres are attached directly to the femur 2.5 cm below and in front of the lesser trochanter.

Relations

In the abdomen, the anterior surface of iliacus is related to its fascia (which separates the muscle from extraperitoneal tissue and peritoneum), the lateral femoral cutaneous nerve, the caecum (on the right) and the iliac part of the descending colon (on the left). On its posterior surface is the iliac fossa; at its medial border, psoas major and the femoral nerve. In the thigh, its anterior surface is in contact with the fascia lata, rectus femoris, sartorius and profunda femoris artery, and its posterior surface is in contact with the capsule of the hip joint, from which it is partially separated by a bursa it shares with psoas major.

Vascular supply

Iliacus is supplied by the same arterial network as psoas major, and there is mutual overlap of the arterial territories of each muscle. The main supply is from the iliac branches of the iliolumbar artery, with contributions from the deep circumflex iliac and obturator arteries, and branches of the femoral artery.

Innervation

Iliacus is innervated by branches of the femoral nerve, L2 and 3.

Actions

Psoas major, acting from above together with iliacus, flexes the thigh upon the pelvis. Electromyographic studies do not support the common view that psoas major acts as a medial rotator of the hip joint, but activity has been described in lateral rotation, particularly in the young. When psoas major and iliacus of both sides act from below, they contract powerfully to bend the trunk and pelvis forwards against resistance, as in raising the trunk from the recumbent to the sitting posture when undertaking a ‘sit-up’ exercise.

Electromyography does not support the commonly held belief that unilateral action of psoas causes lateral and forward flexion of the trunk to that side.

In symmetrical upright stance, iliopsoas has some action from below to maintain the vertebral column upright. Psoas major is active in balancing the trunk while sitting.

Testing

Both psoas and iliacus may be the sites of pathological collections of fluid. An abscess (typically tuberculous) of vertebral origin may track down through psoas and present as a mass in the thigh. Haematoma or infection within the iliacus fascia may present as a mass or as a flexion deformity of the hip.

Iliopsoas may be tested clinically by actively flexing the hip against resistance, in the supine position with hip and knee flexed.

MUSCLES OF THE GLUTEAL REGION

Tensor fasciae latae

Attachments

Tensor fasciae latae (Fig. 80.19) arises from the anterior 5 cm of the outer lip of the iliac crest, from the lateral surface of the anterior superior iliac spine and part of the border of the notch below it, between gluteus medius and sartorius, and from the deep surface of the fascia lata. Proximal attachments may extend to the aponeurotic fascia superficial to gluteus medius. It descends between, and is attached to, the two layers of the iliotibial tract of the fascia lata and usually ends approximately one-third of the way down the thigh, although it may occasionally extend as far as the lateral femoral condyle.

Vascular supply

The muscle itself is supplied mainly by a large ascending branch of the lateral circumflex femoral artery. The tensor fasciae latae musculocutaneous flap is raised on this pedicle. The superior part of the muscle receives branches from the superior gluteal artery. The fascia surrounding the muscle is supplied on its superficial aspect by the superficial circumflex iliac artery and on its deep surface by the lateral circumflex femoral artery.

Innervation

Tensor fasciae latae is innervated by the superior gluteal nerve, L4, 5 and S1.

Actions

Tensor fasciae latae, acting through the iliotibial tract, extends the knee with lateral rotation of the leg; it may also assist in abduction and medial rotation of the thigh, though its role as an abductor is debatable. The muscle helps to maintain upright posture while minimizing energy expenditure on muscle activity: when the subject is standing it acts from below to steady the pelvis on the head of the femur and, through the iliotibial tract, to steady the condyles of the femur on the tibial condyles while the knee extensors are relaxed. The muscle aids gluteus medius in postural abduction at the hip. Postural control is its main function.

In the last 20° or so of extension the pull of the iliotibial tract is anterior to the flexion axis of the knee and so the tensor fasciae latae is a weak extensor. Flexion greater than 20° leads to the iliotibial tract passing posterior to the axis of flexion so that the muscle becomes a weak flexor.

Testing

When the thigh is flexed against gravity and the knee is extended, an angular depression appears immediately below the anterior superior iliac spine: its lateral boundary is tensor fasciae latae. If the thigh is then abducted against resistance, the muscle can be felt, and sometimes seen.

Gluteus maximus

Attachments

Gluteus maximus (Fig. 80.20) is the largest and most superficial muscle in the gluteal region. It is a broad, thick quadrilateral mass, which, with its overlying adipose fascia, forms the familiar prominence of the buttock. Gluteus maximus is thicker and more extensive in man than in any non-human primate, features that presumably correlate with the evolutionary transition to bipedality and a permanently upright posture. The muscle has a coarse fascicular architecture, with large bundles of fibres separated by fibrous septa. It arises from the posterior gluteal line of the ilium, and the rough area of bone, including the crest, immediately above and behind it; from the aponeurosis of erector spinae; the dorsal surface of the lower part of the sacrum and the side of the coccyx; the sacrotuberous ligament; and the fascia (gluteal aponeurosis) which covers gluteus medius. There may be additional slips from the lumbar aponeurosis or ischial tuberosity. The muscle may also be bilaminar. The fibres descend laterally; the upper part of the muscle, together with the superficial fibres of the lower part, ends in a thick tendinous lamina which passes lateral to the greater trochanter and is attached to the iliotibial tract of the fascia lata. The deeper fibres of the lower part of the muscle are attached to the gluteal tuberosity between vastus lateralis and adductor magnus.

Coccyx
Greater trochanter
Adductor magnus
Biceps femoris
Semitendinosus
Fascia lata
Gracilis

Fig. 80.20 Gluteus maximus, posterior view.

Relations

A thin fascia separates the superficial surface of gluteus maximus from the overlying thick adipose subcutaneous tissue. The deep surface of the muscle is related to the ilium, sacrum, coccyx, sacrotuberous ligament, part of gluteus medius, piriformis, the gemelli, obturator internus, quadratus femoris, the ischial tuberosity, greater trochanter, and the attachments of biceps femoris, semitendinosus, semimembranosus and adductor magnus to the ischial tuberosity. Three bursae lie deep to gluteus maximus: trochanteric, over the greater trochanter; gluteofemoral, between the tendon of gluteus maximus and that of vastus lateralis; and ischiofemoral, over the gluteal tuberosity, which is less commonly present.

The superficial division of the superior gluteal artery reaches the deep surface of the muscle between piriformis and gluteus medius. The inferior gluteal and internal pudendal vessels, the sciatic, pudendal and posterior femoral cutaneous nerves, muscular branches from the sacral femoral cutaneous nerves, and muscular branches from the sacral plexus all leave the pelvis below piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also deep to the lower part of gluteus maximus. Its upper border is thin and overlies gluteus medius. Its prominent lower border is free and slopes downwards and laterally. It is crossed by the horizontal gluteal fold (the posterior flexure line of the hip joint), which marks the upper limit of the back of the thigh on the surface.

Vascular supply

The dominant vascular pedicle is usually that of the inferior gluteal artery, which supplies approximately two-thirds of the muscle. The remainder is supplied mainly by the superior gluteal artery, though this may sometimes be the dominant vessel. The lateral and distal borders of the muscle receive a supply from the first profunda perforator and from the medial circumflex femoral artery. Minor branches may be derived from the lateral circumflex femoral, lateral sacral and internal pudendal arteries.

Gluteus maximus musculocutaneous flaps may be based on either of the gluteal vessels or on the first profunda perforator, depending on the site and size of the defect requiring coverage.

Innervation

Gluteus maximus is innervated by the inferior gluteal nerve, L5 and S1 and 2.

Actions

Acting from the pelvis, gluteus maximus can extend the flexed thigh and bring it into line with the trunk. Acting from its distal attachment, it may prevent the forward momentum of the trunk from producing flexion at the supporting hip during bipedal gait. The muscle is inactive during standing, when swaying forwards at the ankle joints, or when bending forwards at the hip joints to touch the toes. However, it acts with the hamstrings in raising the trunk after stooping, by rotating the pelvis backwards on the head of the femur. It is intermittently active in the walking cycle and in climbing stairs, and continuously active in strong lateral rotation of the thigh. Its upper fibres are active in powerful abduction of the thigh. It is a tensor of the fascia lata, and through the iliotibial tract it stabilizes the femur on the tibia when the knee extensor muscles are relaxed.

Testing

Extension of the hip against resistance, in the supine or prone position.

Gluteus medius

Attachments

Gluteus medius is a broad, thick muscle (Fig. 80.20, Fig. 80.21A). It arises from the outer surface of the ilium between the iliac crest and posterior gluteal line above, and the anterior gluteal line below, and also from the strong fascia superficial to its upper part. The fibres converge to a flat tendon that attaches to a ridge that slants downwards and forwards on the lateral surface of the greater trochanter.

(From Sobotta 2006.)

A deep slip of the muscle may be attached to the upper border of the trochanter. The posterior edge of gluteus medius sometimes blends with piriformis.

Relations

The posterior third of gluteus medius is covered by gluteus maximus, but it is superficial in its anterior two-thirds, where it is covered by a strong layer of deep fascia. Its deep surface is related to gluteus minimus. Branches of the deep divisions of the superior gluteal nerve and artery run between the medius and minimus muscles and are vulnerable during anterolateral and lateral approaches to the hip that involve splitting gluteus medius (see Fig. 80.22). Where the tendon glides on the anterosuperior part of the lateral surface of the trochanter, a bursa (trochanteric bursa of gluteus medius) separates it from the bone.

Fig. 80.22 The arteries and muscles of the left gluteal and femoral regions. **A**, Posterior aspect. **B**, Anterior aspect.

(From Drake, Vogl and Mitchell 2005.)

Vascular supply

The main supply to gluteus medius is from the deep branch of the superior gluteal artery. The distal part of the muscle is supplied by the trochanteric anastomosis.

Innervation

Gluteus medius is innervated by the superior gluteal nerve, L4, 5 and S1.

Actions

Considered below with gluteus minimus.

Testing

Considered below with gluteus minimus.

Gluteus minimus

Attachments

Gluteus minimus lies deep to gluteus medius (Fig. 80.21B). The fan-shaped muscle arises from the outer surface of the ilium between the anterior and inferior gluteal lines and, behind, from the margin of the greater sciatic notch. The fibres converge below to the deep surface of an aponeurosis that ends in a tendon which is attached to an anterolateral ridge on the greater trochanter and contributes an expansion to the capsule of the hip joint.

The muscle may divide into anterior and posterior parts. Separate slips may pass to piriformis, gemellus superior, or vastus lateralis.

Relations

Branches of the deep division of the superior gluteal artery and nerve run on the superficial surface of the muscle. The reflected tendon of rectus femoris and the capsule of the hip joint are deep to gluteus minimus. A bursa (trochanteric bursa of gluteus minimus) separates the tendon from the medial part of the anterior surface of the greater trochanter.

Vascular supply

Gluteus minimus is supplied from both its surfaces, from the main trunk and the deep branch of the superior gluteal artery, with a contribution at its femoral attachment from the trochanteric anastomosis (Fig. 80.22).

Innervation

Gluteus minimus is innervated by the superior gluteal nerve, L4, 5 and S1.

Actions of gluteus medius and minimus

Both gluteus medius and minimus, acting from the pelvis, abduct the thigh, and their anterior fibres rotate it medially. Acting from the femur, they play an essential part in maintaining the trunk upright when the foot of the opposite side is raised from the ground in walking and running. In this phase the body weight tends to make the pelvis sag downwards on the unsupported side. This is counteracted by the gluteus medius and minimus of the supporting side, which, acting from below, exert such powerful traction on the hip bone that the pelvis is actually raised a little on the unsupported side. In symmetrical standing with the feet somewhat separated, the abductor muscles are usually ‘silent’ on electromyography, but with the feet placed parallel and close together they are active.

Testing

The supportive effect of the glutei (medius and minimus) on the pelvis when the contralateral foot is raised depends on the following conditions. The two muscles, and their innervation, must be functioning normally. The components of the hip joint, which forms the fulcrum, must be in their usual relation. The neck of the femur must be intact, with its normal angulation to the shaft.

When any one of these conditions is not fulfilled, e.g. in paralysis of the glutei, congenital dislocation of the hip, or coxa vara, the supporting mechanism is upset and the pelvis sinks on the unsupported side when the patient tries to stand on the affected limb. This is known clinically as Trendelenburg’s sign. Individuals with paralysis of gluteus medius and minimus have a characteristic lurching gait. Provided that these two muscles are intact, paralysis of other muscles acting on the hip joint produces remarkably little deficit in walking, or even in running.

Gluteus medius and minimus may be tested together by medial (internal) rotation of the thigh against resistance, in the supine position with hip and knee flexed. Both muscles may be tested together with tensor fasciae latae by abduction of the lower limb against resistance, in the supine position with the knee extended.

Piriformis

Attachments

Piriformis (see Fig. 63.1, Fig. 80.21B) occupies a central position in the buttock, where it lies in the same plane as gluteus medius. It arises from the anterior surface of the sacrum by three digitations, which are attached to the portions of bone between the pelvic sacral foramina, and to the grooves leading from the foramina (see Fig. 42.36). It also arises from the gluteal surface of the ilium near the posterior inferior iliac spine, from the capsule of the adjacent sacroiliac joint, and sometimes from the upper part of the pelvic surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, which it substantially fills. Here it constitutes an important surgical landmark in the identification of structures that emerge above and below it. It inserts into the medial side of the upper border of the greater trochanter of the femur via a rounded tendon that lies behind and above, but is often partially blended with, the common tendon of obturator internus and the gemelli. The muscle itself may be fused with gluteus medius.

Relations

Within the pelvis, the anterior surface of piriformis is related to the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels. The posterior surface lies against the sacrum. Outside the pelvis, its anterior surface is in contact with the posterior surface of the ischium and capsule of the hip joint and its posterior surface with gluteus maximus. Its upper border is in contact with gluteus medius and the superior gluteal vessels and nerve, its lower border with coccygeus and gemellus superior. The inferior gluteal and internal pudendal vessels, the sciatic, posterior femoral cutaneous and pudendal nerves, and muscular branches from the sacral plexus appear in the buttock in the interval between piriformis and gemellus superior. The relationship between piriformis and the sciatic nerve is variable. The undivided nerve may emerge above the muscle or through the muscle. The major divisions of the nerve may lie either side of the muscle, or (the most common variant) one division passes between the heads of a divided muscle and one division either above or below.

Piriformis can occasionally cause entrapment of the sciatic nerve in the buttock, giving rise to the so-called ‘piriformis syndrome’.

Vascular supply

In the buttock, piriformis is supplied mainly from the superior gluteal artery, with contributions from the gemellar branches of the internal pudendal. There may be a separate branch from the inferior gluteal artery. In the pelvis the main supply is from the lateral sacral artery, with contributions from both gluteal vessels.

Innervation

Piriformis is innervated by branches from L5, S1 and 2.

Actions

Piriformis rotates the extended thigh laterally, but abducts the flexed thigh.

Testing

Clinically it is not possible to test piriformis alone; however, for suspected injury to piriformis the best provocative test is to ask the seated subject to abduct the thighs. Buttock pain suggests piriformis injury.

Obturator internus

Attachments

Obturator internus (see Fig. 63.1, Fig. 80.21B) is situated partly within the true pelvis and partly posterior to the hip joint. It arises from the internal surface of the anterolateral wall of the lesser pelvic cavity. Its attachments, which almost surround the obturator foramen, are to the inferior ramus of the pubis, the ischial ramus, and the pelvic surface of the hip bone below and behind the pelvic brim, to the upper part of the greater sciatic foramen above and behind, to the obturator foramen below and in front (Fig. 80.5B). It also arises from the medial part of the pelvic surface of the obturator membrane, from the tendinous arch that completes the obturator canal, and, to a small extent, from the obturator fascia that covers the muscle. The fibres converge towards the lesser sciatic foramen and end in four or five tendinous bands on the deep surface of the muscle. These bands make a lateral right-angled turn around the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered with a smooth layer of hyaline cartilage and is separated from the tendon by a bursa: ridges on the surface correspond to furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite to form a single flattened tendon that passes horizontally across the capsule of the hip joint. The gemelli fuse with this tendon before it inserts into an anterior impression on the medial surface of the greater trochanter anterosuperior to the trochanteric fossa. A long, narrow bursa is usually interposed between the tendon and the capsule of the hip joint, and occasionally communicates with the bursa between the tendon and the ischium.

Relations

Within the pelvis, the anterolateral surface of the muscle is in contact with the obturator membrane and inner surface of the lateral wall of the pelvis. Its posteromedial surface is related to the obturator fascia, the origin of levator ani, and the sheath that surrounds the internal pudendal vessels and pudendal nerve, and forms the lateral wall of the ischiorectal fossa. Outside the pelvis, the muscle is covered by gluteus maximus, is crossed posteriorly by the sciatic nerve and passes behind the hip joint. As the tendon of obturator internus emerges from the lesser sciatic foramen it is overlapped both above and below by the two gemelli, which form a muscular canal for it. Near its termination the gemelli pass anterior to the tendon and form a groove in which it lies.

Vascular supply

The main arterial supply of the extrapelvic part of obturator internus is from the gemellar branches of the internal pudendal artery. The intrapelvic part is supplied by the obturator artery, which gives branches to both surfaces of the muscle: it is also supplied by small branches from the internal pudendal artery.

Innervation

Obturator internus is innervated by the nerve to obturator internus, L5 and S1.

Actions

See below, with obturator externus.

Obturator externus

Attachments

Obturator externus (Fig. 80.23) is a flat, triangular muscle covering the external surface of the anterior pelvic wall. It arises from the anteromedial two-thirds of the external surface of the obturator membrane, and from the adjacent bone of the pubic and ischial rami, extending for a short distance onto their pelvic surfaces between the margin of the obturator foramen and the obturator membrane. The whole muscle, and the tendon into which its fibres converge, spirals backwards, laterally and upwards, and thus crosses the inferior aspect and then the back of the neck of the femur and lower part of the capsule of the hip joint to end in the trochanteric fossa of the femur.

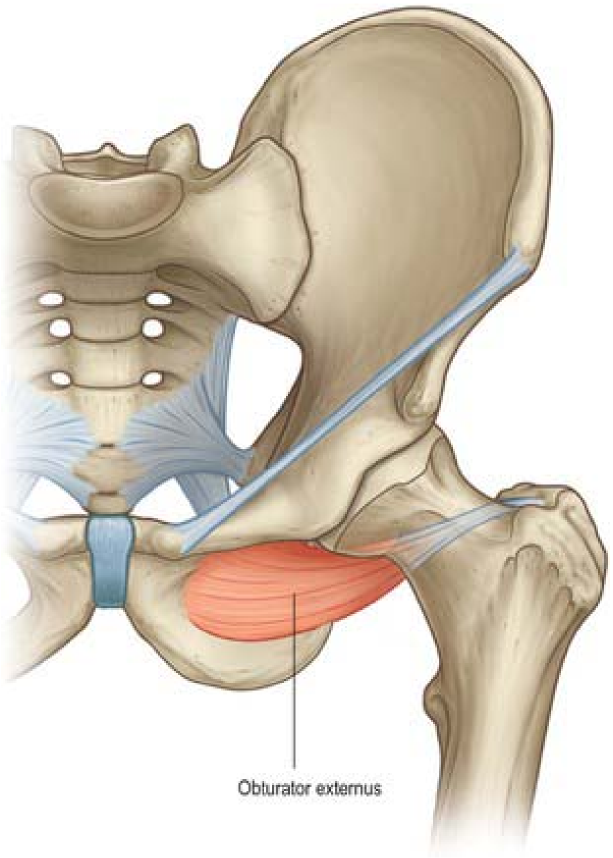

Fig. 80.23 Obturator externus: anteroinferior aspect.

(Adapted from Drake, Vogl and Mitchell 2005.)

Relations

A bursa, which communicates with the hip joint, may be interposed between the tendon and the hip joint capsule and femoral neck. The obturator vessels lie between the muscle and the obturator membrane. The anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it.

Vascular supply

Obturator externus receives a variable pattern of supply from the obturator and medial circumflex femoral arteries.

Innervation

Obturator externus is innervated by the posterior branch of the obturator nerve, L3 and 4.

Actions

It has been suggested that the short muscles around the hip joint, pectineus, piriformis, obturators, gemelli and quadratus femoris, are more important as postural muscles than as prime movers, acting as adjustable ligaments to maintain the stability and integrity of the hip. However, these muscles are largely inaccessible to direct observation, and because of the hazards presented by their close relationship to important neurovascular structures there is a total lack of electromyographic data in man. In both bipedal walking and vertical climbing obturator externus is recruited during the early part of swing phase: in climbing it effects lateral rotation of the thigh, and in walking it probably counteracts the tendency to medial rotation produced by the anterior adductor muscles at this stage of the cycle. Obturator internus differs from externus in its pattern of use but its role in bipedal walking remains unclear. Its attachments suggest that it, like the gemelli, is a lateral rotator of the extended thigh and an abductor of the flexed thigh. These actions may be used to antagonize unwanted components of movement produced by the primary locomotor muscles.

Testing

The short rotators cannot be tested individually, but external rotation of the extended hip and abduction of the flexed hip against resistance tests them as a group.

Gemellus inferior and gemellus superior

Attachments

Gemellus inferior arises from the upper part of the lateral surface of the ischial tuberosity, immediately below the groove for the tendon of obturator internus. It blends with the lower border of this tendon, and inserts with it into the medial surface of the greater trochanter.

Gemellus superior, the smaller of the two gemelli, arises from the dorsal surface of the ischial spine, blends with the upper border of the tendon of obturator internus, and inserts with it into the medial surface of the greater trochanter. It is sometimes absent.

The two gemelli can be regarded as accessory to obturator internus (see Fig. 80.21B).

Relations

The relations of the gemelli are as for the extrapelvic part of obturator internus.

Vascular supply

The superior gemellus is supplied by the internal pudendal artery and its gemellar branches; by the inferior gluteal and sometimes also by the superior gluteal artery. The inferior gemellus is supplied mainly by the medial circumflex femoral artery.

Innervation

Gemellus superior is innervated by the nerve to obturator internus, L5, S1 and S2. Gemellus inferior is innervated by the nerve to quadratus femoris,L4, L5 and S1.

Actions

The gemelli rotate the extended thigh laterally and abduct the flexed thigh.

Testing

See testing of obturator externus above.

Quadratus femoris

Attachments

Quadratus femoris (see Fig. 80.21B) is a flat, quadrilateral muscle lying between gemellus inferior and the upper margin of adductor magnus, from which it is separated by the transverse branch of the medial circumflex femoral artery. It arises from the upper part of the external aspect of the ischial tuberosity and inserts into a small tubercle a little above the middle of the trochanteric crest of the femur and into the bone for a short distance below. It may be absent.

Relations

The muscle passes behind the hip joint and the neck of the femur, separated from them by the tendon of obturator externus and the ascending branch of the medial circumflex femoral artery (which may cause troublesome bleeding if injured during the posterior approach to the hip). The sciatic nerve crosses the muscle posteriorly. A bursa is often present between the muscle and the lesser trochanter.

Vascular supply

Branches pass to the superficial surface of the muscle from the inferior gluteal artery and from the medial circumflex femoral artery. The latter vessel also supplies the deep surface.

Innervation

Quadratus femoris is innervated by the nerve to quadratus femoris, L5 and S1.

Action

Quadratus femoris produces lateral rotation of the thigh.

Testing

See testing of obturator externus.

MUSCLES OF THE THIGH

The presence and position of the femoral neck cause the femoral shaft to lie obliquely, which means that the anterior (extensor) muscle group, the quadriceps, runs obliquely distally and medially and so applies a pull to the patella which is both laterally and proximally directed. The adductor muscles occupy the region between the quadriceps and the medial margin of the thigh. They are attached distally to the posterior surface of the femur and lie more posteriorly than the quadriceps. The posterior (flexor) muscle group, the hamstrings, lie behind the adductors. The attachments of these muscles determine the nature and direction of displacement of femoral shaft fractures.

Anterior compartment

The muscles of the anterior compartment (Figs 80.2, 80.19) include sartorius and rectus femoris, which can act both at the hip and knee joints, and vasti medialis, lateralis, and intermedius, which act only at the knee. Articularis genu, a derivative of vastus intermedius, completes the group: it retracts the synovial capsule of the knee joint. Rectus femoris and the vasti extend the knee joint through a common tendon and hence are collectively termed the quadriceps femoris muscle. Adductor longus and pectineus are sometimes considered to be part of both the anterior and the adductor compartments.

Sartorius

Attachments

Sartorius is a narrow strap muscle, and is the longest muscle in the body. It arises by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it. It crosses the thigh obliquely over to the medial side, then descends more vertically to the medial side of the knee. The muscle fibres terminate at this point and a thin, flattened tendon curves obliquely forwards and expands into a broad aponeurosis. The aponeurosis is attached to the proximal part of the medial surface of the tibia in front of gracilis and semitendinosus, together forming the ‘pes anserinus’ (Fig.

80.24). A slip from its upper margin blends with the capsule of the knee joint, and another from its lower margin merges with the superficial layer of the deep fascia on the medial side of the leg. This sheet of tissue passes inferiorly to lie superficial to and over the distal insertions of gracilis and semitendinosus. It has to be split by sharp dissection to reveal these two tendons if they need to be harvested, e.g. in cruciate ligament surgery (Fig. 80.24).

Fig. 80.24 Distal attachment of muscles of the thigh: medial aspect.

(From Sobotta 2006.)

In some cases sartorius is absent, while in others the muscle may possess an extra head: when the latter occurs, the extra head is attached to the pectineal line or to the femoral sheath. Variations in the distal attachment of sartorius, in the vicinity of the knee, have been described.

Relations

The relations of sartorius are described in the femoral triangle (see below).

Vascular supply

The main arterial supply to sartorius is derived from multiple branches of the femoral system, and enters the medial half of the muscle from its deep surface. Vessels supplying the proximal third of sartorius may arise from the common femoral, the main trunk of the profunda, the artery of the quadriceps, the superficial femoral or the lateral circumflex femoral artery. There may be an additional proximal supply from the superficial circumflex iliac artery. Those supplying the middle third of the muscle arise from the superficial femoral artery. The distal vessels arise from the superficial femoral within the adductor canal and from the descending genicular artery.

Innervation

Sartorius is innervated by the femoral nerve, L2 and 3.

Actions

Sartorius assists in flexing the leg at the knee, and the thigh on the pelvis, particularly when these two movements are combined. It also helps to abduct the thigh and to rotate it laterally. (Together with inversion of the foot, these movements bring the sole of the foot into direct view.) The fact that sartorius represents only 1% of the physiological cross-sectional area of all muscles which cross the hip or knee joint would appear to suggest that its role in walking is a minor one. In a subject ascending steps, electromyographic activity of sartorius increases during lateral rotation of the thigh at the end of the swing phase immediately preceding heel strike, which presumably decelerates the limb. Sartorius may therefore have a significant involvement in climbing.

Testing

When it contracts against gravity, as it usually does, sartorius can be both seen and felt in the living subject.

Femoral triangle

The femoral triangle is a depressed, intermuscular space in the anteromedial aspect of the proximal thigh, lying immediately distal to the inguinal ligament. The latter constitutes the base of the femoral triangle’s inverted triangular outline. Its lateral boundary is the medial margin of sartorius. Its medial boundary is the medial margin of adductor longus. Its distal extremity, the apex, is where sartorius overlaps adductor longus. Its floor is provided laterally by iliacus and psoas major, medially by pectineus and adductor longus. Its roof is the overlying fascia lata. The femoral vessels, passing from midbase to apex, are in the deepest part of the triangle. Lying lateral to the artery and outside the femoral sheath is the femoral nerve, which, on entering the femoral triangle divides into multiple branches. The triangle also contains fat and lymph nodes.

Quadriceps femoris

Quadriceps femoris (Figs 80.2, 80.19), the great extensor muscle of the leg, covers almost all of the front and sides of the femur. It can be divided into four parts, each named individually. One, rectus femoris, arises from the ilium and travels straight down the middle of the thigh, its shape and path determining its name. The other three arise from the shaft of the femur and surround it (apart from the linea aspera) from the trochanters to the condyles: vastus lateralis is lateral to the femur, vastus medialis is medial to it, and vastus intermedius lies in front of the femur. Rectus femoris crosses both hip and knee joints, while the three vasti only cross the knee joint.

The tendons of the four components of quadriceps unite in the lower part of the thigh to form a single strong tendon attached to the base of the patella, and some fibres continue over it to blend with the patellar tendon. The patella is a sesamoid bone in the quadriceps tendon, and the patellar tendon, which extends from the patellar apex to the tubercle of the tibia, is the continuation of the main tendon. The medial and lateral patellar retinacula are expansions from its borders. The suprapatellar bursa (a synovial extension of the knee joint) lies between the femur and the suprapatellar part of the quadriceps tendon. The deep infrapatellar bursa lies between the patellar tendon and the proximal end of the tibia.

The arterial supply to the quadriceps group has been traditionally ascribed to a single branch of either the profunda femoris or of the lateral circumflex femoral, the ‘artery of the quadriceps’. This vessel, which may be large, occasionally arises directly from the femoral artery. However, according to Taylor & Razaboni (1994) this artery does not supply all four components of the quadriceps: vastus medialis is supplied directly from the (superficial) femoral artery. The supply of the individual muscle components is described below: their sheaths may have an additional and variable supply.

Quadriceps as a group shows little anatomical variation.

Rectus femoris

Attachments

Rectus femoris is fusiform. Its superficial fibres are bipennate, the deep fibres parallel. It has a double origin on the ilium: a straight tendon arises from the anterior inferior iliac spine, and a thinner, flatter reflected tendon from a groove above the acetabulum and from the fibrous capsule of the hip joint. The two unite at an acute angle and spread into an aponeurosis that is prolonged downwards on the anterior surface of the muscle: the muscular fibres arise from this aponeurosis. The fibres end in a broad, thick aponeurosis that forms over the lower two-thirds of its posterior surface and gradually narrows into the thick, flat tendon by which it is attached to the base of the patella. This constitutes the superficial central part of the quadriceps tendon.

Rectus femoris may arise from the anterior superior iliac spine, and its reflected head may be absent.

Relations

Proximally the muscle is covered by tensor fasciae latae, iliacus and sartorius. The reflected head lies beneath gluteus minimus. The capsule of the hip joint, vastus intermedius, the anterior borders of vasti lateralis and medius, the lateral circumflex femoral artery and some branches of the femoral nerve all lie deep to rectus femoris.

Vascular supply

There are two main pedicles, a superior and an inferior. The superior enters rectus femoris at the junction of its upper and middle thirds and arises from the ‘artery of the quadriceps’. The inferior and larger branch arises from the ‘artery of the quadriceps’ at about midthigh level and enters the muscle a few centimetres more distally. There are additional contributions from the lateral circumflex femoral and, less often, the superficial circumflex iliac arteries.

Vastus medialis and vastus medialis obliquus

Attachments

Vastus medialis arises from the lower part of the intertrochanteric line, spiral line, medial lip of the linea aspera, proximal part of the medial supracondylar line, the tendons of adductor longus and magnus, and the medial intermuscular septum. Its fibres pass downwards and forwards at an average angle of 15° to the long axis of the femur, most of them into an aponeurosis on the deep surface of the muscle which is attached to the medial border of the patella and quadriceps tendon. An expansion from this aponeurosis reinforces the capsule of the knee joint and is attached below to the medial condyle of the tibia.

The lowest fibres are nearly horizontal and form a bulge in the living subject, medial to the upper half of the patella. Some authors distinguish this part of the muscle as the vastus medialis obliquus, with fibres that originate largely from the tendon of adductor magnus and insert into the medial border of the patella. It plays an important role in the function of patellofemoral joint.

Relations

Vastus medialis is partly covered by rectus femoris and sartorius. In the central part of the thigh it forms the lateral wall of the adductor (Hunter’s) canal.

Vascular supply

Vastus medialis is supplied by three branches of the (superficial) femoral artery. The superior and middle branches arise, sometimes from a common trunk, proximal to the adductor canal, while the inferior arises within the canal. There may also be minor branches from the profunda femoris and descending genicular arteries.

Vastus lateralis

Attachments

Vastus lateralis is the largest component of quadriceps femoris. It arises by a broad aponeurosis from the upper part of the intertrochanteric line, the anterior and inferior borders of the greater trochanter, the lateral lip of the gluteal tuberosity, and the proximal half of the lateral lip of the linea aspera. This aponeurosis covers the proximal three-quarters of the muscle; many additional fibres arise from its deep surface. A few fibres also arise from the tendon of gluteus maximus and the lateral intermuscular septum between vastus lateralis and the short head of biceps femoris. The muscular mass thus formed is attached to a strong aponeurosis on the deep surface of the lower part of the muscle. This narrows to a flat tendon, which is attached to the base and lateral border of the patella and blends into the compound quadriceps femoris tendon. It contributes an expansion to the capsule of the knee joint which descends to the lateral condyle of the tibia and blends with the iliotibial tract.

Relations

Vastus lateralis is covered laterally by the fascia lata and the aponeurotic insertions of tensor fasciae latae and gluteus maximus. It is separated from vastus intermedius by branches of the femoral nerve and the lateral circumflex femoral artery. Posteriorly it is separated from biceps femoris by the lateral intermuscular septum.

Vascular supply

There are three main arteries of supply: the superior medial artery arises directly from the lateral circumflex femoral, the inferior medial (the largest of the three) from the ‘artery of the quadriceps’, and the lateral from the first perforating branch of the profunda femoris artery.

Vastus intermedius

Attachments

Vastus intermedius arises from the anterior and lateral surfaces of the upper two-thirds of the femoral shaft, and from the lower part of the lateral intermuscular septum. Its fibres end on the anterior surface of the muscle in an aponeurosis which forms the deep part of the quadriceps tendon and is attached to the lateral border of the patella and the lateral condyle of the tibia.

Vastus intermedius appears to be inseparable from vastus medialis. However, when rectus femoris is reflected a narrow cleft can be seen extending upwards from the medial border of the patella between the two muscles, sometimes as far as the lower part of the intertrochanteric line, proximal to which, the two muscles are frequently fused.

Relations

Vastus intermedius is almost completely covered by the other quadriceps components, except laterally where a small part becomes superficial behind vastus lateralis.

Vascular supply

Vastus intermedius receives a lateral artery of supply, which arises from the ‘artery of the quadriceps’, and a medial artery that arises directly from the profunda. Arteries to the other quadriceps components may also contribute. There is an anastomotic network deep to the muscle: this supplies the suprapatellar pouch and articularis genu and may form a collateral pathway when the (superficial) femoral artery is blocked.

Articularis genu

Articularis genu is a small muscle, usually distinct from vastus intermedius but occasionally blending with it. It consists of several muscular bundles that arise from the anterior surface of the lower part of the femoral shaft and are attached to a proximal reflection of the synovial membrane of the knee joint. It is visible during knee arthroscopy when viewed looking superiorly from within the suprapatellar pouch.

Innervation of quadriceps group

Quadriceps femoris and articularis genu are supplied by the femoral nerve, L2, 3 and 4.

Actions of quadriceps group

Quadriceps femoris extends the knee. Rectus femoris helps to flex the thigh on the pelvis; if the thigh is fixed, it helps to flex the pelvis on the thigh. Rectus can flex the hip and extend the knee simultaneously. Electromyographic studies indicate that the three vasti are not equally active in different phases of extension or rotation. There is little or no activity in quadriceps during standing. Rectus femoris pulls the patella along the line of the mechanical axis of the lower limb (i.e. the line connecting the centres of the hip, knee, and ankle) because its attachment is anterior to the hip joint. The remaining quadriceps are attached to the shaft of the femur and so the pull is lateral as well as proximal. An extremely important dynamic function of vastus medialis obliquus is to counter this lateral vector on the patella during knee motion. Other static factors that help are the depth of the femoral trochlear groove, the buttressing effect of the lateral femoral condyle in the groove, and the restraining action of the medial patellofemoral ligament. Inadequacy of vastus medialis obliquus is a factor in producing patellar instability and pain. Strengthening of this muscle to improve patellar ‘tracking’ on the femur and stability is an important part of physiotherapy regimens for patellofemoral problems.

Articularis genu retracts the synovial suprapatellar bursa proximally during extension of the leg, presumably to prevent interposition of redundant synovial folds between patella and femur.

Testing

The quadriceps group is tested by extending the knee against resistance, in the supine position with the hip flexed.

Adductor compartment

The muscles of the adductor compartment, gracilis, pectineus, adductor longus, adductor brevis, and adductor magnus (Fig. 80.25), have evolved, as their nerve supply suggests, both from flexor and extensor columns. All five muscles cross the hip joint, but only gracilis reaches beyond the knee. They are known collectively as the adductors of the thigh, although their actions are more complex than this, e.g. acting from below they have important roles in balancing the trunk on the lower limb during walking.

Their blood supply is derived from the profunda, medial circumflex femoral, (superficial) femoral and obturator arteries. The profunda (or sometimes the first perforator) supplies a large branch, the ‘artery of the adductor muscles’.

Gracilis

Attachments

Gracilis (Figs 80.2, 80.19) is the most superficial of the adductor group. It is thin and flat, broad above, narrow and tapering below. It arises by a thin aponeurosis from the medial margins of the lower half of the body of the pubis, the whole of the inferior pubic ramus, and the adjoining part of the ischial ramus. The fibres descend vertically into a rounded tendon, often harvested as a knee ligament graft, which passes across the medial condyle of the femur posterior to the tendon of sartorius. It then curves around the medial condyle of the tibia, where it fans out and is attached to the upper part of the medial surface of the tibia, just below the condyle, forming part of the pes anserinus. A few fibres from the lower part of the tendon continue into the deep fascia of the lower leg. Often there is a slip that blends with the tendon of the medial head of gastrocnemius. Unless divided this can lead to problems during surgical harvesting of the gracilis tendon.

Relations

The muscle is covered medially by the fascia lata throughout most of its length. Deep to gracilis lie adductor brevis and adductor magnus. The tibial attachment is immediately proximal to that of semitendinosus, and its upper edge is overlapped by the tendon of sartorius, with which it is partly blended. It is separated from the medial collateral ligament of the knee joint by the tibial intertendinous bursa.

Vascular supply

The arterial supply to gracilis enters via its lateral surface. The main pedicle arises from the ‘artery to the adductors’ of the profunda and enters at the junction of the upper and middle thirds of the muscle. The gracilis musculocutaneous flap is based on this pedicle. A less important artery enters the distal third of the muscle from the femoral artery. There is a minor proximal supply from the medial circumflex femoral.

Innervation

Gracilis is innervated by the obturator nerve, L2 and 3.

Actions

Gracilis flexes the leg and rotates it medially. It may also act as an adductor of the thigh. When the foot is fixed, gracilis rotates the femur and pelvis laterally on the tibia, and helps balance the trunk during walking.

Testing

While palpating over the tendon posteromedially at the flexed knee, the knee is actively further flexed and the leg actively medially rotated. Gracilis can also be tested with the other adductors of the hip.

Adductor longus

Attachments

Adductor longus (Figs 80.2, 80.26), the most anterior of the three adductors, is a large, fan-shaped muscle that lies in the same plane as pectineus. It arises by a narrow tendon with a flattened (sometimes C-shaped) cross-section, which is attached to the front of the pubis in the angle between the crest and the symphysis. It expands into a broad fleshy belly which descends posterolaterally and inserts by an aponeurosis into the linea aspera in the middle third of the femur, between vastus medialis and adductors magnus and brevis, usually blending with all of them. Its proximal attachment is vulnerable to overload from sporting activity: this is one cause of sport-related groin pain.

Obturator externus
Adductor brevis
Adductor magnus
Opening in adductor magnus (adductor hiatus)

Fig. 80.26 Adductor muscles of the left thigh: anterior aspect.

Adductor longus is occasionally double.

Relations

Anterior to adductor longus are the spermatic cord, fascia lata (which separates it from the long saphenous vein) and, near its attachment, the femoral artery and vein and sartorius. Posterior to it are adductor brevis and adductor magnus, the anterior branch of the obturator nerve and, near its attachment, the profunda femoris vessels. Lateral and medial to adductor longus are, respectively, pectineus, and gracilis.

Vascular supply

The main supply to adductor longus is to the central part of the muscle from the ‘artery to the adductors’ of the profunda. There is an additional proximal supply from the medial circumflex femoral artery, and a more distal supply from the femoral artery and sometimes the descending genicular artery.

Innervation

Adductor longus is innervated by the anterior division of the obturator nerve, L2, 3 and 4.

Actions

The actions of the named adductors as a group are discussed below, after each muscle has been described.

Testing

The adductors are tested as a group by adduction of the thigh against resistance, in the supine position and with the knee extended.

Adductor brevis

Attachments

Adductor brevis (Figs 80.2A, 80.26) lies posterior to pectineus and adductor longus. It arises by a narrow attachment from the external aspect of the body and inferior ramus of the pubis, between gracilis and obturator externus. Like adductor longus it is somewhat triangular, and expands as it descends posterolaterally to insert via an aponeurosis into the femur, along a line from the lesser trochanter to the linea aspera, and on the upper part of the linea immediately behind pectineus and the upper part of adductor longus.

Adductor brevis often has two or three separate parts, or may be integrated into adductor magnus.

Relations

Anteriorly lie pectineus, adductor longus, the profunda femoris artery, and the anterior branch of the obturator nerve; posteriorly are adductor magnus and the posterior branch of the obturator nerve. The upper border of adductor brevis is related to the medial circumflex femoral artery, obturator externus, and the conjoined tendon of psoas major and iliacus. Its lower border is related to gracilis and adductor magnus. The second, or first and second perforating arteries pierce it near its femoral attachment.

Vascular supply

The vascular supply to adductor brevis is variable. Usually the main supply is directly from the profunda femoris distally and from the ‘artery to the adductors’ more proximally. There is an additional proximal supply from the medial circumflex femoral artery. The deep surface receives branches from the obturator artery.

Innervation

Adductor brevis is innervated by the obturator nerve, L2 and 3.

Actions

The actions of the named adductors as a group are discussed below, after each muscle has been described.

Testing

Adductor brevis is tested in the same way as adductor longus.

Adductor magnus

Attachments

Adductor magnus (see Figs 80.2, 80.26), a massive triangular muscle, arises from a small part of the inferior ramus of the pubis, from the conjoined ischial ramus, and from the inferolateral aspect of the ischial tuberosity. The short, horizontal fibres from the pubic ramus are inserted into the medial margin of the gluteal tuberosity of the femur, medial to gluteus maximus; this part of the muscle, in a plane anterior to the rest, is sometimes called adductor minimus. The fibres from the ischial ramus fan out downwards and laterally, to insert via a broad aponeurosis into the linea aspera and the proximal part of the medial supracondylar line. The medial part of the muscle, composed mainly of fibres from the ischial tuberosity, is a thick mass which descends almost vertically, and ends in the lower third of the thigh in a rounded tendon, which can be palpated proximal to its attachment to the adductor tubercle on the medial condyle of the femur. The tendon is connected by a fibrous expansion to the medial supracondylar line.

The long, linear attachment of the muscle is interrupted by a series of osseo-aponeurotic openings, bridged by tendinous arches attached to the bone. The upper four are small and transmit the perforating branches and the termination of the profunda femoris artery. The lowest is large and allows the femoral vessels to cross to the popliteal fossa.

The vertical, ischiocondylar part of the muscle varies in its degree of separation from the rest. The upper border of adductor magnus may fuse with quadratus femoris.

Relations

Anteriorly lie pectineus, adductor brevis and adductor longus, the femoral and profunda vessels, and the posterior branch of the obturator nerve. A bursa separates the proximal part of the muscle from the lesser trochanter of the femur. Posteriorly are the sciatic nerve, gluteus maximus, biceps femoris, semitendinosus and semimembranosus. The superior border is parallel with quadratus femoris, and the transverse branch of the medial circumflex femoral artery passes between the muscles. The medial border is related to gracilis, sartorius and the fascia lata.

Vascular supply

As expected from its position, adductor magnus is supplied from both its anterior and posterior aspects. The contribution from the anterior compartment is the more important. Here the obturator, profunda femoris and (superficial) femoral arteries contribute; the main supply is directly from the distal part of the profunda. Distally there may be contributions from the femoral and descending genicular arteries. Posteriorly there are branches from the medial circumflex femoral, the first and second perforating and the popliteal vessels.

Innervation

Adductor magnus is composite and is doubly innervated by the obturator nerve and the tibial division of the sciatic nerve (L2, 3 and 4); the latter supplies the ischiocondylar part. Both nerves are derived from anterior divisions in the lumbosacral plexus, indicating a primitive flexor origin for both parts of the muscle.

Actions of the adductors

Extensive or forcible adduction of the femur is not often required. Although the adductors can act in this way, they more commonly act as synergists in the complex patterns of gait activity, and to some degree as controllers of posture. They are active during flexion and extension of the knee. Magnus and longus are probably medial rotators of the thigh. The adductors are inactive during adduction of the abducted thigh in the erect posture (when gravity assists), but active in other postures, such as the supine position, or during adduction of the flexed thigh when standing. They are also active during flexion (longus) and extension (magnus) of the thigh at the hip joint. In symmetrical easy standing their activity is minimal.

Testing of the adductors

The adductors are usually tested as a group by adduction of the thigh against resistance, in the supine position with the knee extended. The tendon of adductor magnus can be felt just proximal to the adductor tubercle on the medial condyle of the femur. Clinical testing of the other actions mentioned above is not feasible for the individual muscles.

Pectineus

Attachments

Pectineus (Fig. 80.19) is a flat, quadrangular muscle in the femoral triangle. It may also be considered as part of the anterior compartment of the thigh. It arises from the pecten pubis, from the bone in front of it between the iliopubic ramus and the pubic tubercle, and from the fascia on its own anterior surface. The fibres descend, initially posteromedially and then posterolaterally to be attached along a line from the lesser trochanter to the linea aspera.

Pectineus may be bilaminar, in which case the two layers receive separate nerve supplies. Proximally it may be partially or wholly attached to the capsule of the hip joint.

Relations

Pectineus is related anteriorly to the deep lamina of the fascia lata, which separates it from the femoral vessels and long saphenous vein; posteriorly to the capsule of the hip joint, adductor brevis, obturator externus and the anterior branch of the obturator nerve; laterally to psoas major and the medial circumflex femoral vessels; and medially to the lateral margin of adductor longus.

Vascular supply

The main arterial supply to pectineus is derived from the medial circumflex femoral artery, which enters the superficial surface of the muscle. There may be a branch from the (common) femoral more proximally, and a deep supply from the obturator artery.

Innervation

Pectineus is innervated by the femoral nerve, L2 and 3, and accessory obturator nerve, L3, when present. Occasionally it receives a branch from the obturator nerve. The muscle may be incompletely divided into dorsal and ventral layers, which are supplied respectively by the obturator and femoral (or rarely accessory obturator) nerves.

Actions

Pectineus adducts the thigh and flexes it on the pelvis.

Testing

The action of pectineus cannot be tested clinically in isolation.

Adductor canal

The adductor canal (Hunter’s canal; subsartorial canal) is a trough-shaped intermuscular tunnel occupying the distal two-thirds of the medial aspect of the thigh (Fig. 80.2). It starts at the apex of the femoral triangle and extends distally as far as the distal attachment of the tendon of adductor magnus. It is triangular in section, and is bounded anterolaterally by vastus medialis, posteromedially by adductor longus, and distal to adductor longus, by adductor magnus. Its anteromedial boundary (often referred to as the roof) is a strong and dense fascia that extends from the medial surface of vastus medialis to the medial edge of the adductors longus and magnus, overlapping in its stride, the femoral vessels in the adductor canal. This fascia, on account of being overlain by sartorius, is termed the subsartorial fascia.

The adductor canal contains the femoral artery and vein, the descending genicular and muscular branches of the femoral artery and their corresponding venous tributaries, the saphenous nerve, and the nerve to vastus medialis (until it enters its muscle). The femoral vessels pass from the adductor canal into the popliteal fossa via the adductor hiatus, an opening in the tendon of adductor magnus adjacent to the femoral shaft, two-thirds of the way down the adductor canal.

Posterior compartment

The posterior femoral muscles, biceps femoris, semitendinosus, and semimembranosus, are colloquially termed the ‘hamstrings’. They cross both hip and knee joints, and integrate extension at the hip with flexion at the knee. As the muscles span the back of the knee, they form the proximal lateral and medial margins of the popliteal fossa. The actions of these muscles and their clinical anatomy will be considered as a group after they have been described individually.

The muscles of the posterior compartment (see Figs 80.2, 80.22) receive their blood supply from the perforating branches of the profunda femoris, most importantly through the first perforator. This vessel has important anastomoses with the inferior gluteal artery (on or within semitendinosus) and with the medial circumflex femoral artery, while the third perforator anastomoses with the medial superior genicular artery within the short head of biceps. This anastomotic chain forms an important collateral arterial pathway when the femoral artery is blocked.

Semitendinosus

Attachments

Semitendinosus (see Fig. 80.2B), notable for the length of its tendon, lies posteromedial in the thigh. It arises from an inferomedial impression on the upper area of the ischial tuberosity (Fig. 80.5), by a tendon it shares with the long head of biceps femoris, and from an aponeurosis connecting the adjacent surfaces of the two muscles for 7.5 cm from their common origin. The belly is fusiform and ends a little below midthigh in a long, rounded tendon that runs on the posterior surface of semimembranosus. The tendon curves around the medial condyle of the tibia, passes over the medial collateral ligament of the knee joint (from which it is separated by the bursa of the pes anserinus), and inserts into the upper part of the medial surface of the tibia behind the attachment of sartorius and distal to that of gracilis (Fig. 80.24). At its termination it is united with the tendon of gracilis and gives off a prolongation to the deep fascia of the leg and to the medial head of gastrocnemius. A tendinous intersection is usually present near the midpoint of the muscle, which may also receive a muscular slip from the long head of biceps femoris. These connections with the medial head of gastrocnemius and biceps can cause difficulty when harvesting the tendon surgically for a graft.

Relations

Semitendinosus lies on semimembranosus throughout its length. The relations of the distal part of the muscle are described above and with the pes anserinus.

Vascular supply

The two main arteries of supply to semitendinosus are superior and inferior. The superior is derived from either the medial circumflex femoral artery or from the first perforating artery. The inferior and larger branch arises from the first perforator distal to the origin of the superior branch. There is an accessory supply at the attachments of the muscle: at the ischial attachment this is derived from the inferior gluteal artery, and at the tibial attachment from the medial inferior genicular artery.

Innervation

Semitendinosus is innervated by the sciatic nerve, L5, S1 and 2, through its tibial division.

Semimembranosus

Attachments

Semimembranosus (see Fig. 80.2B), so named because of the flattened form of its upper attachment, is posteromedial in the thigh. It arises by a long, flat tendon from a superolateral impression on the ischial tuberosity (Fig. 80.5). Inferomedially the tendinous fibres intermingle to some extent with those of biceps femoris and semitendinosus. The tendon receives, from the ischial tuberosity and ramus, two fibrous expansions that flank adductor magnus. It then broadens and descends deep to semitendinosus and the long head of biceps femoris. Muscle fibres arise from the tendon at about midthigh and converge to a second aponeurosis on the posterior aspect of the lower part of the muscle, which tapers to the heavy, rounded tendon of the distal attachment. The tendon divides at the level of the knee into five components. The main one is attached to a tubercle (sometimes called the tuberculum tendinis) on the posterior aspect of the medial tibial condyle. The others are: a series of slips to the medial margin of the tibia, immediately behind the medial collateral ligament; a thin fibrous expansion to the fascia over popliteus; a cord-like tendon to the inferior lip and adjacent part of the groove on the back of the medial tibial condyle, deep to the medial collateral ligament; and a strong expansion which passes obliquely upwards to the femoral intercondylar line and lateral femoral condyle and forms much of the oblique popliteal ligament of the knee joint.

Semimembranosus varies considerably in size, and may be absent. It may be double, and arise mainly from the sacrotuberous ligament. Slips to the femur or to adductor magnus may occur.

Relations

Semimembranosus overlaps the popliteal vessels and is itself partly overlapped by semitendinosus throughout its extent (see Fig. 80.2). Its deep surface lies on adductor magnus. The sciatic nerve lies laterally and surprisingly close to the surface. The distal end of the muscle partially overlies the medial head of gastrocnemius before passing anteromedially to it. An important bursa lies between the semimembranosus tendon and gastrocnemius, and often communicates with the knee joint and with a smaller bursa between the tendon and the posterior tibial margin.

Vascular supply

Semimembranosus is supplied from the perforating arteries, usually from all, though predominantly from the first. Sometimes the predominant artery arises from the fourth perforator. A branch of the femoral or popliteal artery supplies the distal part of the muscle, and there may be a contribution from the inferior gluteal artery at the proximal attachment.

Innervation

Semimembranosus is innervated by the sciatic nerve, L5, S1 and 2, through its tibial division.

Biceps femoris

Attachments

Biceps femoris (see Fig. 80.2) occupies a posterolateral position in the thigh. It has two proximal attachments. One, the long head, arises from an inferomedial impression on the upper area of the ischial tuberosity (Fig. 80.5), via a tendon which it shares with semitendinosus, and from the lower part of the sacrotuberous ligament. The other, the short head, arises from the lateral lip of the linea aspera, between adductor magnus and vastus lateralis. This attachment extends proximally almost to gluteus maximus and distally along the lateral supracondylar line to within 5 cm of the lateral femoral condyle, and from the lateral intermuscular septum. The long head forms a fusiform belly that descends laterally across the sciatic nerve. The fibres end in an aponeurosis which covers the posterior surface of the muscle. This aponeurosis receives on its deep surface the fibres of the short head, and gradually narrows to a tendon (the lateral hamstring). The main part of the tendon splits round the fibular collateral ligament and is attached to the head of the fibula. The remainder splits into three laminae. The intermediate lamina fuses with the fibular collateral ligament, while the others pass superficial and deep to the ligament to attach to the lateral condyle of the tibia.

The short head may be absent. Additional slips may arise from the ischial tuberosity, linea aspera, or medial supracondylar line.

Relations

Proximally biceps femoris is covered by gluteus maximus, but elsewhere it lies relatively superficially. Deep to it lie semimembranosus proximally, and the sciatic nerve, adductor magnus and the lateral head of gastrocnemius more distally. Semitendinosus and semimembranosus lie medially. The common fibular nerve descends along the medial border of the tendon and separates it distally from the lateral head of gastrocnemius. As a guide during surgery, it is safest to find a nerve proximally and dissect it free distally. The common fibular nerve is found emerging posterior to the biceps tendon, which is thus a useful guide to locating the nerve and thereby, to avoiding injury to the nerve. For example, when the lateral meniscus is sutured arthroscopically, care must be taken that all needle passages are anterior to biceps. The nerve is adherent to the biceps tendon: if part of the fibular head or the biceps attachment, usually with the insertion of the lateral collateral ligament, is avulsed, then the tendon will exert proximal traction on the nerve. This may contribute to common fibular nerve traction injury. Also, the abnormal position of the nerve may render it vulnerable to inadvertent injury during surgical exploration. A proximal fibular fracture may result in the nerve being trapped in the fracture line. A bursa may lie between the tendon and the fibular collateral ligament.

Vascular supply

The long head of biceps femoris is supplied by the first and second perforating arteries, with accessory supplies at the ischial attachment from the inferior gluteal and medial circumflex femoral arteries and in the distal quarter from the lateral superior genicular artery. The short head is supplied superiorly by the second or third perforating artery and inferiorly by the lateral superior genicular artery.

Innervation

Biceps femoris is innervated by the sciatic nerve, L5, S1 and 2; the long head through the tibial division and the short head through the common fibular division, which reflects the composite derivation from flexor and extensor musculature.

Actions of posterior femoral muscles

Acting from above, the posterior femoral muscles flex the knee. Acting from below, they extend the hip joint, pulling the trunk upright from a stooping posture against the influence of gravity, biceps being the main agent. When the knee is semi-flexed, biceps femoris can act as a lateral rotator and semimembranosus and semitendinosus as medial rotators of the lower leg on the thigh at the knee. When the hip is extended, biceps is a lateral rotator and semimembranosus and semitendinosus are medial rotators of the thigh. As is the case with quadriceps femoris, the adductors and gluteus maximus, the hamstrings are quiescent in easy symmetrical standing. However, any action that takes the centre of gravity in front of a transverse axis through the hip joints, e.g. forward reaching, forward sway at the ankle joints, or forward bending at the hips, is immediately accompanied by strong contraction of the hamstrings. (This is in marked contrast to gluteus maximus, which contracts only when there is a call for powerful extension at the hip joint.)

When the knee is flexed against resistance, the tendon of biceps can be felt lateral to the popliteal fossa. Medial to the fossa, the tendons of gracilis (which is the more medial) and semitendinosus stand out sharply. The semimembranosus tendon is just palpable in the interval between them (and also by deep pressure from a ‘pincer’ grip beyond their margins). There is some evidence that semimembranosus, semitendinosus and biceps femoris, although they cross both hip and knee joints, may produce movement at one of these joints without resisting antagonists at the other. Usually, however, each of these muscles contracts as a whole, and whether or not movement takes place at hip or knee is determined by other muscles which act as fixators of these joints.

Testing

The posterior femoral muscles are tested clinically by active knee flexion against resistance in the supine or prone position. In the prone position the individual hamstring tendons can be identified more easily.

When relaxed, these muscles show considerable variation in length: in some individuals the muscles are so short as to impose a serious limitation on flexion of the trunk at the hip joints when the knees are kept extended. Movements such as stooping must then be accomplished by flexing the vertebral column or squatting. Perhaps the need for more stress on the lumbar spine accounts for the occurrence of hamstring tightness in adolescents who develop spondylolysis. These muscles are prone to tearing, which may be related to the relative complexity of muscles that cross two joints, or to the fact that they are subject to large forces including eccentric contractions.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Iliac vessels and external iliac arteries and veins

The iliac vessels are described on page 1086, and the external iliac arteries and veins on pages 1089, and page 1090 respectively.

ARTERIES

Gluteal vessels

The superior and inferior gluteal arteries (Fig. 80.27) are described on pages 1087, 1089.

(From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)

Arteria comitans nervi ischiadici (artery to sciatic nerve)

The arteria comitans nervi ischiadici is a branch of the internal iliac artery, and runs on the surface of, or within, the sciatic nerve. It represents the primitive axial artery of the lower limb. The artery is usually a very small vessel; occasionally it persists as a large vessel, in which case the femoral artery is correspondingly reduced in size. The artery may participate in collateral circulatory pathways.

Femoral artery

The femoral artery (Figs 80.2, 80.3, 80.28, 80.29) is a continuation of the external iliac artery. It begins behind the inguinal ligament, midway between the anterior superior iliac spine and the pubic symphysis, descends along the anteromedial part of the thigh in the femoral triangle, enters and passes through the adductor (subsartorial) canal, and becomes the popliteal artery as it passes through an opening in adductor magnus near the junction of the middle and distal thirds of the thigh. Its first three or four centimetres are enclosed, with the femoral vein, in the femoral sheath. The femoral artery gives off several branches in the proximal thigh, including the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal and profunda femoris arteries. It gives off the descending genicular artery within the adductor canal. In clinical parlance, the part of the femoral artery proximal to the origin of profunda femoris is often termed the common femoral artery, while that distal to the origin of the profunda is termed the superficial femoral artery.

Fig. 80.29 The profunda femoris artery and its branches.

(From Sobotta 2006.)

Rarely, the femoral artery divides, distal to the origin of the profunda femoris artery, into two trunks that reunite near the adductor opening. It may be replaced by the inferior gluteal artery, accompanying the sciatic nerve to the popliteal fossa and representing a persistence of the original axial artery. The external iliac artery is then small, ending as the profunda femoris artery.

Relations

Anterior to the artery in the femoral triangle are the skin, superficial fascia, superficial inguinal lymph nodes, fascia lata, femoral sheath, superficial circumflex iliac vein (crossing in the superficial fascia) and the femoral branch of the genitofemoral nerve (which is at first lateral then anterior). Near the apex of the triangle, the medial femoral cutaneous nerve crosses in front of the artery from the lateral to the medial side. Posteriorly, the posterior wall of the femoral sheath separates the artery from the tendons of psoas, pectineus and adductor longus. The artery is separated from the hip joint by the tendon of psoas major, from pectineus by the femoral vein and profunda vessels, and from adductor longus by the femoral vein. Proximally, the nerve to pectineus passes medially behind the artery. The femoral nerve lies lateral to the artery, outside the femoral sheath. The femoral vein is medial to the artery in the proximal part of the triangle and becomes posterior distally at the apex.

Within the adductor canal, the artery is covered by skin, superficial and deep fasciae, sartorius and the fibrous roof (subsartorial fascia) of the canal. The saphenous nerve lies at first lateral, then anterior and finally medial to the artery. Adductor longus and adductor magnus are posterior, vastus medialis and its nerve are anterolateral, and the femoral vein is also posterior proximally, but it becomes lateral distally (Fig. 80.28).

Compression of the femoral artery is most effective just distal to the inguinal ligament, where it is superficial and separated from the bone (iliopubic ramus) only by the psoas tendon. For this reason arterial injury proximal to the inguinal ligament, such as laceration by a knife, cannot be controlled simply by compression. Gaining proximal control of bleeding involves major exposure of the more proximal arteries as a life-saving manoeuvre.

Branches

Superficial epigastric artery

The superficial epigastric artery arises anteriorly from the femoral artery approximately 1 cm distal to the inguinal ligament and traverses the cribriform fascia to ascend anterior to the ligament and run in the abdominal superficial fascia almost to the umbilicus. It supplies the superficial inguinal lymph nodes and superficial fascia and skin, and anastomoses with branches of the inferior epigastric artery and its contralateral fellow (Fig. 80.28).

Superficial circumflex iliac artery

The superficial circumflex iliac artery is the smallest superficial branch of the femoral artery and arises near or with the superficial epigastric artery. It usually emerges through the fascia lata, lateral to the saphenous opening, and turns laterally distal to the inguinal ligament towards the anterior superior iliac spine. It supplies the skin, superficial fascia and superficial inguinal lymph nodes, anastomosing with the deep circumflex iliac, superior gluteal and lateral circumflex femoral arteries.

The superficial circumflex iliac artery is the basis for the important axial-pattern pedicled groin skin flap. Free flaps based on the vessel may also be raised.

Superficial external pudendal artery

The superficial external pudendal artery arises medially from the femoral artery, close to the preceding branches. Emerging from the cribriform fascia, it passes medially, usually deep to the long saphenous vein, across the spermatic cord (or round ligament) to supply the lower abdominal, penile, scrotal or labial skin, and anastomoses with branches of the internal pudendal artery.

Deep external pudendal artery

The deep external pudendal artery passes medially across pectineus and anterior or posterior to adductor longus, covered by fascia lata which it pierces to supply the skin of the perineum and scrotum or labium majus. Its branches anastomose with the posterior scrotal or labial branches of the internal pudendal artery.

Muscular branches

These branches supply sartorius, vastus medialis and the adductors.

Profunda femoris

The profunda femoris artery (deep femoral artery) (Figs 80.2B, 80.22, 80.28, 80.29) is a large branch that arises laterally from the femoral artery about 3.5 cm distal to the inguinal ligament. At first lateral to the femoral artery, it spirals posterior to this and the femoral vein to reach the medial side of the femur. It passes between pectineus and adductor longus, then between the latter and adductor brevis, before it descends between adductor longus and adductor magnus. It pierces adductor magnus and anastomoses with the upper muscular branches of the popliteal artery. This terminal part is sometimes named the fourth perforating artery.

The profunda is the main supply to the adductor, extensor and flexor muscles, and also anastomoses with the internal and external iliac arteries above and with the popliteal artery below.

The origin of the profunda femoris is sometimes medial, or rarely posterior on the femoral artery; if the former, it may cross anterior to the femoral vein and then pass backwards around its medial side.

Relations

Posteriorly, in proximodistal order, lie iliacus, pectineus, adductor brevis and adductor magnus. Anteriorly, the femoral and profunda veins, and distally, adductor longus, separate the profunda femoris from the main femoral artery. Laterally vastus medialis separates the proximal part of the artery from the femur.

Branches

The profunda femoris artery gives off the lateral and medial circumflex arteries in the proximal thigh, and perforating and muscular branches more distally.

Lateral circumflex femoral artery

The lateral circumflex femoral artery (Figs 80.27, 80.29) is a laterally running branch given off near the root of the profunda. It passes between the divisions of the femoral nerve, posterior to sartorius and rectus femoris and divides into ascending, transverse and descending branches. The ascending branch ascends along the intertrochanteric line, under tensor fasciae latae, lateral to the hip joint. It anastomoses with the superior gluteal and deep circumflex iliac arteries, supplying the greater trochanter, and, with branches of the medial circumflex femoral, forms an anastomotic ring round the femoral neck, from which ring the femoral neck and head are supplied. The descending branch, sometimes direct from the profunda or the femoral, descends posterior to rectus femoris, along the anterior border of vastus lateralis, which it supplies: a long branch descends in vastus lateralis to the knee, anastomosing with the lateral superior genicular branch of the popliteal, accompanied by the nerve to vastus lateralis. The transverse branch, the smallest, passes laterally anterior to vastus intermedius and pierces vastus lateralis to wind round the femur, just distal to the greater trochanter. It anastomoses with the medial circumflex, inferior gluteal and first perforating arteries (cruciate anastomosis).

The ascending branch forms the pedicle of the tensor fasciae latae musculocutaneous flap. The descending branch supplies the anterolateral thigh fasciocutaneous flap, which is based on the fasciocutaneous perforators that arise from the descending branch.

The lateral circumflex femoral artery may arise from the femoral artery.

Medial circumflex femoral artery

The medial circumflex femoral artery (Figs 80.27, 80.29) usually originates from the posteromedial aspect of the profunda, but often originates from the femoral artery itself. It supplies the adductor muscles and curves medially round the femur between pectineus and psoas major and then obturator externus and adductor brevis, finally appearing between quadratus femoris and the upper border of adductor magnus, dividing into transverse and ascending branches. The transverse branch takes part in the cruciate anastomosis. The ascending branch ascends on the tendon of obturator externus, anterior to quadratus femoris, to the trochanteric fossa, where it anastomoses with branches of the gluteal and lateral circumflex femoral arteries. An acetabular branch at the proximal edge of adductor brevis enters the hip joint under the transverse acetabular ligament with one from the obturator artery. It supplies the fat in the fossa, and reaches the femoral head along its ligament. For details of the blood supply of the proximal end of the femur consult Crock (1996).

Perforating arteries

The perforating arteries (Fig. 80.22) perforate the femoral attachment of adductor magnus to reach the flexor aspect of the thigh. There are three perforating branches, and the terminal part of the profunda itself becomes the fourth perforator. They pass close to the linea aspera under small tendinous arches and give off muscular, cutaneous and anastomotic branches. Diminished, they pass deep to the short head of biceps femoris (the first usually through the attachment of gluteus maximus), traverse the lateral intermuscular septum and enter vastus lateralis. The first arises proximal to adductor brevis, the second anterior and the third distal to the muscle. The first perforating artery passes back between pectineus and adductor brevis (sometimes through the latter), pierces adductor magnus near the linea aspera to supply adductor brevis, adductor magnus, biceps femoris and gluteus maximus, and anastomoses with the inferior gluteal, medial and lateral circumflex femoral and second perforating arteries. The larger second perforating artery, often arising with the first, pierces the attachments of adductor brevis and magnus, divides into the ascending and descending branches supplying the posterior femoral muscles and anastomoses with the first and third perforating arteries. The femoral nutrient artery usually arises from it. When two nutrient arteries exist they usually arise from the first and third perforators. The third perforating artery starts distal to adductor brevis, pierces the attachment of adductor magnus and divides into branches to the posterior femoral muscles. It anastomoses proximally with the perforating arteries, and distally with the end of the profunda and muscular branches of the popliteal. The femoral nutrient artery may arise from it. Side branches of the diaphysial nutrient and other branches of the profunda provide subsidiary cortical arteries.

The perforating arteries form a double chain of anastomoses, initially in the adductor muscles and subsequently near the linea aspera.

Muscular branches

Numerous muscular branches arise from the profunda femoris artery. Some end in the adductors, and others pierce adductor magnus, supply the flexors and anastomose with the medial circumflex femoral artery and superior muscular branches of the popliteal artery. The profunda is thus the main supply to the femoral muscles.

Descending genicular artery

The descending genicular artery (see Fig. 82.1), the distal branch of the femoral artery, arises just proximal to the adductor opening and immediately supplies a saphenous branch. It then descends in vastus medialis, anterior to the tendon of adductor magnus, to the medial side of the knee, where it anastomoses with the medial superior genicular artery. Muscular branches supply vastus medialis and adductor magnus and give off articular branches that anastomose round the knee joint (Ch. 82). One articular branch crosses above the femoral patellar surface, forming an arch with the lateral superior genicular artery and supplying the knee joint. The saphenous branch (saphenous artery) emerges distally through the roof of the adductor canal to accompany the saphenous nerve to the medial side of the knee. It passes between sartorius and gracilis and supplies the skin of the proximomedial area of the leg, and anastomoses with the medial inferior genicular artery.

Arterial anastomoses around the hip

Anastomoses on the back of the thigh

An important chain of anastomoses extends on the back of the thigh from the gluteal region to the popliteal fossa. It is formed in proximodistal order by anastomoses between the gluteal arteries and terminals of the medial circumflex femoral artery; the circumflex femoral arteries and the first perforating artery; the perforating arteries themselves; and between the fourth perforating artery and the superior muscular branches of the popliteal artery (Fig. 80.17). The trochanteric and cruciate anastomoses are the proximal elements of this chain.

Trochanteric anastomosis

The trochanteric anastomosis lies near the trochanteric fossa of the femur and is an anastomosis between the ascending branch of the medial circumflex femoral artery and descending branches of the superior and inferior gluteal arteries (Fig. 80.17). The lateral circumflex femoral artery and the first perforating artery from the profunda may also contribute, creating an extracapsular 'arterial ring of the femoral neck' (Crock 1996). Branches from this ring, the retinacular vessels, pierce the capsule and ascend along the femoral neck to give the main blood supply to the head of the femur.

Cruciate anastomosis

The cruciate anastomosis lies at the level of the lesser trochanter, near the lower edge of the femoral attachment of quadratus femoris and is an anastomosis between the transverse branches of the medial and lateral circumflex femoral arteries, a descending branch of the inferior gluteal artery and an ascending branch from the first perforating artery.

Collateral circulation in proximal femoral artery occlusion

After occlusion of the femoral artery proximal to the origin of the profunda femoris artery, five main anastomotic channels are available. These are between branches of the superior and inferior gluteal arteries, the medial and lateral circumflex femoral arteries and the first perforating branch of the profunda femoris artery; the obturator branch of the internal iliac artery and the medial circumflex femoral artery; the internal pudendal branch of the internal iliac artery and the superficial and deep external pudendal branches of the femoral artery; a deep circumflex iliac branch of the external iliac artery, the lateral circumflex femoral branch of the profunda femoris artery and the superficial circumflex iliac branch of the femoral artery; the inferior gluteal branch of the internal iliac artery and perforating branches of the profunda femoris artery.

Perforator flaps in the hip and thigh

Gluteal region

The gluteal region of the lower limb has an average of 21 perforators which arise from three main source arteries, namely the superior and inferior gluteal and internal pudendal arteries. The flaps which are based on these perforators are used as free flaps for breast reconstruction and as local flaps for covering defects in the sacral and perineal region.

Hip and thigh region

The hip and thigh region has six source arteries and an average of 50 arterial perforators. The thigh can be divided into four areas: antero-medial; antero-lateral and trochanteric; postero-medial; postero-lateral. The perforators that supply the antero-medial thigh are derived from the femoral artery, and those for the antero-lateral thigh are derived from branches of the lateral circumflex femoral artery. Perforators that supply the skin over the posteromedial and posterolateral thigh regions are derived from the profunda femoris and the popliteal arteries. Skin flaps based on the superficial circumflex iliac, superficial external pudendal and superficial inferior epigastric arteries have been used as local flaps, tube pedicles and free tissue transfers. Other popular skin flaps are TFL (tensor-fasciae latae) perforator flaps, ALT (anterolateral thigh) and AMT (anteromedial thigh) flaps, gracilis perforator flap and posterior thigh flaps.

VEINS

Femoral vein

The femoral vein accompanies its artery, beginning at the adductor opening as the continuation of the popliteal vein, and ending posterior to the inguinal ligament as the external iliac vein (Figs 80.3, 80.28). The vein is posterolateral to the femoral artery in the distal adductor canal. More proximally in the canal, and in the distal femoral triangle (i.e. at its apex), the vein lies posterior to the artery and proximally, at the base of the triangle, the vein lies medial to the artery. The vein occupies the middle compartment of the femoral sheath, between the femoral artery and femoral canal; fat in the canal permits expansion of the vein.

The femoral vein has numerous muscular tributaries. The profunda femoris vein joins the femoral vein posteriorly 4–12 cm distal to the inguinal ligament, and the long saphenous vein then enters anteriorly. Veins accompanying the superficial epigastric, superficial circumflex iliac and external pudendal arteries join the long saphenous vein before it enters the saphenous opening. Lateral and medial circumflex femoral veins are usually tributaries of the femoral vein. There are usually four or five valves in the femoral vein: the two most constant are just distal to the entry of the profunda femoris vein and near the inguinal ligament.

Profunda femoris vein

The profunda femoris vein lies anterior to its artery, and receives tributaries corresponding to the branches of the artery. Through these tributaries it connects distally with the popliteal and proximally with the inferior gluteal veins. It sometimes drains the medial and lateral circumflex femoral veins and has a valve just before it empties into the femoral vein.

Long saphenous vein

The long saphenous vein (great saphenous vein) (see Fig. 79.9A), the longest vein in the body, starts distally as a continuation of the medial marginal vein of the foot, and ends in the femoral vein a short distance distal to the inguinal ligament. It ascends immediately anterior to the tibial malleolus, crosses the distal third of the medial surface of the tibia obliquely in an anteroposterior direction to reach its medial border, then ascends a little behind the border to the knee. Proximally it is posteromedial to the medial tibial and femoral condyles (lying the breadth of the subject's hand posterior to the medial edge of the patella), and then ascends the medial aspect of the thigh. It passes through the saphenous opening and finally opens into the femoral vein. The 'centre' of the opening is often said to be 2.5–3.5 cm inferolateral to the pubic tubercle, and the vein is then represented by a line drawn from this point to the femoral adductor tubercle. However, the saphenous opening varies greatly in size and disposition so that this 'centre' is not a reliable surface marking for the saphenofemoral junction.

In its course through the thigh the long saphenous vein is accompanied by branches of the medial femoral cutaneous nerve. At the knee the saphenous branch of the descending genicular artery (the saphenous artery) and, in the leg and foot, the saphenous nerve, are all anterior to the vein. The vein is often duplicated, especially distal to the knee. It has from 10 to 20 valves, which are more numerous in the leg than in the thigh. One is present just before the vein pierces the cribriform fascia, another at its junction with the femoral vein. In almost its entire extent the vein lies in superficial fascia, but it has many connections with the deep veins, especially in the leg.

Tributaries

At the ankle the long saphenous vein drains the sole by medial marginal veins. In the leg it often connects with the short saphenous vein and with deep veins via perforating veins. Just distal to the knee it usually receives three large tributaries: from the front of the leg, from the tibial malleolar region (connecting with some of the 'perforating' veins) and from the calf (communicating with the short saphenous vein). The tributary draining the tibial malleolar region is formed distally from a fine network or 'corona' of delicate veins over the medial malleolus, and then ascends the medial aspect of the calf as the posterior arch vein (Dodd & Cockett 1976). This vein was first illustrated by Leonardo da Vinci, whose name is sometimes given to it. It connects with posterior tibial venae comitantes by a series of perforating (communicating) veins. There are usually three, equally spaced between the medial malleolus and the midcalf. More than three such perforators are uncommon, and an arch vein perforator above midcalf is only very rarely found.

Above the posterior crural arch vein, perforating veins join the long saphenous vein or one of its main tributaries at two main sites. The first is at a level in the upper calf indicated by its name, the tibial tubercle perforator; the second is in the lower/intermediate third of the thigh where it perforates the deep fascial roof of the subsartorial canal to join the femoral vein.

In the thigh the long saphenous vein receives many tributaries. Some open independently, while others converge to form large named channels that frequently pass towards the basal half of the femoral triangle before joining the long saphenous near its termination. These may be grouped as follows: one or more large posteromedial tributaries, one or more large anterolateral tributaries, four or more peri-inguinal veins. The posteromedial vein of the thigh, large and sometimes double, drains a large superficial region indicated by its name: it has (as have the other tributaries) radiological and surgical significance. One of its lower radicles is often continuous with the short saphenous vein. The posteromedial vein is sometimes named the accessory saphenous vein, though some restrict the term accessory to a lower (more distal) posteromedial tributary when two (or more) are present. Another large vessel, the anterolateral vein of the thigh (anterior femoral cutaneous vein), usually commences from an anterior network of veins in the distal thigh and crosses the apex and distal half of the femoral triangle to reach the long saphenous vein. As the latter traverses the saphenous opening, it is joined by the superficial epigastric, superficial circumflex iliac and superficial external pudendal veins. Their mode of union varies. Superficial epigastric and circumflex iliac veins drain the inferior abdominal wall, the latter also receiving tributaries from the proximolateral region of the thigh. The superficial epigastric or the femoral vein may connect with the lateral thoracic veins by means of a thoracoepigastric vein that runs superficially on the anterolateral aspect of the trunk. This vein connects the inferior and superior caval areas of drainage and may be dilated and visible in cases of inferior caval obstruction. Superficial external pudendal veins drain part of the scrotum/labia; one is joined by the superficial dorsal vein of the penis/clitoris. The deep external pudendal veins join the long saphenous vein at the saphenous opening.

The long saphenous vein is often harvested for grafts used both in peripheral and coronary arterial surgery.

LYMPHATIC DRAINAGE

Superficial inguinal nodes

The superficial inguinal nodes form proximal and distal groups. The proximal group usually consists of five or six nodes just distal to the inguinal ligament. Its lateral members receive afferent vessels from the gluteal region and the adjoining infra-umbilical anterior abdominal wall. Medial members receive superficial vessels from the external genitalia (including the inferior vagina), inferior anal canal and perianal region, adjoining abdominal wall, umbilicus and uterine vessels accompanying the round ligament. The distal group usually consists of four or five nodes along the termination of the long saphenous vein. They receive all the superficial vessels of the lower limb, except those from the posterolateral calf. All superficial inguinal nodes drain to the external iliac nodes, some via the femoral canal and others anterior or lateral to the femoral vessels. Numerous vessels interconnect individual nodes.

Superficial inguinal nodes are frequently enlarged in disease or injury in their region of drainage. Thus the proximal inguinal nodes are almost invariably affected in malignant or infective disease of the prepuce, penis, labia majora, scrotum, perineum, anus and lower vagina, or in diseases affecting the skin and superficial structures in these regions, in the infra-umbilical part of the abdominal wall or in the gluteal region. The distal group is implicated only in disease or injury of the limb.

Deep inguinal nodes

The deep inguinal nodes vary from one to three, and are situated medial to the femoral vein. One lies just distal to the saphenofemoral junction, another in the femoral canal, and the most proximal node lies laterally in the femoral ring. The middle node is the most inconstant and the proximal node is often absent. All receive deep lymphatics that accompany the femoral vessels, lymph vessels from the glans penis or clitoris and a few efferents from the superficial inguinal nodes. Their own efferents traverse the femoral canal to the external iliac nodes.

INNERVATION

LUMBAR PLEXUS AND BRANCHES

The lumbar plexus is formed by the first three and most of the fourth, lumbar ventral rami (see p. 1078). The iliohypogastric, iliolingual and genitofemoral nerves are described on pages 1080.

Lateral cutaneous nerve of the thigh

The lateral cutaneous nerve of the thigh arises from the dorsal branches of the second and third lumbar ventral rami and emerges from the lateral border of psoas major, crossing the iliacus obliquely towards the anterior superior iliac spine. It supplies the parietal peritoneum in the iliac fossa. The right nerve passes posterolateral to the caecum, separated from it by the fascia iliaca and peritoneum; the left passes behind the lower part of the descending colon. Both pass behind or through the inguinal ligament, variably medial to the anterior superior iliac spine (commonly 1 cm) and anterior to or through sartorius into the thigh, where they divide into anterior and posterior branches. The anterior branch becomes superficial approximately 10cm distal to the anterior superior iliac spine and supplies the skin of the anterior and lateral thigh as far as the knee. It connects terminally with the cutaneous branches of the anterior division of the femoral nerve and the infrapatellar branch of the saphenous nerve, forming the peripatellar plexus. The posterior branch pierces the fascia lata higher than the anterior, and divides to supply the skin on the lateral surface from the greater trochanter to about midthigh. It may also supply the gluteal skin.

Lesions of the lateral cutaneous nerve of the thigh

The lateral cutaneous nerve of the thigh may become entrapped at three sites along its course: close to the vertebral column; within the abdominal cavity as the nerve travels across the pelvis; as it leaves the pelvis. This last site is where the nerve is most commonly damaged, and entrapment is thought to occur as the nerve passes through or deep to the inguinal ligament just medial to the anterior superior iliac spine. The angulation of the nerve as it crosses the iliac crest means that it is vulnerable to compression during movement, e.g. hip extension may increase angulation and tension on the nerve.

Injury produces an area of impaired sensation, often with pain and paraesthesia on the anterolateral aspect of the thigh (meralgia paraesthetica) in the distal cutaneous distribution of the nerve. This area does not extend across the midline anteriorly, it does not extend below the knee and it does not extend behind the hamstring tendons laterally. Symptoms may be exacerbated when wearing tight belts or tight-waisted clothes or as a result of a recent weight gain or pregnancy. Exceptionally the posterior branch of the lateral cutaneous nerve of the thigh, which supplies a thin strip from the greater trochanter of the femur down about two-thirds of the way to the knee, may be affected separately. This branch leaves the main trunk of the nerve, usually distal to the inguinal ligament, and it then turns laterally to pierce tensor fasciae latae, where it may become entrapped.

Femoral nerve

The femoral nerve is the largest branch of the lumbar plexus and arises from the dorsal branches (posterior divisions) of the second to fourth lumbar ventral rami (Fig. 80.30). It descends through psoas major, emerging low on its lateral border, and then passes between psoas and iliacus, deep to the iliac fascia. Passing behind the inguinal ligament into the thigh, it is split into anterior and posterior divisions by the lateral circumflex femoral artery. Behind the inguinal ligament it is separated from the femoral artery by part of psoas major. In the abdomen the nerve supplies small branches to iliacus and pectineus and a branch to the proximal part of the femoral artery; the latter branch sometimes arises in the thigh.

Fig. 80.30 The nerves of the left thigh: anterior aspect.

(From Sobotta 2006.)

Nerve to pectineus

The nerve to pectineus branches from the medial side of the femoral nerve near the inguinal ligament. It passes behind the femoral sheath and enters the anterior aspect of the muscle.

Anterior division of the femoral nerve

The anterior division of the femoral nerve supplies intermediate and medial cutaneous nerves of the thigh and branches to sartorius.

Medial cutaneous nerve of the thigh

The medial cutaneous nerve of the thigh is at first lateral to the femoral artery. It crosses anterior to the artery at the apex of the femoral triangle, and divides into anterior and posterior branches. Before doing so, it sends a few rami through the fascia lata to supply the skin of the medial side of the thigh, near the long saphenous vein: one ramus emerges via the saphenous opening, another becomes subcutaneous about midthigh. The anterior branch descends on sartorius, perforates the fascia lata beyond midthigh, and divides into a branch which supplies the skin as low as the medial side of the knee, and another which runs lateral to the former and connects with the infrapatellar branch of the saphenous nerve. The posterior branch descends along the posterior border of sartorius to the knee, pierces the fascia lata, connects with the saphenous nerve, and gives off several cutaneous rami, some as far as the medial side of the leg. The nerve contributes to the subsartorial plexus (see below).

Intermediate cutaneous nerve of the thigh

The intermediate cutaneous nerve of the thigh usually pierces the fascia lata 8 cm below the inguinal ligament, either as two branches or as one trunk that quickly divides into two. These descend on the front of the thigh, supplying the skin as far as the knee and ending in the peripatellar plexus. The lateral branch of the intermediate cutaneous nerve communicates with the femoral branch of the genitofemoral nerve, frequently piercing sartorius and sometimes supplying it.

Nerve to sartorius

The main nerve to sartorius arises from the femoral nerve in common with the intermediate cutaneous nerve of the thigh.

Posterior division of the femoral nerve

The branches of the posterior division of the femoral nerve are the saphenous nerve and branches to quadriceps femoris and the knee joint.

Saphenous nerve

See page 1409.

Muscular branches

The muscular branches of the posterior division of the femoral nerve supply quadriceps femoris. A branch to rectus femoris enters its proximal posterior surface and also supplies the hip joint. A larger branch to vastus lateralis forms a neurovascular bundle with the descending branch of the lateral circumflex femoral artery in its distal part and also supplies the knee joint. A branch to vastus medialis descends through the proximal part of the adductor canal, lateral to the saphenous nerve and femoral vessels, and enters the muscle at about its midpoint, sending a long articular filament distally along the muscle to the knee. Two or three branches to vastus intermedius enter its anterior surface about midthigh; a small branch from one of these descends through the muscle to supply articularis genu and the knee joint.

Vascular branches

Vascular branches of the femoral nerve supply the femoral artery and its branches.

Lesions of the femoral nerve

The main trunk of the femoral nerve is not subject to an entrapment neuropathy, but it may be compressed by retroperitoneal tumours or retroperitoneal haemorrhage in patients on anticoagulants or with a bleeding diathesis. A localized lesion of the femoral nerve may occur in diabetes mellitus (one of the forms of diabetic amyotrophy). The most striking feature of femoral neuropathy is wasting and weakness of quadriceps femoris, which results in considerable difficulty in walking and a tendency for the leg to collapse. Pain and paraesthesia may occur on the anterior and medial aspect of the thigh, extending down the medial aspect of the leg in the distribution of the saphenous branch of the femoral nerve.

Obturator nerve

The obturator nerve arises from the ventral branches of the second to fourth lumbar ventral rami. The branch from the third is the largest while that from the second is often very small. The nerve descends in psoas major, emerging from its medial border at the pelvic brim to pass behind the common iliac vessels and lateral to the internal iliac vessels. It then descends forwards along the lateral wall of the lesser pelvis on obturator internus, anterosuperior to the obturator vessels, to the obturator foramen, entering the thigh by its upper part. Near the foramen it divides into anterior and posterior branches, separated at first by part of obturator externus and lower down by adductor brevis.

Anterior branch

The anterior branch (Fig. 80.30) leaves the pelvis anterior to obturator externus, descending in front of adductor brevis, behind pectineus and adductor longus. At the lower border of adductor longus it communicates with the medial cutaneous and saphenous branches of the femoral nerve, to form a subsartorial plexus that supplies the skin on the medial side of the thigh (see below). It descends on, and supplies, the femoral artery. Near the obturator foramen the anterior branch supplies the hip joint. Behind pectineus it supplies adductor longus, gracilis, usually adductor brevis and often pectineus, and connects with the accessory obturator nerve (when this nerve is present). Occasionally the communicating branch to the femoral medial cutaneous and saphenous branches continues as a cutaneous branch to the thigh and leg. When this occurs, the nerve emerges from behind the distal border of adductor longus to descend along the posterior margin of sartorius to the knee, where it pierces the deep fascia and connects with the saphenous nerve to supply the skin halfway down the medial side of the leg.

Subsartorial nerve plexus

The medial cutaneous nerve of the thigh forms a subsartorial plexus with branches of the saphenous and obturator nerves, deep to the fascia lata, at the lower border of adductor longus. When the communicating branch of the obturator nerve is large and reaches the leg, the posterior branch of the medial cutaneous nerve is small, and ends in the plexus from which it gives rise to a few cutaneous filaments.

Posterior branch

The posterior branch pierces obturator externus anteriorly, supplies it and passes behind adductor brevis to the front of adductor magnus, dividing into branches to this and adductor brevis when the latter is not supplied by the anterior division. It usually sends an articular filament to the knee joint which either perforates adductor magnus distally or traverses its opening with the femoral artery to enter the popliteal fossa. Within the fossa the nerve descends on the popliteal artery to the back of the knee, pierces its oblique posterior ligament and supplies the articular capsule. It gives filaments to the popliteal artery.

Lesions of the obturator nerve

Isolated lesions of the obturator nerve are extremely rare, but may occasionally occur as a result of direct trauma (sometimes during parturition) or in anterior dislocations of the hip. The nerve may also be damaged by a rare obturator hernia, or be involved together with the femoral nerve in retroperitoneal lesions that occur close to the origins of the lumbar plexus. A nerve entrapment syndrome causing chronic medial thigh pain is described in athletes with large adductor muscles.

Accessory obturator nerve

Occasionally present (10%), the accessory obturator nerve is small and arises from the ventral branches of the third and fourth lumbar ventral rami. It descends along the medial border of psoas major, crosses the superior pubic ramus behind pectineus and divides into branches: one branch enters the deep surface of pectineus, another supplies the hip joint, and a third connects with the anterior branch of the obturator nerve. Sometimes the accessory obturator nerve is very small and only supplies pectineus. Any branch may be absent and others may occur: an additional branch sometimes supplies adductor longus.

SACRAL PLEXUS AND BRANCHES

The branches of the sacral plexus (see Fig. 79.11) are:

	Ventral divisions	**Dorsal divisions**
To quadratus femoris and gemellus inferior	L4, 5, S1	
To obturator internus and gemellus superior	L5, S1, 2	
To piriformis		S(1), 2
Superior gluteal		L4, 5, S1
Inferior gluteal		L5, S1, 2
Posterior femoral cutaneous	S2, 3	S1, 2
Tibial (sciatic)	L4, 5, S1, 2, 3	
Common fibular (sciatic)		L4, 5, S1, 2
Perforating cutaneous		S2, 3
Pudendal	S2, 3, 4	
To levator ani, coccygeus and sphincter ani externus	S4	
Pelvic splanchnic	S2, 3, (4).	

Sciatic nerve

The sciatic nerve is 2 cm wide at its origin and is the thickest nerve in the body. It leaves the pelvis via the greater sciatic foramen below piriformis and descends between the greater trochanter and ischial tuberosity, along the back of the thigh, dividing into the tibial and common fibular nerves at a varying level proximal to the knee. Superiorly it lies deep to gluteus maximus, resting first on the posterior ischial surface with the nerve to quadratus femoris between them. It then crosses posterior to obturator internus, the gemelli and quadratus femoris, separated by the latter from obturator externus and the hip joint. It is accompanied medially by the posterior femoral cutaneous nerve and the inferior gluteal artery. More distally it lies behind adductor magnus and is crossed posteriorly by the long head of biceps femoris. It corresponds to a line drawn from just medial to the midpoint between the ischial tuberosity and greater trochanter to the apex of the popliteal fossa.

Articular branches arise proximally to supply the hip joint through its posterior capsule; these are sometimes derived directly from the sacral plexus. Muscular branches are distributed to biceps femoris, semitendinosus, semimembranosus and the ischial part of adductor magnus.

The point of division of the sciatic nerve into its major components (tibial and common fibular) is very variable. The common site is at the junction of the middle and lower thirds of the thigh, near the apex of the popliteal fossa, but the division may occur at any level above this point, and rarely may occur below it. It is not uncommon for the major components to leave the sacral plexus separately, in which case the common fibular component usually passes through piriformis at the greater sciatic notch while the tibial component passes below the muscle.

Lesions of the sciatic nerve

The sciatic nerve supplies the knee flexors and all the muscles below the knee, which means that a complete palsy of the sciatic nerve results in a flail foot and severe difficulty in walking. Fortunately complete sciatic nerve palsy is very rare. The nerve is vulnerable in posterior dislocation of the hip. As it leaves the pelvis it passes either behind piriformis or sometimes through the muscle and at that point it may very rarely become entrapped or tethered: the piriformis syndrome is a controversial condition in which an anomalous relationship between piriformis and the sciatic nerve is thought to cause pain in the buttocks and along the course of the sciatic nerve. External compression over the buttock, e.g. in patients who lie immobile on a hard surface for a considerable length of time, can injure the nerve. However, the most common cause of serious sciatic nerve injury (and of the resulting major medicolegal claims) is iatrogenic. The nerve may be damaged in misplaced therapeutic injections into gluteus maximus (Ch. 79). Sciatic nerve palsy occurs after total hip replacement or similar surgery in 1% of cases, and may be caused by sharp injury, burning from bone cement, traction from instruments, manipulation of the hip, inadvertent lengthening of the femur, or haematoma surrounding the nerve. For some reason, possibly anatomical, the common fibular component of the sciatic nerve is more usually affected: the patient has a foot drop and a high stepping gait.

Inferior gluteal nerve

The inferior gluteal nerve arises from the dorsal branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, and divides into branches that enter the deep surface of gluteus maximus.

Superior gluteal nerve

The superior gluteal nerve arises from the dorsal branches of the fourth and fifth lumbar and first sacral ventral rami. Accompanied by the superior gluteal vessels, the nerve leaves the pelvis via the greater sciatic foramen above piriformis, and divides into superior and inferior branches. The superior branch accompanies the upper branch of the deep division of the superior gluteal artery to supply gluteus medius and occasionally gluteus minimus. The inferior branch runs with the lower ramus of the deep division of the superior gluteal artery across gluteus minimus, supplies the glutei medius and minimus and ends in tensor fasciae latae.

Pudendal nerve

See Fig. 62.15 and page 1081.

Perforating cutaneous nerve

The perforating cutaneous nerve usually arises from the posterior aspects of the second and third sacral ventral spinal rami. It pierces the sacrotuberous ligament, curves round the inferior border of gluteus maximus and supplies the skin over the inferomedial aspect of this muscle. The nerve may arise from the pudendal nerve or it may be absent, in which case it may be replaced either by a branch from the posterior femoral cutaneous nerve or from the third and fourth, or fourth and fifth, sacral ventral rami.

Nerve to quadratus femoris and gemellus inferior

The nerve to quadratus femoris and gemellus inferior arises from the ventral branches of the fourth lumbar to the first sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, descends on the ischium deep to the sciatic nerve, the gemelli and the tendon of obturator internus, and supplies gemellus inferior, quadratus femoris and the hip joint.

Nerve to obturator internus and gemellus superior

The nerve to obturator internus and gemellus superior arises from the ventral branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, supplies a branch to the upper posterior surface of gemellus superior, crosses the ischial spine lateral to the internal pudendal vessels, re-enters the pelvis via the lesser sciatic foramen, and enters the pelvic surface of obturator internus.

Posterior cutaneous nerve of the thigh

The posterior cutaneous nerve of the thigh arises from the dorsal branches of the first and second, and the ventral branches of the second and third sacral rami. It leaves the pelvis via the greater sciatic foramen below piriformis and descends under gluteus maximus with the inferior gluteal vessels, lying posterior or medial to the sciatic nerve. It descends in the back of the thigh superficial to the long head of biceps femoris, deep to the fascia lata. It pierces the deep fascia behind the knee and accompanies the short saphenous vein to midcalf, its terminal twigs connecting with the sural nerve. Its branches are all cutaneous and are distributed to the gluteal region, perineum and the flexor aspect of the thigh and leg.

Three or four gluteal branches curl round the lower border of gluteus maximus to supply the skin over the inferolateral portion of the muscle. The perineal branch supplies the superomedial skin in the thigh, curves forwards across the hamstrings below the ischial tuberosity, pierces the fascia lata and then runs in the superficial perineal fascia to the scrotal or labial skin. It communicates with the inferior rectal and posterior scrotal or labial branches of the perineal nerve, and gives numerous branches to the skin of the back and medial side of the thigh, the popliteal fossa and the proximal part of the back of the leg.

Nerve to piriformis

The nerve to piriformis usually arises from the dorsal branches of the first and second sacral ventral rami (sometimes only the second) and enters the anterior surface of piriformis.

Visceral and pelvic muscular branches of sacral plexus

Visceral branches of the sacral plexus are described on page 1092. For pelvic muscular branches, see page 1083.

ARTICULAR SURFACES

The femoral head articulates with the cup-shaped (cotyloid) acetabulum, its centre lying a little below the middle third of the inguinal ligament. (The profile of the anterior margin of the joint is parallel to the middle third of the inguinal ligament.) The articular surfaces are reciprocally curved but neither coextensive nor completely congruent (Fig. 81.2; see Figs 80.4, 80.15). The close-packed position of the hip joint is one of full extension, with slight abduction and medial rotation. As in the shoulder joint, the surfaces are considered ovoid or spheroidal rather than spherical, but this view is controversial. Evidence appears to suggest that the articular surface on the femoral head is a spheroidal, or slightly ovoid, surface in youth but that it tends to become almost spherical with advancing age. The femoral head is covered by articular cartilage, except over the rough pit where the ligamentum teres is attached. In front the cartilage extends laterally over a small area on the adjoining neck. Articular cartilage is, generally, thicker centrally than at the periphery. Cartilage thickness is maximal anterosuperiorly in the acetabulum and anterolaterally on the femoral head, the two areas that correspond to the principal load-bearing areas within the joint The acetabular articular surface, the lunate surface, is an incomplete ring, broadest anterosuperiorly where the pressure of body weight falls in the erect posture, and narrowest in its pubic region. It is deficient inferiorly opposite the acetabular notch. The lunate surface is covered by articular cartilage, which is thickest where the surface is broadest. The acetabular fossa, the central non-articular area in the floor of the acetabulum, is devoid of cartilage but contains fibroelastic fat largely covered by synovial membrane. The acetabular labrum, a fibrocartilaginous rim attached to the acetabular margin, serves to deepen the acetabulum and bridges the acetabular notch by attaching to the peripheral edge of the transverse acetabular ligament. The labrum is triangular in section; it is attached by its base to the acetabular margin and its acute free edge projects beyond the acetabular margin. The diameter of the acetabular cavity is constricted by the labral rim which embraces the femoral head, maintaining joint stability both as a static restraint and by providing proprioceptive information.

FIBROUS CAPSULE

The capsule is strong and dense. It is attached above to the acetabular margin 5–6 mm medial to the labral attachment, in front to the outer labral aspect and, near the acetabular notch, to the transverse acetabular ligament and the adjacent rim of the obturator foramen. From its acetabular attachment it extends laterally to surround the femoral head and neck, and is attached anteriorly to the intertrochanteric line, superiorly to the base of the femoral neck, posteriorly 1 cm superomedial to the intertrochanteric crest, and inferiorly to the femoral neck near the lesser trochanter. Anteriorly many fibres ascend along the neck as longitudinal retinacula, containing blood vessels for both the femoral head and neck. The capsule is thicker anterosuperiorly, where maximal stress occurs, particularly in standing. Posteroinferiorly it is relatively thin and loosely attached. It has two sets of fibres, circular and longitudinal. The circular fibres (zona orbicularis) are internal and form a collar round the femoral neck; although partly blended with the pubofemoral and ischiofemoral ligaments, these fibres are not directly attached to bone. Externally, longitudinal fibres are most numerous in the anterosuperior region, where they are reinforced by the iliofemoral ligament. The capsule is also strengthened inferiorly by the pubofemoral ligament, and posteriorly by the ischiofemoral ligament. Externally it is rough, covered by muscles and tendons and separated anteriorly from psoas major and iliacus by a bursa (see below). The capsular attachment to the femur lies well distal to the growth plate of the femoral head both anteriorly and posteriorly. Thus the upper femoral epiphysis is entirely intracapsular. The capsular attachment intersects the growth plate of the greater trochanter on the upper surface of the base of the neck (see Fig. 80.18).

Relations

The joint capsule is surrounded by muscles (Fig. 81.4). Anteriorly, lateral fibres of pectineus separate it from the femoral vein. Lateral to this the tendon of psoas major, with iliacus lateral to it, descends across it, partly separated from the capsule by a bursa. The femoral artery is anterior to the tendon of psoas major, and the femoral nerve lies deep in a groove between the tendon and iliacus. More laterally the straight head of rectus femoris crosses the joint with a deep layer of the fascial iliotibial tract, which blends with the capsule under the lateral border of the muscle. Superiorly, the reflected head of rectus femoris contacts the capsule medially, while gluteus minimus covers it laterally, being closely adherent. Inferiorly, medial fibres of pectineus adjoin the capsule and, more posteriorly, obturator externus spirals obliquely to its posterior aspect. Posteroinferiorly, the capsule is covered by the tendon of obturator externus, separating it from quadratus femoris and accompanied by an ascending branch of the medial circumflex femoral artery. Above this the tendon of obturator internus and the gemelli contact the joint capsule, separating it from the sciatic nerve. The nerve to quadratus femoris is deep to the obturator internus tendon, and descends medially on the capsule. Above this, the posterior surface of the joint is crossed by piriformis.

LIGAMENTS

The ligaments of the hip joint (Fig. 81.3) are the iliofemoral, pubofemoral, ischiofemoral and transverse acetabular ligaments and the ligamentum teres. As the hip moves so the capsular ligaments, as capsular thickenings, wind and unwind, tightening around the hip, affecting stability, excursion and joint capacity. Joint capacity is maximal when the hip is held in a partially flexed and abducted position: a patient with an effusion in the hip joint is therefore most comfortable when the joint is held in a position of flexion and abduction. See Fuss & Bacher (1991) for details.

Iliofemoral ligament

The iliofemoral ligament is very strong and shaped like an inverted Y, lying anteriorly and intimately blended with the capsule. Its apex is attached between the anterior inferior iliac spine and acetabular rim, its base to the intertrochanteric line. Fuss & Bacher describe a relatively weaker central portion, the greater iliofemoral ligament, with thicker and stronger marginal portions which they refer to as the lateral and medial iliofemoral ligaments. The obliquely disposed lateral ligament is attached to a tubercle at the superolateral end of the intertrochanteric line, while the vertically oriented medial ligament reaches the inferomedial end of the line.

Pubofemoral ligament

The pubofemoral ligament is triangular, its base attaching to the iliopubic eminence, superior pubic ramus, obturator crest and obturator membrane. It blends distally with the capsule and deep surface of the medial iliofemoral ligament. Fuss & Bacher describe this ligament as consisting of multiple crura.

Ischiofemoral ligament

The ischiofemoral ligament thickens the back of the capsule and consists of three distinct parts. The central part, the superior ischiofemoral ligament, spirals superolaterally from the ischium, where it is attached posteroinferior to the acetabulum, behind the femoral neck to attach to the greater trochanter deep to the iliofemoral ligament. Some fibres blend with the zona orbicularis. Lateral and medial inferior ischiofemoral ligaments embrace the posterior circumference of the femoral neck.

Transverse acetabular ligament

The transverse acetabular ligament (see Fig. 80.4) is continuous peripherally with the labrum but does not, itself, possess any cartilage cells. Its strong, flat fibres cross the acetabular notch forming a foramen through which vessels and nerves enter the joint.

Ligamentum teres (ligament of the head of the femur)

The ligamentum teres (Fig. 81.5) is a triangular and somewhat flattened band. Its apex is attached anterosuperiorly in the fovea on the femoral head and its base is attached principally to both edges of the acetabular notch, between which it blends with the transverse ligament. It also receives weaker contributions from the margins of the acetabular fossa. The ligamentum teres is ensheathed by synovial membrane, and varies in strength. Occasionally the synovial sheath exists by itself in the absence of the ligament; rarely both ligament and sheath are absent. The ligament appears to become tense when the hip joint is semi-flexed and adducted, and appears to relax when the joint is abducted.

SYNOVIAL MEMBRANE

Starting from the femoral articular margin, the synovial membrane covers the intracapsular part of the femoral neck, then passes to the internal surface of the capsule to cover the acetabular labrum, ligamentum teres and fat in the acetabular fossa. It is thin on the deep surface of the iliofemoral ligament where it is compressed against the femoral head and sometimes is even absent here.

BURSAE

The hip joint may communicate with the subtendinous iliac (psoas) bursa through a circular aperture between the pubofemoral ligament and the vertical band of the iliofemoral ligament. More distant bursae are associated with the tendons of attachment of glutei medius and minimus at the greater trochanter, and between gluteus maximus and vastus lateralis.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Articular arteries are branches from the obturator, medial circumflex femoral, and superior and inferior gluteal arteries, with corresponding venous drainage. They form the cruciate and trochanteric anastomoses (Ch. 80). Lymphatics from the anterior aspect of the hip joint drain to the deep inguinal nodes, while those from the medial and posterior aspects run with the obturator and gluteal arteries respectively to reach the internal iliac nodes.

INNERVATION

The nerve supply to the hip is from the femoral nerve or its muscular branches, the obturator and accessory obturator nerves, the nerve to quadratus femoris and the superior gluteal nerve.

Hip and groin pain

Pain in the hip and groin may be due to any of a number of possible causes. True hip joint pain is usually felt deep in the crease of the groin. Pain over the lateral aspect of the hip usually suggests a local problem such as trochanteric bursitis. Pain in the buttock is only occasionally from the hip joint: most frequently it is referred from the lumbosacral spine or may be caused by vascular claudication pain. Pain in the groin may be due to inguinal or femoral hernias (see Ch. 61). In the younger age group groin pain afflicts those engaged in sport, especially running ball sports. Here the pain is sometimes due to a hernia but more commonly related to adductor tendinitis secondary to acute or chronic overload of the adductor longus tendon. Another common problem is attritional chronic overload of the anterior abdominal wall at its attachments to the pubis and inguinal ligament, or of external oblique at the external inguinal ring. Rarely problems may occur at the symphysis pubis.

FACTORS MAINTAINING STABILITY

The hip joint is very stable. The femoral head is closely fitted to the acetabulum in an area exceeding half a sphere, and is embraced closely by the acetabular labrum, which restrains it in the socket. In addition a ‘vacuum effect’ is present. The thick capsule is reinforced by the three major ligaments, of which the iliofemoral is the strongest, and is progressively tightened when the femur extends to the line of the trunk. The pubofemoral and ischiofemoral ligaments also tighten and, as the joint approaches the close packed position, resistance to an extending torque increases rapidly. The transverse ligament and the ligament of the head also contribute to stability. Only slight separation of the articular surfaces can be achieved by strong traction on the joint, and to aid insertion of an arthroscope, a needle is first inserted into the joint to eliminate the suction effect; with traction, the joint will then open sufficiently. Traumatic dislocation usually occurs only when the joint is subjected to extreme force.

BIOMECHANICS OF THE HIP JOINT

The transition from quadrapedal to bipedal gait was a considerable biomechanical milestone in the evolution of *Homo sapiens*. The biomechanical features of the human lower limb, whose function is primarily to allow stance and bipedal propulsion, are very different from those of the quadraped lower limb, and these differences are reflected in the anatomy and biomechanics of the human hip, knee, ankle and foot joints.

The acetabulum and femoral head form a multiaxial spheroidal (‘ball and socket’) joint, which allows relatively unhindered motion in three degrees of freedom, i.e. flexion/extension, abduction/adduction, medial (internal) and lateral (external) rotation. This articulation is innately limited in its capacity for translational motion in anteroposterior, transverse and vertical planes.

FEMUR

The femur is essentially a tubular structure with distortions that consist of bows and twists. The most notable is the anterior bow in its mid-portion, where the radius of curvature is relatively constant along the length of the femoral shaft. In the coronal plane, the femoral neck is inclined obliquely to the shaft at an angle of 135° (range 120–145°; Fig. 81.6). Although the neck/shaft angle and neck length are variable, the centre of the neck in the coronal plane is at the level of the apex of the greater trochanter. In the axial plane the femoral neck is anteverted, i.e. rotated anteriorly relative to the posterior surfaces of the femoral condyles: in the adult, this angle is 10–15º (Fig. 81.7). The degree of anteversion affects many aspects of lower limb biomechanics, including the abductor moment arm (the perpendicular distance from the centre of rotation of the femur to the line of action of the resultant abductor muscle force); patellar tracking (the motion of the patella relative to the femur or femoral groove on knee flexion and extension); foot orientation.

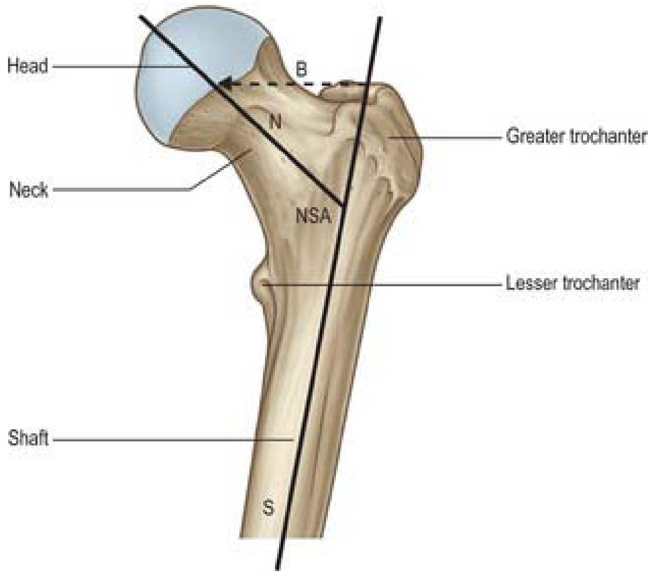

Fig. 81.6 The angle (NSA) between the long axis of the femoral shaft (S) and the axis of the femoral neck (N) is on average 135° (range 125–140°). In addition, in most hips, a line perpendicular to S from the tip of the greater trochanter (B) passes through the centre of the femoral head. This

approximation can be utlilized in judging the position of the femoral osteotomy in hip arthroplasty.

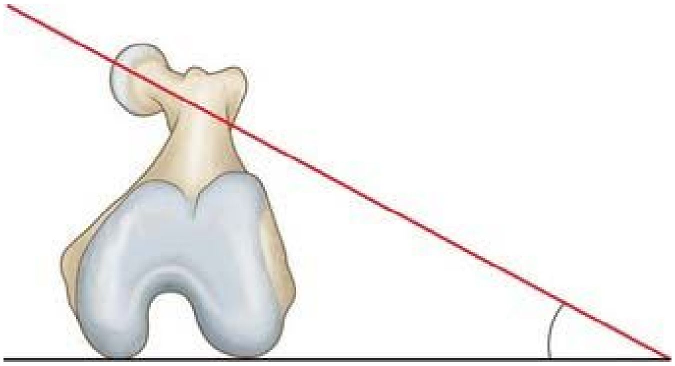

Fig. 81.7 The femoral anteversion angle is the angle subtended between the femoral neck and a line touching the posterior borders of the femoral condyles in the axial plane. This is 10–15° in the adult (greater in adult females than in males and children).

ACETABULUM

The acetabulum consists of the confluence of the ilium, ischium and pubis at the triradiate cartilage. By itself, the acetabulum covers an area slightly less than a hemisphere: it is deepened by the acetabular labrum. The degree of acetabular anteversion in the erect position is 14° (men) and 19° (women). In the coronal plane, the acetabular axis is inclined approximately 45° from the horizontal.

MOVEMENTS

When femoral movements are considered in relation to the articular surfaces, the length and angulation of the neck in relation to the shaft must be remembered. When the thigh is flexed or extended, the femoral head ‘spins’ in the acetabulum on an approximately transverse axis. Conversely, the acetabula rotate around similar axes in flexion and extension of the trunk on stationary femoral heads.

With the foot stationary on the ground, medial and lateral femoral rotation occur around a vertical axis through the centre of the femoral head and medial condyle. This axial medial rotation is the inevitable conjunct rotation that accompanies terminal extension of the knee and is often referred to as ‘screw-home’. The reverse occurs in initial flexion at the knee joint. The ‘screw-home’ phenomenon allows achievement of a ‘close packed position’ for the tibiofemoral joint, so aiding stability in the extended knee. The relationship of this axis to the whole femur (which has an angulated neck and oblique shaft) means that the medial condyle moves very little on the medial tibial condyle during medial rotation, while the lateral condyle moves forward on its tibial surface, and the greater trochanter moves simultaneously in a forward arc: converse movements occur during lateral rotation. With the foot either free or in loose contact with the ground, medial and lateral adjunct rotation of the whole lower limb occur around variable axes, all of which pass through the femoral head and any part of the foot. Conversely, with one foot stationary and the other free, the whole trunk may rotate on one femoral head, as in cross-kicking. Abduction and adduction occur about an anteroposterior axis through the femoral head, but since the latter is not strictly spherical, the axis is not a fixed one. Some kinesiologists refer to a mechanical axis coincident with the topographical long axis of the femoral neck, impinging on the approximate centre of the articular surface of the head, making extension and flexion of the thigh relatively pure ‘spins’ at the hip joint and most effective in tightening or relaxing the capsular ligaments. All other movements are regarded as pure or impure swings. While this permits analysis closer to actual articular function than a cardinal triaxial system related arbitrarily to the ‘anatomical’ position, the mechanical axis is itself regarded (incorrectly) by some as dynamic because forms of apparent dynamic ‘spin’ may occur in many positions. This view stems from an imprecise definition of the varieties of axes employed in arthrokinematics. The mechanical axis is not dynamic relative to the femur. It is stationary during pure spins, and moves relative to its coarticular surface in chordal or arcuate paths during pure or impure swings respectively.

Simple flexion is possible to 110–120° from the vertical; extension beyond the vertical is limited (perhaps 10–20°). Both movements are augmented by adjustments of the spinal column and pelvis, flexion of the knee and concomitant medial or lateral hip rotation. For example, knee flexion (lessening tension in the posterior femoral muscles) increases hip flexion to 120°; the thigh can be drawn passively to the trunk, though with some spinal flexion. Extension in walking and running is increased by forward inclination of the body, pelvic tilting and rotation and lateral rotation of the hip (Joseph 1975). Abduction and adduction can be similarly increased.

MUSCLES PRODUCING MOVEMENTS

Flexion is produced by psoas major and iliacus, assisted by pectineus, rectus femoris and sartorius. The adductors, particularly adductor longus, also assist, especially in early flexion following full extension.

Extension is produced by gluteus maximus and the hamstring (posterior femoral) muscles. In the fully erect posture with pendent arms a vertical line through the centre of gravity of the body passes behind a line joining the centres of the femoral heads. The body therefore tends to incline backwards but this is counterbalanced by ligamentous tension and congruence and compression of the articular surfaces with the hip joints in the close-packed position. Under increased loading of the trunk or leaning backwards, these resistive but passive factors are assisted by active contraction of the hip flexors. In swaying forwards at the ankles, or when the arms are stretched forward, and also in forward bending at the hip, the line of body weight moves in front of the transverse axis. The posture adopted, or the rate of change of posture, is largely controlled by the hamstrings which, besides being powerful flexors of the knee, are strong extensors of the hip. Gluteus maximus only becomes active when the thigh is extended against resistance, as in rising from a bending position or during climbing.

Abduction is produced by gluteus medius and minimus, assisted by tensor fasciae latae and sartorius; it is limited by adductor tension, the pubofemoral ligament and the medial band of the iliofemoral ligament. The muscles are consistently involved in walking or running, and contract periodically at precise phases of the walking or running cycle.

Adduction is produced by adductors longus, brevis and magnus, assisted by pectineus and gracilis; it is limited when the moving limb contacts the contralateral limb. The range of adduction is enhanced with the thigh flexed, when it is limited by the increasing tension in the abductor muscles, the lateral band of the iliofemoral ligament and ligament of the femoral head.

Medial rotation is produced by tensor fasciae latae and the anterior fibres of gluteus minimus and medius. It is a relatively weak movement and is limited by the lateral rotators, the ischiofemoral ligament and the posterior part of the capsule. Electromyographic data suggest that the adductors usually assist in medial rather than lateral rotation, but this is, of course, dependent on the primary position.

Lateral rotation is produced by the obturator muscles, the gemelli and quadratus femoris, assisted by piriformis, gluteus maximus and sartorius. It is a powerful action which is limited by tension in the medial rotators and the lateral band of the iliofemoral ligament.

FORCES ACTING ON THE HIP

Under bipedal loading conditions, the femoral heads support the weight of the body minus the weight of both legs (approximately one-third body weight) and the resultant vectors are vertical. When viewed in the sagittal plane, minimal muscle forces are required to maintain equilibrium and balance when the weight of the upper body is directly over the femoral heads. If the upper body is tilted posteriorly such that the body weight vector lies behind the femoral heads, the anterior hip structures (rectus femoris, iliopsoas and iliofemoral ligament) will act to counter the rotational moment causing hip extension.

The range of motion of the hip far exceeds that required for normal walking. The muscles of the joint are the major stabilizing factors: the ligaments of the hip joint provide little rotational stability when walking. During normal gait the hip is subjected to wide variations in load bearing, ranging from one third of body weight in the double-leg support phase to four times body weight in the single-leg support phase. The walking cycle is characterized by two load peaks (see p. 1460) at heel strike (see Fig. 81.9) and toe off, corresponding to maximal acceleration and deceleration respectively in single-leg stance (see Fig. 84.25). Between these two peaks the body translates smoothly with little vertical acceleration.

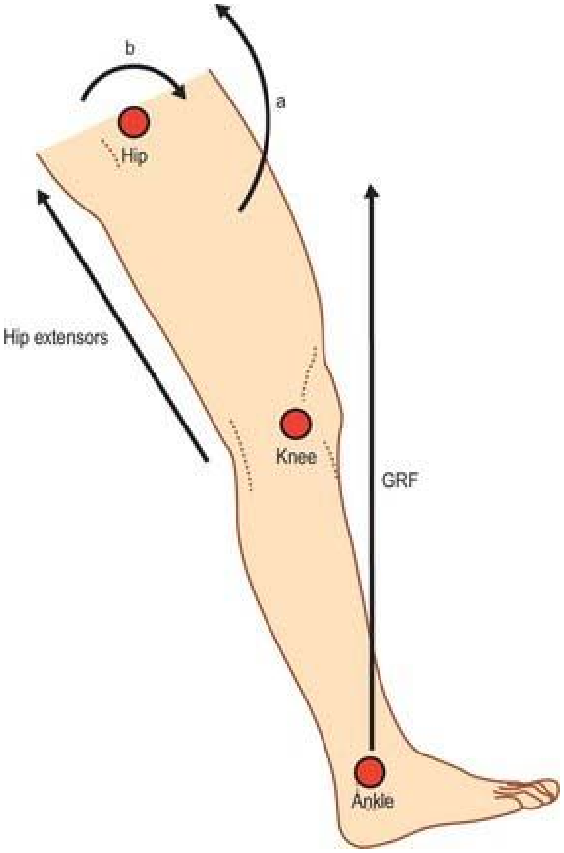

Fig. 81.9 Simplified kinetics of heel strike. At heel strike the ground reaction force (GRF) exerts a flexion (anticlockwise) moment about the hip (arrow a). The hip extensors counteract this moment with a clockwise moment (arrow b).

The factors influencing both the magnitude and direction of the compressive forces acting on the hip are the position of the centre of gravity; the abductor moment arm, which is a function of neck length (offset) and neck-shaft angle; the magnitude of body weight. Shortening of the abductor arm, e.g. in coxa valga or excessive femoral anteversion, will increase abductor demand and therefore increase joint reaction force. If the muscles cannot meet this demand, compensation takes place either in the form of a gluteus lurch (leaning towards the affected side to shorten the body weight lever arm), or a Trendelenburg gait (where the pelvis tilts away from the affected side).

Single-leg stance

In single-leg stance, the effective centre of gravity moves away from the supporting leg as the unsupported leg contributes to body weight. Body weight will exert a turning moment around the centre of the supporting femoral head: in order to maintain equilibrium, an equal but opposite turning moment is provided by the abductor muscles (primarily gluteii medius and minimus, tensor fasciae latae, piriformis and obturator internus). Since the lever arm of the abductors is much shorter than that of body weight acting through the centre of gravity, an abduction force greater than body weight is required to maintain equilibrium (Fig. 81.8). The vectors of these two forces produce a resultant compressive load on the femur that is oriented approximately 16° obliquely, laterally and distally. The joint reaction vector is exactly equal and opposite to this vector and is approximately four times body weight.

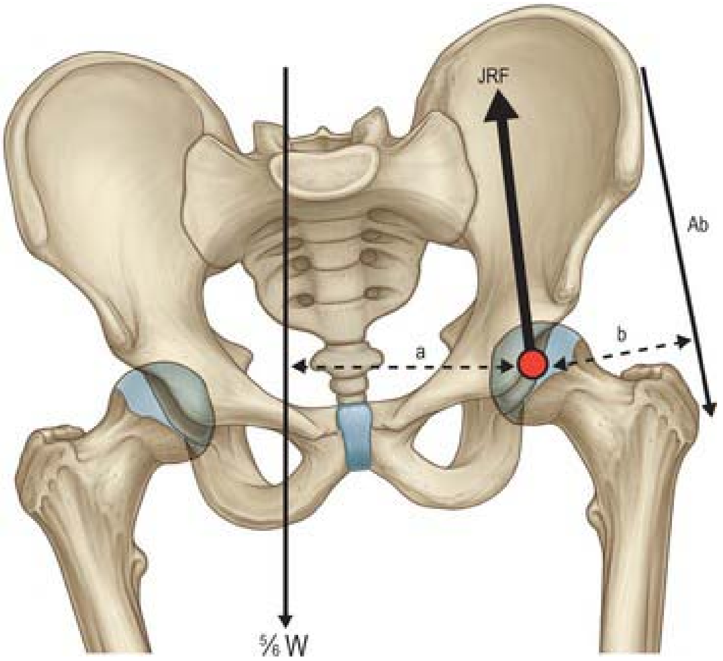

Fig. 81.8 In single-leg stance, 5/6 of total body weight (W) passes just lateral to the midline, exerting a clockwise moment on the pelvis; this is counteracted by the pull of the abductors, whose lever arm (a) is approximately half that of the body centre (b). Thus the abductor force (Ab) required to maintain equilibrium is approximately twice that of body

weight, resulting in a joint reaction force (JRF) approximately 3 to 4 times that of body weight.

Simplified kinetics of heel strike

Contact with the ground produces a reaction force equal to body weight multiplied by acceleration (see p. 1443). This ground reaction force acting at the foot produces a flexion moment about the hip which is approximately 3.3 times body weight, and is counterbalanced by the hip extensors (gluteus maximus and hamstrings) (Fig. 81.9).

CHAPTER 82

Knee

The knee is the largest synovial joint in the body. It consists of three distinct and partially separated compartments that collectively form a complex ‘hinge’ joint. This arrangement offers a fulcrum for the powerful extensor and flexor muscles that act on the joint during propulsion. A number of stabilizing factors counter the considerable biomechanical demands that are imposed upon the joint: most important is a complex arrangement of intracapsular and extracapsular ligaments. Our understanding of the anatomy of the knee has improved considerably in recent years, due in large measure to significant technological advances in diagnostic imaging and surgery.

SKIN AND SOFT TISSUE

SKIN

Cutaneous vascular supply and lymphatic drainage

The arterial supply of the skin covering the knee is derived from genicular branches of the popliteal artery, the descending genicular branch of the femoral artery, and the anterior recurrent branch of the anterior tibial artery, with small contributions from the arteries to vastus medialis and the hamstrings (Fig. 82.1). For further details consult Cormack & Lamberty (1994).

Fig. 82.1 The arterial anastomoses around the knee joint.

Cutaneous veins are tributaries of the vessels that correspond to the named arteries. Cutaneous lymphatic drainage is initially to the superficial inguinal nodes, and possibly also to the popliteal nodes and thence to the deep inguinal group of lymph nodes.

Cutaneous innervation

Infrapatellar branch of the saphenous nerve

The infrapatellar branch of the saphenous nerve reaches the anterior aspect of the knee from the medial side. It is invariably divided in the medial approach to the knee, which accounts for the numbness that inevitably occurs lateral to the scar of a medial knee incision. A painful neuroma may form if the nerve is partially sectioned, e.g. by the incision for an arthroscopy portal or a small medial arthrotomy. Unfortunately the position of the nerve relative to the line of the joint is variable. In most cases it crosses just below the joint line, passing over the patellar tendon at its insertion into the tibia. For further details see Tennant et al (1998).

Peripatellar plexus

Proximal to the knee, the infrapatellar branch of the saphenous nerve connects with branches of the medial and intermediate femoral cutaneous nerves, and lateral femoral cutaneous nerve. Distal to the knee it connects with other branches of the saphenous nerve. This fine, subcutaneous network of communicating nerve fibres over and around the patella is termed the peripatellar plexus.

SOFT TISSUE

Popliteal fossa

The popliteal fossa (Figs 82.2, 82.3) is a narrow intermuscular space posterior to the knee joint, with a diamond-shaped outline that is rendered more apparent when its boundaries are artificially separated during dissection. The boundaries are biceps femoris proximolaterally; semimembranosus and the overlying semitendinosus proximomedially; the lateral head of gastrocnemius with the underlying plantaris distolaterally, and the medial head of gastrocnemius distomedially. The anterior boundary (or floor) of the fossa is formed, in proximodistal sequence, by the popliteal surface of the femur, the oblique popliteal ligament (overlying the posterior surface of the capsule of the knee joint), and the posterior aspect of the proximal tibia covered by popliteus and the fascia overlying popliteus. The fossa is covered posteriorly by the popliteal fascia, which is referred to as the roof of the fossa. The popliteal fascia is continuous with the fascia lata proximally and with the fascia cruris distally. It is a dense layer that is strongly reinforced by transverse fibres and is often perforated by the short saphenous vein and sural nerve; these two structures are useful landmarks in the direct posterior approach to the knee joint. (Note that ‘popliteal fascia’ refers to the deep fascia that forms the ‘roof’ of the fossa, in contradistinction to the ‘fascia overlying popliteus’, which forms part of the floor.)

Contents

With its boundaries undisturbed, the popliteal fossa is typically 2.5 cm wide. Its contents are largely hidden, especially in its distal part, where the heads of gastrocnemius are in contact with each other. When its boundaries are separated, its contents are revealed as the popliteal vessels (Figs 82.2, 82.4), tibial and common fibular nerves, short saphenous vein, sural nerve, posterior femoral cutaneous nerve, an articular branch from the obturator nerve, lymph nodes, fat and a variable number of collapsed bursal sacs. The tibial nerve descends centrally immediately anterior to the popliteal fascia, crossing the vessels posteriorly from lateral to medial. The common fibular nerve descends laterally immediately medial to the tendon of biceps femoris. Popliteal vessels are deeply located and held together by dense areolar tissue. They lie on the floor of the fossa, the popliteal vein being superficial to the artery. Proximally, the thick-walled vein lies lateral to the artery, crossing to its medial side distally. At times the popliteal vein is duplicated, and the artery lies between the two veins, which are usually bridged by connecting channels. An articular branch from the obturator nerve descends on the artery to the knee. Six or seven popliteal lymph nodes are embedded in the fat, one under the popliteal fascia near the termination of the short saphenous vein, one between the popliteal artery and knee joint, the others around the popliteal vessels.

BONE

FEMUR, TIBIA AND FIBULA

The femur is described in Chapter 80 and the tibia and fibula are described in Chapter 83.

PATELLA

Topography

The patella is the largest sesamoid bone (Figs 82.5, 82.6) and is embedded in the tendon of quadriceps femoris, anterior to the distal femur (femoral condyles). It is flat, distally tapered, proximally curved, and has anterior and posterior surfaces, three borders and an apex which is the distal end of the bone. With the knee in extension, the apex is just proximal to the line of the knee joint.

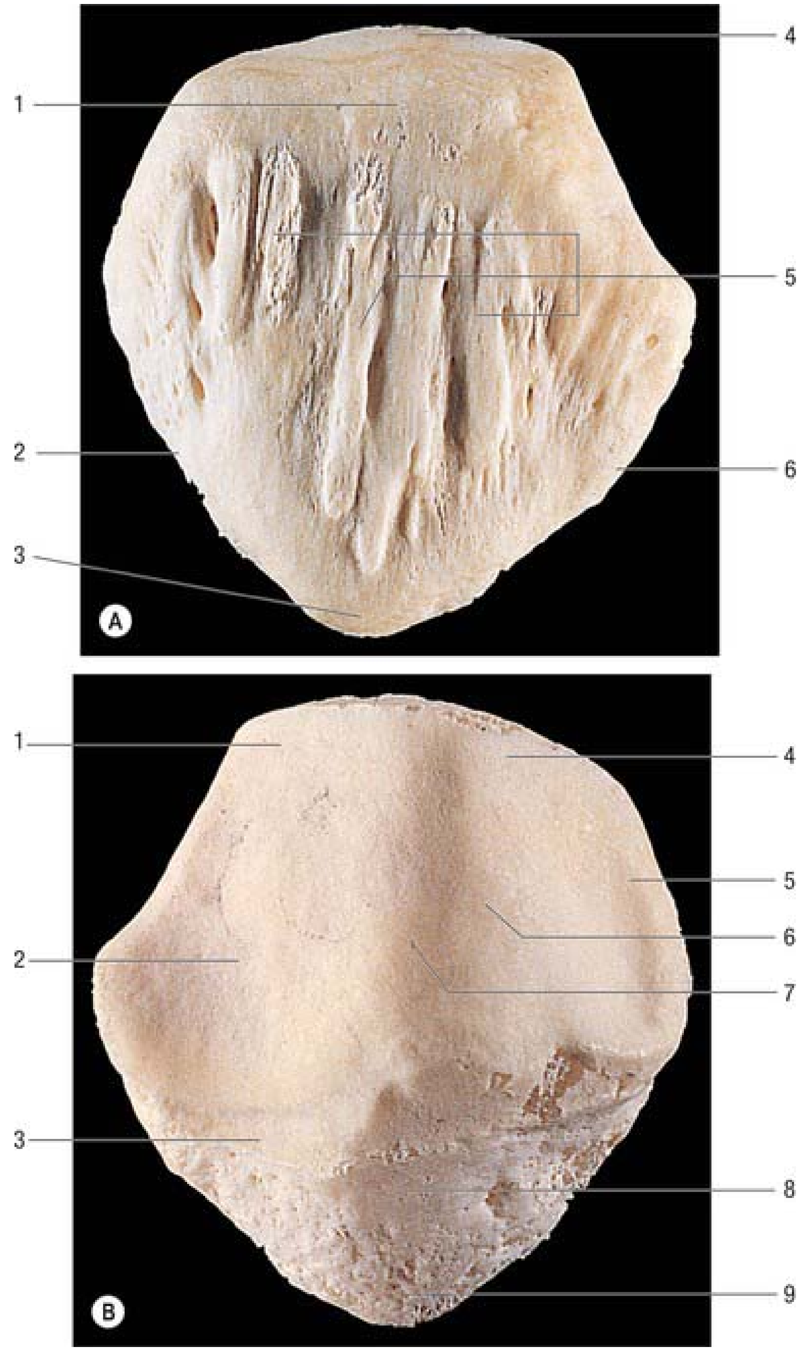

Fig. 82.5 **A**, Left patella: anterior aspect. **1**. Area of attachment of rectus femoris. **2**. Medial border: attachment of medial retinaculum (expansion). **3**. Apex. **4**. Area of attachment of vastus intermedius. **5**. Markings of attachment of quadriceps tendon. **6**. circumferential fat pad. **4**. Upper medial facet: in contact with femur in flexion. **5**. Medial vertical (‘odd’) facet: in contact with femur in extreme flexion. **6**. Lower medial facet: in contact with femur in extension. **7**. Ridge. **8**. Area covered by infrapatellar fat pad. **9**. Area for attachment of patellar tendon.

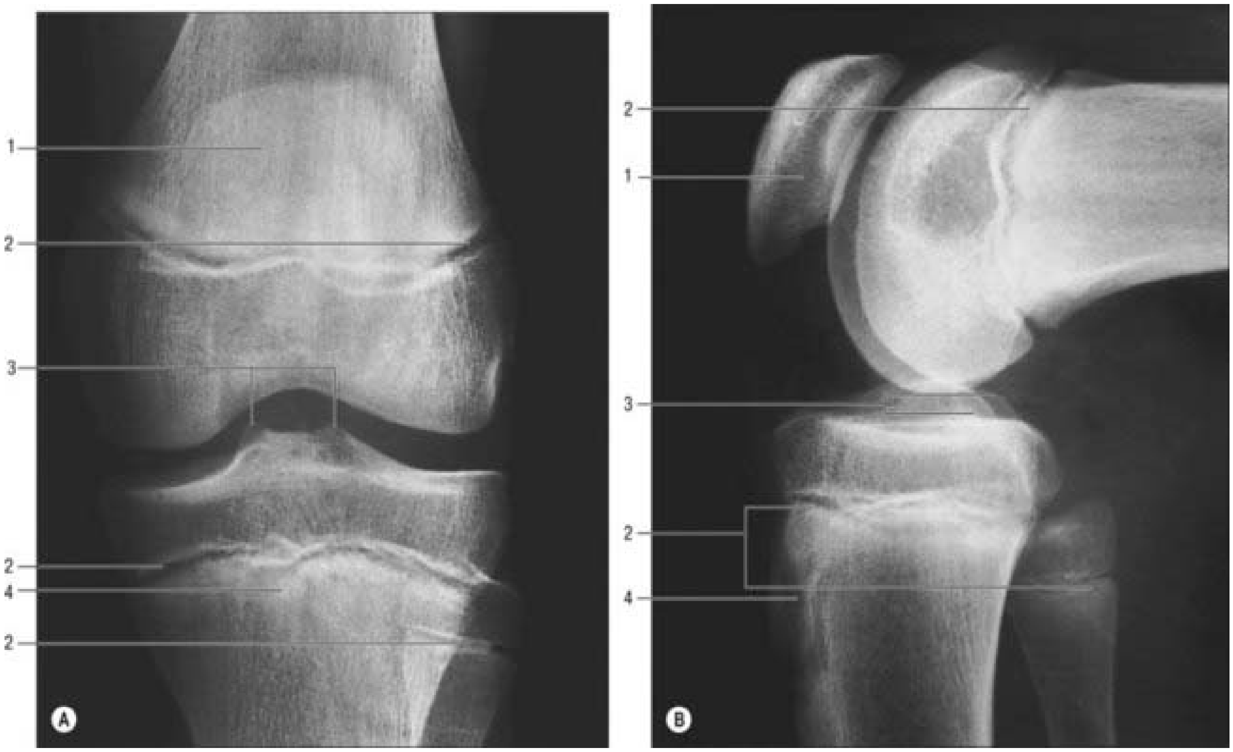

Fig. 82.6 Anteroposterior (**A**) and lateral (**B**) radiographs of the knee in a boy aged 14 years. **1**. Patella. **2**. Cartilaginous growth plates. **3**. Intercondylar eminence. **4**. Prolongation of proximal tibial epiphysis and growth plate forming the tibial tuberosity.

The subcutaneous, convex anterior surface is perforated by nutrient vessels. It is longitudinally ridged, separated from the skin by a prepatellar bursa, and covered by an expansion from the tendon of quadriceps femoris, which blends distally with superficial fibres of the patellar tendon (patellar ligament), the continuation of the tendon of quadriceps. The posterior surface has a proximal smooth, oval articular area, crossed by a smooth vertical ridge, which fits the intercondylar groove on the femoral patellar surface and divides the patellar articular area into medial and lateral facets; the lateral is usually larger. Each facet is divided by faint horizontal lines into equal thirds. A seventh ‘odd’ facet is present as a narrow strip along the medial border of the patella; it contacts the medial femoral condyle in extreme flexion. Distal to the articular surface, the apex is roughened by the attachment of the patellar tendon. Proximal to this, the area between the roughened apex and the articular margin is covered by an infrapatellar pad of fat. The articular cartilage is the thickest in the body, reflecting the magnitude of the stresses to which it is subjected.

The thick superior border (surface) slopes anteroinferiorly. The medial and lateral borders are thinner and converge distally; the expansions of the tendons of vastus medialis and lateralis (medial and lateral patellar retinacula respectively) are attached to them. The lateral retinaculum receives contributions from the iliotibial tract. Ossification occasionally extends from the lateral margin of the patella into the tendon of vastus lateralis.

The shape of the patella can vary, and certain configurations are associated with patellar instability. Not infrequently a bipartite patella is seen on radiographs. The bone seems to be in two parts, usually with a smaller superolateral fragment: this has long been attributed to the presence of a separate ossification centre, but in some cases could represent failed union following a stress fracture.

Structure

The patella consists of more or less uniformly dense trabecular bone, covered by a thin compact lamina. Trabeculae beneath the anterior surface are parallel to the surface; elsewhere they radiate from the articular surface into the substance of the bone.

Muscle attachments

Quadriceps femoris is attached to the superior surface, except near its posterior margin; the attachment extends distally onto the anterior surface. The attachment for rectus femoris lies anteroinferior to that for vastus intermedius. Rough markings can be traced in continuity around the periphery of the bone from the anterosuperior surface to the deep surface of the apex. Those at the lateral and medial borders represent the attachments of the lateral and medial vasti, and those at the apex represent the attachment of the patellar tendon.

Vascular supply

The arterial supply of the patella is derived from the genicular anastomosis, particularly from the genicular branches of the popliteal artery and from the anterior tibial recurrent artery.

Ossification

Several centres appear during the third to sixth years and these coalesce rapidly. Accessory marginal centres appear later and fuse with the central mass.

JOINTS

SUPERIOR TIBIOFIBULAR JOINT

The superior (proximal) tibiofibular joint is an almost plane synovial joint between the lateral tibial condyle and fibular head.

Articulating surfaces

The articulating surfaces vary in size, form and inclination. The joint line may be transverse or oblique. The fibular facet is usually elliptical or circular, almost flat or slightly grooved. The surfaces are covered with hyaline cartilage.

Fibrous capsule

The capsule is attached to the margins of the tibial and fibular articular, and is thickened anteriorly and posteriorly.

Ligaments

The ligaments of the superior tibiofibular joint are not entirely separate from the capsule. The anterior ligament is made up of two or three flat bands which pass obliquely up from the fibular head to the front of the lateral tibial condyle: it is closely related to the tendon of biceps. The posterior ligament is a thick band that ascends obliquely between the posterior aspect of the fibular head and the lateral tibial condyle: it is covered by the popliteal tendon.

Synovial membrane

The synovial membrane of the superior tibiofibular joint is sometimes (in approximately 10% of subjects) continuous with that of the knee joint via the subpopliteal recess.

Vascular supply and lymphatic drainage

The superior tibiofibular joint receives an arterial supply from the anterior and posterior tibial recurrent branches of the anterior tibial artery. Lymphatics follow the arteries and drain to the popliteal nodes.

Innervation

The superior tibiofibular joint is innervated by branches from the common fibular nerve and from the nerve to popliteus.

Factors maintaining stability

Stability of the superior tibiofibular joint is maintained by the fibrous capsule and the anterior and posterior ligaments, assisted by the biceps tendon and the interosseous membrane.

Movements

Very little movement other than limited gliding takes place at the superior tibiofibular joint. Some movement must occur in conjunction with movement occurring at the inferior tibiofibular joint, however, surgical fusion (arthrodesis) of the superior tibiofibular joint seems to have no effect on movements of the ankle joint.

Relations

The common fibular nerve runs posterior to the fibular head, medial to the tendon of biceps, which is closely associated with the anterior capsule. The anterior and posterior tibial branches of the popliteal artery, and the fibular artery, are all vulnerable inferomedial to the joint.

PATELLOFEMORAL JOINT

The patellofemoral joint is a synovial joint and is part of the knee joint.

Articulating surfaces

The articular surface of the patella is adapted to that of the femur. The latter extends onto the anterior surfaces of both femoral condyles like an inverted U. Since the whole area is concave transversely and convex in the sagittal plane, it is an asymmetrical sellar surface. The ‘odd’ facet on the articular surface of the patella contacts the anterolateral aspect of the medial femoral condyle in full flexion, when the highest lateral patellar facet contacts the anterior part of the lateral femoral condyle. As the knee extends, the middle patellar facets contact the lower half of the femoral surface; in full extension only the lowest patellar facets are in contact with the femur. In summary, on flexion the patellofemoral contact point moves proximally. The contact area also broadens to cope with the increasing stress that accompanies progressive flexion.

Patellar tendon sheath and patellar tendon

The patellar tendon (patellar ligament) is the central band of the tendon of quadriceps femoris, and is continued distally from the patella to the tibial tuberosity (see Fig. 80.25). It is strong, flat and 6 to 8 cm in length. Proximally it is attached to the patellar apex and adjoining margins, to roughened areas on the anterior surface and to a depression on the distal posterior patellar surface. Distally it is attached to the superior smooth area of the tibial tuberosity. This insertion is oblique, and is more distal laterally. Its superficial fibres are continuous over the patella with the tendon of quadriceps femoris, the medial and lateral parts of which descend, flanking the patella, to the sides of the tibial tuberosity, where they merge with the fibrous capsule as the medial and lateral patellar retinacula. The patellar tendon is separated from the synovial membrane by a large infrapatellar fat pad and from the tibia by a bursa, and lies within its own well-defined sheath.

In the procedure of tibial osteotomy, the tibia is cut transversely just above the patellar tendon insertion. Failure to appreciate the obliquity of the tibial attachment of the tendon may lead to inadvertent division of the tendon during this procedure, with unfortunate consequences.

All other aspects of the patellofemoral joint are described with the tibiofemoral joint.

TIBIOFEMORAL JOINT

The tibiofemoral joint is a complex synovial joint and is part of the knee joint.

Articulating surfaces

Proximal tibial surface

The proximal tibial surface (often referred to as the tibial plateau) slopes posteriorly and downwards relative to the long axis of the shaft (Fig. 82.7). The tilt, which is maximal at birth, decreases with age, and is more marked in habitual squatters. The tibial plateau presents medial and lateral articular surfaces (facets) for articulation with the corresponding femoral condyles. The posterior surface, distal to the articular margin, displays a horizontal, rough groove to which the capsule and posterior part of the medial collateral ligament are attached. The anteromedial surface of the medial tibial condyle is a rough strip, separated from the medial surface of the tibial shaft by an inconspicuous ridge. The medial patellar retinaculum is attached to the medial tibial condyle along its anterior and medial surfaces, which are marked by vascular foramina.

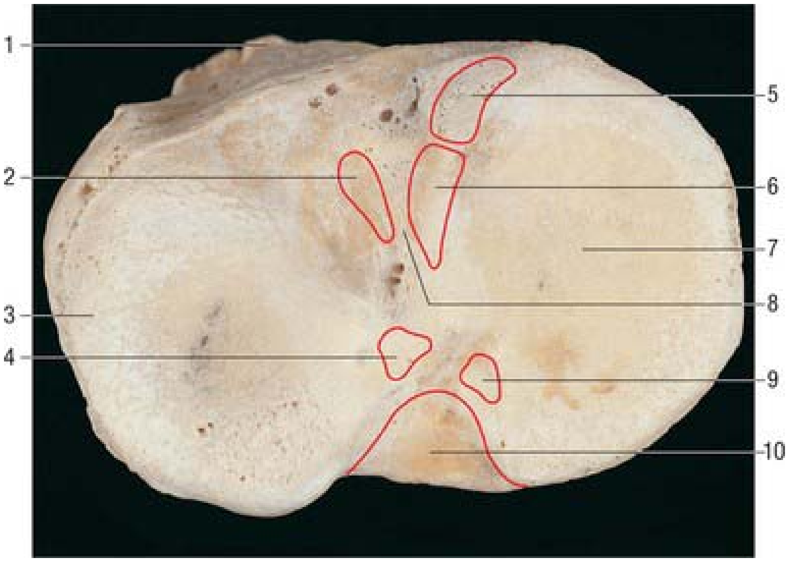

Fig. 82.7 The left tibial plateau. **1**. Tibial tuberosity. **2**. Attachment of anterior horn, lateral meniscus. **3**. Lateral condyle. **4**. Attachment of posterior horn, lateral meniscus. **5**. Attachment of anterior horn, medial meniscus. **6**. Attachment of anterior cruciate ligament. **7**. Medial condyle. **8**. Intercondylar eminence. **9**. Attachment of posterior horn, medial meniscus. **10**. Attachment of posterior cruciate ligament.

The medial articular surface is oval (long axis anteroposterior) and longer than the lateral articular surface. Around its anterior, medial, and posterior margins, it is related to the medial meniscus; the meniscal imprint, wider posteriorly and narrower anteromedially, is often discernible. The surface is flat in its posterior half and the anterior half slopes upwards about 10°. Much of the posterior surface is covered by the meniscus, so that overall a concave surface is presented to the medial femoral condyle. Its lateral margin is raised as it reaches the intercondylar region.

The lateral tibial condyle overhangs the shaft posterolaterally above a small circular facet for articulation with the fibula. The lateral articular surface is more circular and coapted to its meniscus. In the sagittal plane the articular surface is fairly flat centrally, and anteriorly and posteriorly the surface slopes inferiorly. Overall this creates a rather convex surface, so that, with the lateral femoral condyle in contact, there are anterior and posterior recesses (triangular in section), which are occupied by the anterior and posterior meniscal horns. Elsewhere the surface has a raised medial margin that spreads to the lateral intercondylar tubercle. Its articular margins are sharp, except posterolaterally, where the edge is rounded and smooth: here the tendon of popliteus is in contact with bone.

Intercondylar area

The rough-surfaced area between the condylar articular surfaces is narrowest centrally where there is an intercondylar eminence, the edges of which project slightly proximally as the lateral and medial intercondylar tubercles.

The intercondylar area widens behind and in front of the eminence as the articular surfaces diverge (Fig. 82.8).

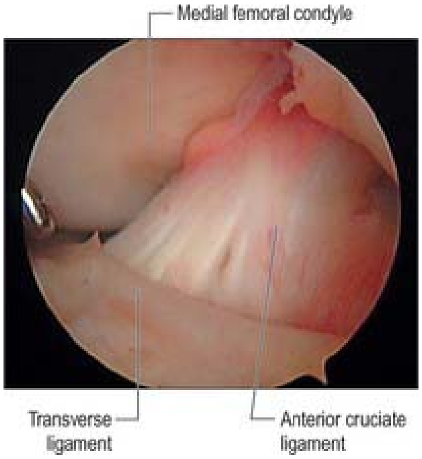

Fig. 82.8 The intercondylar notch at arthroscopy, showing the anterior cruciate and intermeniscal ligaments.

(By courtesy of Smith and Nephew Endoscopy.)

The anterior intercondylar area is widest anteriorly. Anteromedially, anterior to the medial articular surface, a depression marks the site of attachment of the anterior horn of the medial meniscus. Behind this a smooth area receives the anterior cruciate ligament. The anterior horn of the lateral meniscus is attached anterior to the intercondylar eminence, lateral to the anterior cruciate ligament. The eminence, with medial and lateral tubercles, is the narrow central part of the area. The raised tubercles are thought to provide a slight stabilizing influence on the femur.

The posterior horn of the lateral meniscus is attached to the posterior slope of the intercondylar area. The posterior intercondylar area inclines down and backwards behind the posterior horn of the lateral meniscus. A depression behind the base of the medial intercondylar tubercle is for the posterior horn of the medial meniscus. The rest of the area is smooth and provides attachment for the posterior cruciate ligament, spreading back to a ridge to which the capsule is attached.

Femoral surface

The femoral condyles, bearing articular cartilage, are almost wholly convex. Opinions as to the contours of their sagittal profiles tend to vary. One view is that they are spiral with a curvature increasing posteriorly (‘a closing helix’); that of the lateral condyle being greater. An alternative view is that the articular surface for contact with the tibia on the medial femoral condyle describes the arcs of two circles. According to this view, the anterior arc makes contact with the tibia near extension and is part of a virtual circle of larger radius than the more posterior arc, which makes contact during flexion. The lateral femoral condyle is believed to describe a single arc and thus to possess a single radius of curvature.

Tibiofemoral congruence is improved by the menisci, which are shaped to produce concavity of the surfaces presented to the femur; the combined lateral tibiomeniscal surface is deeper. The lateral femoral condyle has a faint groove anteriorly which rests on the peripheral edge of the lateral meniscus in full extension. A similar groove appears on the medial condyle, but does not reach its lateral border, where a narrow strip contacts the medial patellar articular surface in full flexion. These grooves demarcate the femoral patellar and condylar surfaces. The differences between the shapes of the articulating surfaces correlate with the movements of the joint.

Menisci

The menisci (semilunar cartilages) are crescentic, intracapsular, fibrocartilaginous laminae (Figs 82.9, 82.10). They serve to widen and deepen the tibial articular surfaces that receive the femoral condyles. Their peripheral attached borders are thick and convex and their free, inner borders thin and concave. Their peripheries are vascularized by capillary loops from the fibrous capsule and synovial membrane, while their inner regions are avascular. Tears of the menisci are common. Most occur in the avascular, inner zones and seldom heal spontaneously; if surgery is indicated, these menisci are best resected. Peripheral tears (i.e. in the vascularized zone) have the potential to heal satisfactorily if repaired surgically. The meniscal horns are richly innervated compared with the remainder of the meniscus. The central thirds are devoid of innervation (Gronblad et al 1985). The proximal surfaces are smooth and concave and in contact with the articular cartilage on the femoral condyles. The distal surfaces are smooth and flat, resting on the tibial articular cartilage. Each covers approximately two-thirds of its tibial articular surface. Canal-like structures open onto the surface of menisci in infants and young children and may transport nutrients to deeper avascular areas.

(By courtesy of Dr Justin Lee, Chelsea and Westminster Hospital, London.)

Two structurally different regions of the menisci have been identified. The inner two-thirds of each meniscus consists of radially organized collagen bundles, and the peripheral third consists of larger circumferentially arranged bundles (Ghadially et al 1983). The articular surfaces of the inner part are lined by thinner collagen bundles parallel to the surface, while the outer portion is covered by synovium. This structural arrangement suggests specific biomechanical functions for the two regions: the inner portion of the meniscus is suited to resisting compressive forces while the periphery is capable of resisting tensional forces. With ageing and degeneration, compositional changes occur within the menisci which reduce their ability to resist tensional forces. Outward displacement of the menisci by the femoral condyles is resisted by firm anchorage of the peripheral circumferential fibres to the intercondylar bone at the meniscal horns.

Menisci spread load by increasing the congruity of the articulation; give stability by their physical presence and as providers of proprioceptive feedback; probably assist lubrication; and may cushion the underlying bone from the considerable forces generated during extremes of flexion and extension.

Medial meniscus

The medial meniscus broader posteriorly, is almost a semicircle in shape (Fig. 82.9). It is attached by its anterior horn to the anterior tibial intercondylar area in front of the anterior cruciate ligament; the posterior fibres of the anterior horn are continuous with the transverse ligament. The anterior horn is in the floor of a depression medial to the upper part of the patellar tendon. The posterior horn is fixed to the posterior tibial intercondylar area, between the attachments of the lateral meniscus and posterior cruciate ligament. Its peripheral border is attached to the fibrous capsule and the deep surface of the medial collateral ligament. The tibial attachment of the meniscus is known as the ‘coronary ligament’. Collectively these attachments ensure that the medial meniscus is relatively fixed and moves much less than the lateral meniscus.

Lateral meniscus

The lateral meniscus forms approximately four-fifths of a circle, and covers a larger area than the medial meniscus. Its breadth, except at its short tapered horns, is more or less uniform. It is grooved posterolaterally by the tendon of popliteus, which separates it from the fibular collateral ligament. Its anterior horn is attached in front of the intercondylar eminence, posterolateral to the anterior cruciate ligament, with which it partly blends. Its posterior horn is attached behind this eminence, in front of the posterior horn of the medial meniscus. Its anterior attachment is contorted so that the free margin faces posterosuperiorly, and the anterior horn rests on the anterior slope of the lateral intercondylar tubercle. Near its posterior attachment it commonly sends a posterior meniscofemoral ligament superomedially behind the posterior cruciate ligament to the medial femoral condyle. An anterior meniscofemoral ligament may also connect the posterior horn to the medial femoral condyle anterior to the posterior cruciate ligament. The meniscofemoral ligaments are often the sole attachments of the posterior horn of the lateral meniscus. More laterally, part of the tendon of popliteus is attached to the lateral meniscus, and so mobility of its posterior horn may be controlled by the meniscofemoral ligaments and by popliteus. A meniscofibular ligament occurs in most knee joints. There is a tibial attachment via a coronary ligament, but the meniscus has no peripheral bony attachment in the region of popliteus: in surgical literature this gap is referred to as the popliteus hiatus.

Discoid lateral meniscus

A discoid lateral meniscus occurs in up to 5% of the population, often bilaterally. The distinguishing features of a discoid lateral meniscus are its shape and posterior ligamentous attachments. The following classification of the abnormality is based on Watanabe et al (1979). In its mildest form, the partial discoid meniscus is simply a wider form of the normal lateral meniscus. The acute, medial free edge is interposed between femoral and tibial condyles, but it does not completely cover the tibial plateau. A complete discoid meniscus appears as a biconcave disc with a rolled medial edge and totally covers the lateral tibial plateau. The Wrisberg type of meniscus has the same shape as a complete discoid meniscus, but its only peripheral posterior attachment is by the meniscofemoral ligaments. The normal tibial attachment of the posterior horn of the lateral meniscus is lacking, but the posterior meniscofemoral ligament persists. As a result, this type of meniscus is attached anteriorly to the tibia and posteriorly to the femur, which renders the posterior horn unstable. Under these circumstances, the meniscus is liable to get caught between the femur and tibia: this accounts for the classic presenting symptom of the ‘clunking knee’ in some patients.

The aetiology of discoid meniscus is not clear. Most are asymptomatic, and are often found by chance at arthroscopy. However, they may cause difficulty in gaining access to the lateral compartment at arthroscopy.

Discoid medial meniscus is extremely rare.

Transverse [intermeniscal] ligament

The transverse ligament connects the anterior convex margin of the lateral meniscus to the anterior horn of the medial meniscus (Figs 82.8, 82.9). It varies in thickness and is often absent. Its exact role is conjectural; presumably it helps to decrease tension generated in the longitudinal circumferential fibres of the menisci when the knee is subjected to load. A posterior meniscomeniscal ligament is sometimes present.

Meniscofemoral ligaments

The two meniscofemoral ligaments (MFLs) connect the posterior horn of the lateral meniscus to the inner (lateral) aspect of the medial femoral condyle (Figs 82.11, 82.12). The anterior MFL (aMFL; ligament of Humphry) passes anterior to the posterior cruciate ligament. The posterior MFL (pMFL; ligament of Wrisberg) passes behind the posterior cruciate ligament and attaches proximal to the margin of attachment of the posterior cruciate.

(By kind permission from Dr Justin Lee, Chelsea and Westminster Hospital, London.)

Anatomical studies found that at least one meniscofemoral ligament was present in 92% of cadaveric knees examined, whilst both coexisted in 32% (Gupte et al 2003). Biomechanical studies have revealed the cross-sectional area and strength of the meniscofemoral ligaments to be comparable to those of the posterior fibre bundle of the posterior cruciate ligament.

The meniscofemoral ligaments are believed to act as secondary restraints, supporting the posterior cruciate ligament in minimizing displacement caused by posteriorly directed forces on the tibia. These ligaments are also involved in controlling the motion of the lateral meniscus in conjunction with the tendon of popliteus during flexion.

Soft tissues

Recent advances in knee ligament surgery have contributed to a better understanding of the anatomy of the medial and lateral soft tissues of the knee.

Capsule and retinacula

The capsule is a fibrous membrane of variable thickness. Anteriorly it is replaced by the patellar tendon and does not pass proximal to the patella or over the patellar area. Elsewhere it lies deep to expansions from vasti medialis and lateralis, separated from them by a plane of vascularized loose connective tissue. The expansions are attached to the patellar margins and patellar tendon, extending back to the corresponding collateral ligaments and distally to the tibial condyles. They form medial and lateral patellar retinacula, the lateral being reinforced by the iliotibial tract.

Posteriorly the capsule contains vertical fibres that arise from the articular margins of the femoral condyles and intercondylar notch and from the proximal tibia. The fibres mainly pass downwards and somewhat medially. The oblique popliteal ligament is a well-defined thickening across the posteromedial aspect of the capsule, and is essentially an extension from the tendon of insertion of semimembranosus.

Medial soft tissues

The medial soft tissues (see Fig. 80.25, Fig. 82.13) are arranged in three layers (Warren & Marshall 1979).

(From Sobotta 2006.)

Layer 1

Layer 1 is the most superficial and is the deep fascia that invests sartorius. The saphenous nerve and its infrapatellar branch are superficial to the fascia. Sartorius inserts into the fascia as an expansion rather than as a distinct tendon. The layer 1 fascia spreads inferiorly and anteriorly to lie superficial to the distinct and readily identifiable tendons of gracilis and semitendinosus and their insertions. The latter two tendons are commonly harvested for surgical reconstruction of damaged cruciate ligaments. To gain access to them the upper edge of sartorius can be identified. The sartorius (layer 1) fascia is then incised to reveal the tendons. Deep to the tendons is the pes bursa, which overlies the superficial medial collateral ligament: this bursa is sometimes the seat of inflammation, especially in track and field athletes. Posteriorly, layer 1 overlies the tendons of gastrocnemius and the structures of the popliteal fossa. Anteriorly, layer 1 blends with the anterior limit of layer 2 and the medial patellar retinaculum. More inferiorly, layer 1 blends with periosteum.

A condensation of tissue passes from the medial border of the patella to the medial epicondyle of the femur (the medial patellofemoral ligament), the anterior horn of the medial meniscus (the meniscopatellar ligament), and the medial tibial condyle (the patellotibial ligament).

Layer 2

Layer 2 is the plane of the superficial medial collateral ligament, which means that the tendons of gracilis and semitendinosus lie between layers 1 and 2. The superficial medial collateral ligament has vertical and oblique portions. The former contains vertically orientated fibres that pass from the medial epicondyle of the femur to a large insertion on the medial surface of the proximal end of the tibial shaft. It extends to an area about 5 cm distal to the joint line. Its anterior edge is rolled and easily seen just posterior to the insertions of gracilis and semitendinosus once layer 1 has been opened. The posteriorly placed oblique fibres run posteroinferiorly from the medial epicondyle of the femur to blend with the underlying layer 3 (capsule), effectively to insert on the posteromedial tibial articular margin and posterior horn of the medial meniscus. This area is reinforced by a part of the insertion of semimembranosus. There is a vertical split in layer 2 anterior to the superficial medial collateral ligament. The fibres anterior to the split pass superiorly to blend with vastus medialis fascia and layer 1 in the medial patellar retinaculum. The fibres posterior to the split pass superiorly to the medial epicondyle and thence anteriorly as the medial patellofemoral ligament.

Layer 3

Layer 3 is the capsule of the knee joint and can be separated from layer 2 everywhere except anteriorly close to the patella, where it blends with the more superficial layers. Deep to the superficial medial collateral ligament it is thick and has vertically orientated fibres that make up the deep medial collateral ligament. It sends fibres to the medial meniscus. Anteriorly, the separation of the superficial and deep parts of the medial collateral ligament is distinct. Posteriorly, layers 2 and 3 blend to form a conjoined posteromedial capsule.

Lateral soft tissues

The lateral soft tissues (Figs 82.13, 82.15) are also arranged in three layers (Seebacher et al 1982). Most superficial is the lateral patellar retinaculum. The middle layer consists of the lateral collateral ligament, popliteofibular ligament, fabellofibular ligament and arcuate ligament. The deep layer is the lateral part of the capsule.

(From Sobotta 2006.)

The lateral patellar retinaculum consists of superficial oblique and deep transverse portions. The former runs from the iliotibial band to the patella. The latter is thicker and subdivided into three parts: the lateral patellofemoral ligament, running from the lateral patellar border to the lateral epicondyle of the femur; the transverse retinaculum, running from the iliotibial band to the mid patella; and the patellotibial band, running from the patella to the lateral tibial condyle.

The fascia lata and the iliotibial band lie posterior to the lateral retinaculum. They come together distally to insert onto the tibia at Gerdy's tubercle on the anterolateral proximal tibia, and some fibres continue to the tibial tuberosity. Proximally the fascia lata merges with the lateral intermuscular septum. Posteriorly it blends with the biceps fascia. Here, as it emerges from behind the biceps tendon, the common fibular nerve lies in a thin layer of fat bound by the fascia.

The lateral collateral ligament arises from the lateral epicondyle of the femur posterior to the popliteus insertion and just proximal to the popliteus groove. It is a cord-like structure that passes distally, superficial to the popliteus tendon and deep to the lateral retinaculum, to attach to the fibular head, where it blends with the biceps tendon just anterior to the apex of the fibular head. It is separated from the capsule by a thin layer of fat and the inferior lateral genicular vessels.

The single most important stabilizer of the posterolateral knee is the popliteofibular ligament. It passes from the popliteus tendon at a level just below the joint line, posteriorly, laterally and inferiorly, to the fibular head. It is probably what was previously described as the short lateral genual ligament. As a passive ‘tether’ combined with the popliteus tendon proximal to it, it resists external rotation of the tibia. Its connection to the tendon of popliteus also allows ‘dynamic’ tensioning.

The fabellofibular ligament is a condensation of fibres that runs from the fabella, or from the lateral head of gastrocnemius if the fabella is absent, to the fibular styloid. The arcuate ligament is a condensation of fibres that runs from the fibular styloid, posteromedially over the emerging tendon of popliteus below the level of the tibial joint surface, to the tibial intercondylar area. The lateral joint capsule is thin and blends posteriorly with the arcuate ligament. Anteriorly it forms the weak, lax coronary ligament, which attaches the inferior border of the meniscus to the lateral tibia.

Ligaments

Cruciate ligaments

The cruciate ligaments, so named because they cross each other, are very strong intracapsular structures. The point of crossing is located a little posterior to the articular centre. They are named anterior and posterior with reference to their tibial attachments (Fig. 82.14). Synovial membrane almost surrounds the ligaments but is reflected posteriorly from the posterior cruciate to adjoining parts of the capsule: the intercondylar part of the posterior region of the fibrous capsule therefore has no synovial covering.

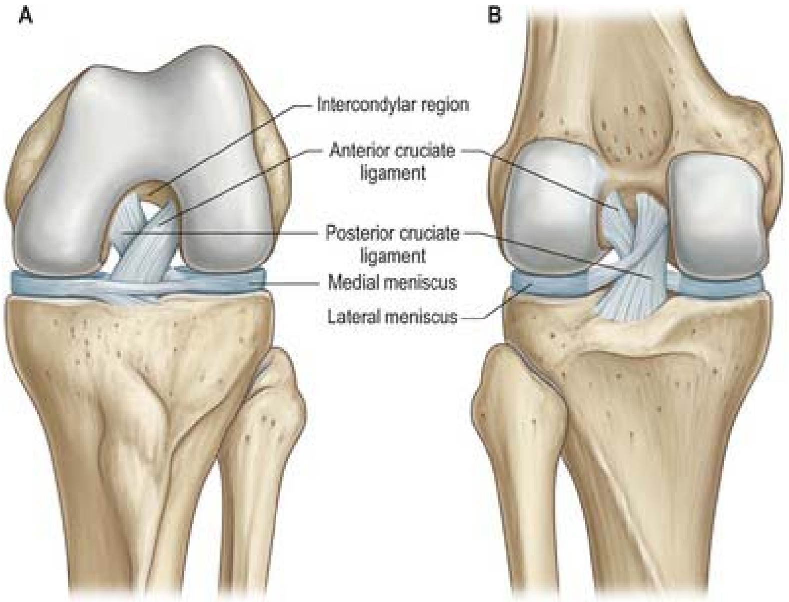

Fig. 82.14 The left knee joint. **A**, Anterior aspect in full flexion. **B**, Posterior aspect in extension.

(From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)

Anterior cruciate ligament

The anterior cruciate ligament is attached to the anterior intercondylar area of the tibia, just anterior and slightly lateral to the medial tibial eminence, partly blending with the anterior horn of the lateral meniscus (Figs 82.8, 82.9). It ascends posterolaterally, twisting on itself and fanning out to attach high on the posteromedial aspect of the lateral femoral condyle (Girgis et al 1975). The average length and width of an adult anterior cruciate ligament are 38 mm and 11 mm respectively. It is formed of two, or possibly three, functional bundles that are not apparent to the naked eye, but can be demonstrated by microdissection techniques. The bundles are named anteromedial, intermediate, and posterolateral, according to their tibial attachments (Amis and Dawkins 1991).

Absent anterior cruciate ligament

Congenital absence of the anterior cruciate ligament is rare. The condition is usually associated with lower limb dysplasia (Thomas et al 1985), and may be a cause of instability of the knee.

Posterior cruciate ligament

The posterior cruciate ligament is thicker and stronger than the anterior cruciate ligament (Fig. 82.9), the average length and width of an adult posterior cruciate ligament being 38 mm and 13 mm respectively. It is attached to the lateral surface of the medial femoral condyle and extends up onto the anterior part of the roof of the intercondylar notch, where its attachment is extensive in the anteroposterior direction. Its fibres are adjacent to the articular surface. They pass distally and posteriorly to a fairly compact attachment posteriorly in the intercondylar region and in a depression on the adjacent posterior tibia. This gives a fan-like structure in which fibre orientation is variable. Anterolateral and posteromedial bundles have been defined: they are named (against convention) according to their femoral attachments. The anterolateral bundle tightens in flexion whilst the posteromedial is tight in extension of the knee. Each bundle slackens as the other tightens. Unlike the anterior cruciate ligament, it is not isometric during knee motion, i.e. the distance between attachments varies with knee position. The posterior cruciate ligament ruptures less commonly than the anterior cruciate; rupture is usually better tolerated by patients than that of the anterior cruciate ligament.

Synovial membrane, plicae and fat pads

The synovial membrane of the knee is the most extensive and complex in the body. It forms a large suprapatellar bursa between quadriceps femoris and the lower femoral shaft proximal to the superior patellar border (Fig. 82.16). The bursa is an extension of the joint cavity. The attachment of articularis genu to its proximal aspect prevents the bursa from collapsing into the joint. Alongside the patella the membrane extends beneath the aponeuroses of the vasti, especially under vastus medialis. It extends proximally a hand's breadth above the superior pole of the patella. Distal to the patella, the synovial membrane is separated from the patellar tendon by an infrapatellar fat pad. Where it lies beneath the fat pad, the membrane projects into the joint as two fringes, alar folds, which bear villi. The folds converge posteriorly to form a single infrapatellar fold or plica (ligamentum mucosum), which curves posteriorly to its attachment in the femoral intercondylar fossa (Fig. 82.17). This fold may be a vestige of the inferior boundary of an originally separate femoropatellar joint. The extent of the infrapatellar plica ranges from a thin cord to a complete sheet that can obstruct the passage of instruments during knee arthroscopy. When substantial, it has been mistaken for the anterior cruciate ligament, which is directly posterior to it. The medial plica extends in the midline anteriorly from the medial alar fold medially to the suprapatellar pouch. Occasionally it can be thickened and inflamed, usually following acute or chronic trauma.

Fig. 82.17 Left knee joint in full flexion: the quadriceps tendon has been sectioned and the patellar flap retracted distally. Compare with **Fig. 82.14A**.

The suprapatellar plicae are remnants of an embryonic septum that completely separates the suprapatellar pouch from the knee joint. Very occasionally a septum persists, either in its entirety, or perforated by a small peripheral opening. Loose bodies can lie hidden above this septum.

The infrapatellar fat pad is the largest part of a circumferential extrasynovial fatty ring which extends around the patellar margins (Newell 1991).

At the sides of the joint the synovial membrane descends from the femur and lines the capsule as far as the menisci, whose surfaces have no synovial covering. Posterior to the lateral meniscus the membrane forms a subpopliteal recess between a groove on the meniscal surface and the tendon of popliteus which may connect with the superior tibiofibular joint. The relationship of the synovial membrane to the cruciate ligaments is described above.

Bursae

Numerous bursae are associated with the knee. Anteriorly, there is a large subcutaneous prepatellar bursa between the lower half of the patella and skin; a small deep infrapatellar bursa between the tibia and patellar tendon; a subcutaneous infrapatellar bursa between the distal part of the tibial tuberosity and skin; and a large suprapatellar bursa which is the superior extension of the knee joint cavity (Fig. 82.16). Posterolaterally, there are bursae between the lateral head of gastrocnemius and the joint capsule (this bursa is sometimes continuous with the joint cavity); the fibular collateral ligament and the tendon of biceps femoris; the fibular collateral ligament and the tendon of popliteus; the tendon of popliteus and the lateral femoral condyle, which is usually an extension of the synovial cavity of the joint. The last two bursae may communicate with each other.

Medially, the arrangement of bursae is complex. The bursa between the medial head of gastrocnemius and the fibrous capsule is prolonged between the medial tendon of gastrocnemius and the tendon of semimembranosus (the semimembranosus bursa) and usually communicates with the joint. The bursa between the tendon of semimembranosus and the medial tibial condyle and the medial head of gastrocnemius may communicate with this bursa. There is a bursa between the medial collateral ligament and the tendons of sartorius, gracilis and semitendinosus (the ‘pes bursa’). Bursae that vary both in number and position lie deep to the medial collateral ligament between the capsule, femur, medial meniscus, tibia or tendon of semimembranosus. Occasionally there may be a bursa between the tendons of semimembranosus and semitendinosus.

Posteriorly, bursae associated with the knee are variable.

The clinically important bursae are the anterior group, the pes bursa, and the semimembranosus bursa. Inflammation of the subcutaneous prepatellar bursa and infrapatellar bursa are referred to colloquially as ‘housemaid’s knee’ and ‘clergyman’s knee’, respectively. The pes bursa can become inflamed in athletes. In adults, bursal inflammation producing a popliteal fossa swelling commonly occurs secondary to degeneration within the knee joint: regardless of size and position, it almost always arises from the plane between semimembranosus and the medial tendon of gastrocnemius.

Movements

Movements at the knee are customarily described as flexion, extension, internal (medial) and external (lateral) rotation. Flexion and extension differ from true hingeing in that the articular surface profiles of the femoral and tibial articular surfaces produce a variably placed axis of rotation during the flexion arc, and when the foot is fixed, flexion entails corresponding conjunct (coupled) external (lateral) rotation. These conjunct rotations are a product of the complex geometry of the articular surfaces and, to an extent, the disposition of the associated ligaments. There is differential motion in the medial and lateral tibiofemoral compartments. Laterally, there is considerable displacement of the femur on the tibia, with rolling as well as sliding at the joint surface. In contrast, medially, for most of the flexion arc there is minimal relative motion of the femur and tibia, and the motion almost exclusively involves one joint surface sliding on the other. In full flexion, the lateral femoral condyle is close to posterior subluxation off the lateral tibial articular surface. Medially, significant posterior femoral displacement only occurs when flexion exceeds 120°. The menisci move with the femoral condyles, the anterior horns more than the posterior, and the lateral meniscus considerably more than the medial.

The axial rotations have a smaller range than the arc of flexion and extension. These rotations are conjunct, and integral with flexion and extension, i.e. they are obligatory. They can also be adjunct and independent, i.e. voluntary, and are best demonstrated with the knee semi-flexed. The degree of axial rotation therefore varies with flexion and extension.

The range of extension is 5–10° beyond the ‘straight position’. Active flexion is approximately 120° with the hip extended, 140° when it is flexed, and 160° when aided by a passive element, e.g. sitting on the heels. Voluntary rotation is 60–70°, but conjunct rotation only 20°.

Conjunct medial rotation of the femur on the tibia in the later stages of extension is part of a ‘locking’ mechanism, the so-called ‘screw-home movement’, which is an asset when the fully extended knees are subjected to strain. Full extension results in the close-packed position, with maximal spiralization and tightening of the ligaments. The roles of the articular surfaces, musculature and ligaments in generating conjunct rotations remain controversial (Girgis et al 1975, Rajendran 1985), but the following points can be made. The lateral combined meniscotibial ‘receiving surface’ is smaller, more circular and more deeply concave. Since the articular surface is virtually convex in sagittal section the depth of the receiving surface is largely due to the presence of the lateral meniscus. The lateral femoral articular surface is also smaller. Consequently, the lateral femoral condyle approaches full congruence with the opposed surface some 30° before full extension (well before the medial condyle). Simple extension cannot continue, but medial rotation of the femur occurs on a vertical axis through its head and medial condyle: the medial femoral condyle moves very little in the sagittal plane and is stabilized by the ‘upslope’ of the anterior half of the medial tibia, while rotation of the lateral femoral condyle and meniscus brings the anterior horn of the latter onto the anterior ‘downslope’ of the lateral tibial condyle. Rotation and extension follow simultaneously and smoothly until final close packing of both condyles is accomplished. At the beginning of flexion from full extension (with the foot fixed) lateral femoral rotation occurs, which ‘unlocks’ the joint. While joint surfaces and many ligaments are involved, electromyographic evidence reveals that contraction of popliteus is important, and that it pulls down and backwards on the lateral femoral condyle, lateral to the axis of femoral rotation. It also retracts the posterior horn during lateral rotation and continuing flexion, via its attachment to the lateral meniscus, and so prevents traumatic compression.

Any position of extension adopted is a balance between forces (torque) extending the joint and passive mechanisms resisting them. The range near to close packing is functionally important. In symmetrical standing, the line of body weight is anterior to the transverse axes of the knee joints, but the passive mechanisms noted above preserve posture with minimal muscular effort (Joseph 1960). Active contraction of the extensors and a close-packed position only occur in asymmetrical postures, e.g. in leaning forward, heavy loading, or when powerful thrust is needed.

In extension, parts of both cruciate ligaments, the tibial and fibular collateral ligaments, the posterior capsular region, the oblique popliteal ligament, skin and fasciae are all taut. Passive and sometimes active tension exists in the hamstrings and gastrocnemius, and the anterior part of the medial meniscus is compressed between the femoral and tibial condyles. During extension the patellar tendon is tightened by quadriceps femoris but is relaxed in the erect attitude. When the knee flexes, the fibular collateral ligament and the posterior part of the medial collateral ligament relax but the cruciate ligaments and the anterior part of the medial collateral ligament remain taut: the posterior parts of the menisci are compressed between the femoral and tibial condyles. Flexion is checked by quadriceps femoris, anterior parts of the capsule, posterior cruciate ligament and compression of soft tissues behind the knee. In extreme passive flexion, contact of the calf with the thigh may be the limiting factor and parts of both cruciate ligaments are also tense. In addition to conjunct rotation with terminal extension or initial flexion, relaxed collateral ligaments also allow independent medial and lateral rotation (adjunct rotation) when the joint is flexed.

Accessory movements

Wider rotation can be obtained by passive movements when the knee is semi-flexed. To a limited extent, the tibia can also be translated backwards and forwards on the femur. Abduction and adduction are prevented in full extension by the collateral ligaments and secondary restraints such as the cruciate ligaments. With the knee slightly flexed, limited adduction and abduction are possible, both passive and active. Slight separation of the femur and tibia can be achieved by strong traction on the leg with countertraction applied to the thigh.

Muscles producing the movements

Flexion

Biceps femoris, semitendinosus and semimembranosus, assisted by gracilis, sartorius and popliteus. With the foot stationary, gastrocnemius and plantaris also assist (See Fig. 82.3).

Extension

Quadriceps femoris, assisted by tensor fasciae latae.

Medial rotation of the flexed leg

Popliteus, semimembranosus and semitendinosus, assisted by sartorius and gracilis.

Lateral rotation of the flexed leg

Biceps femoris.

Relations and ‘at risk’ structures

Anteriorly are the tendon of quadriceps femoris (which encloses and is attached to the non-articular surfaces of the patella), the patellar tendon, tendinous expansions from vastus medialis and lateralis (which extend over the anteromedial and anterolateral aspects of the capsule respectively), and the patellar retinacula. Posteromedial is sartorius, and the tendon of gracilis which lies along its posterior border, both descending across the joint. Posterolaterally, the tendon of biceps and the common fibular nerve (which lies medial to the tendon) are in contact with the capsule, and thereby separated from the tendon of popliteus. Posteriorly the popliteal artery and associated lymph nodes lie posterior to the oblique popliteal ligament; the popliteal vein is posteromedial or medial, and the tibial nerve is posterior to both. The nerve and vessels are overlapped by both heads of gastrocnemius and laterally by plantaris. Gastrocnemius contacts the capsules on either side of the vessels. Semimembranosus lies between the capsule and semitendinosus, medial to the medial head of gastrocnemius.

Factors maintaining stability

The control of the stability of the knee is of considerable importance.

Patellofemoral joint

The alignment of the femoral and tibial shafts is such that the pull of the quadriceps on the patella imparts a force on the patella that is directed both superiorly and laterally. The static bony factors that counter this tendency to move laterally are the congruity of the patellofemoral joint and the buttressing effect of the larger lateral part of the trochlear groove. Instability may result if the patella is small, or resides too high above the trochlea, or if the trochlear groove is too shallow. The static ligamentous factors are the medial patellofemoral ligament and medial patellar retinaculum.

Dynamic muscular control is important. The most distal part of vastus medialis (vastus medialis obliquus) consists of transverse fibres that are attached directly to the medial edge of the patella: these pull the patella medially, countering the tendency to lateral movement. This is the muscle that is preferentially strengthened in a physiotherapy programme aimed at treating patellofemoral problems.

Tibiofemoral joint

The tibiofemoral joint surfaces are inherently unstable, especially laterally. Medially some stability is afforded by the relatively concave tibial surface and the relatively fixed posterior horn of the medial meniscus. Both medially and laterally the menisci are helpful, particularly as they move with the femoral condyles. Ligaments play a major role in providing stability: their function is partly static, in that they bind the bones in positions of extreme stress, but they also provide proprioceptive feedback which aids coordination of stabilizing muscle activity. Taking a somewhat ‘two-dimensional’ view, the medial and lateral collateral ligaments may be considered as resistors of valgus and varus forces on the knee respectively, and the anterior and posterior cruciate ligaments as resistors of anterior and posterior tibial translation respectively. However in reality the situation is more complex than this. The stresses are rarely applied in orthogonal planes and so a combination of forces, especially rotational, is involved. Moreover, many structures other than the collateral and cruciate ligaments are involved in stabilizing the joint. The ‘posterolateral corner’, which resists tibial external rotation, consists of the popliteofibular, fabellofibular, arcuate, and lateral collateral ligaments and iliotibial band, together with popliteus, the lateral head of gastrocnemius and biceps femoris. The ‘posteromedial corner’, which resists tibial rotation, consists of the posterior oblique portion of the superficial medial collateral ligament, the capsule (including the oblique popliteal ligament) and semimembranosus. Since stresses are often a combination of force plus rotation, structures usually operate together rather than in isolation.

Loading at the knee

During level walking, the force across the tibiofemoral joint for most of the cycle is between two and four times body weight, and can be more. In contrast, the force across the patellofemoral joint is no more than 50% body weight. Peak force transmission across the joint increases sequentially as the menisci, articular cartilage and subchondral bone are damaged or removed. Walking up or down stairs has little influence on tibiofemoral forces, but significantly increases patellofemoral forces to two (walking up) or three (walking down) times body weight, reflecting the changed angle of the quadriceps tendon and patellar tendon during flexion. There are two mechanisms for ameliorating forces transmitted across the patella: the extensor lever arm is lengthened as the axis of rotation moves posteriorly during flexion, and the contact area between the patella and femur almost triples between 30° and 90°. To cope with the potential large forces generated by activities such as running, the patella has the thickest articular cartilage in the body.

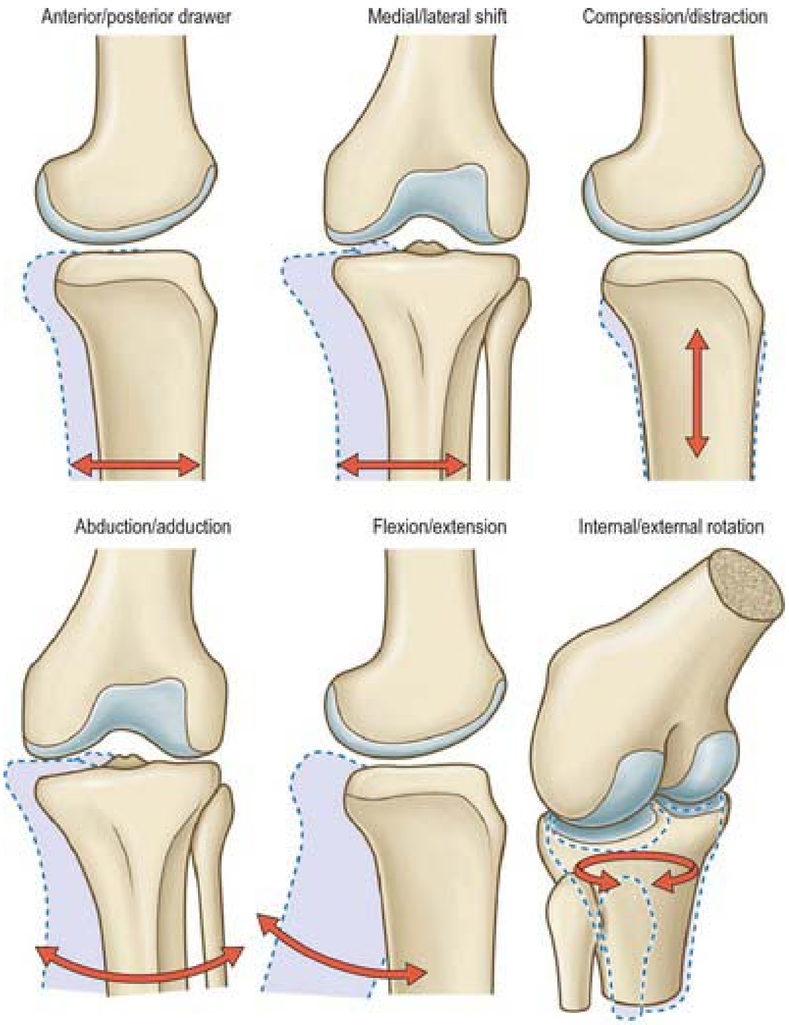
BIOMECHANICS OF THE KNEE

The knee joint is a complex synovial joint consisting of the tibiofemoral and patellofemoral articulations. It functions to control centre of body mass and posture in the activities of daily living. This necessitates a large range of movement in three dimensions coupled with the ability to withstand high forces. These conflicting parameters of mobility and stability are only achieved by the interactions between the articular surfaces, the passive stabilizers and the muscles that cross the joint.

The relatively incongruent nature of the joint surfaces makes the knee joint *inherently* unstable. In addition, because it acts as a pivot between the longest bones in the body, and is subjected to considerable loads in locomotion, the joint is also *potentially* unstable. The long bones may act as levers, increasing the stresses on the stabilizing ligaments.

KNEE JOINT KINEMATICS

The surfaces of the tibia and femur are not as conforming as those of the relatively congruent hip joint. Although this variation in geometry permits motion to occur in six degrees of freedom (Fig. 82.18), the primary motion of the knee occurs in the sagittal plane, and a relatively minor degree of movement occurs in the transverse plane. The knee joint may therefore be described simplistically as a modified hinge joint allowing flexion–extension and a measure of rotatory motion. Knee motion is normally defined as starting from 0° (the neutral position), when the tibia and femur are in line in the sagittal plane. Biomechanically, it is important that the knee reaches the neutral position in extension, because that allows the leg to support the body weight like a simple strut when standing still. When standing upright, if the knee is flexed, the vertical line of action of the body weight passes posterior to the centre of rotation of the knee, tending to cause the body to tilt posteriorly. To counterbalance this, continuous quadriceps contraction is required, causing expenditure of energy.



Anterior/posterior drawer
Medial/lateral shift
Compression/distraction
Abduction/adduction
Flexion/extension
Internal/external rotation

Fig. 82.18 Knee joint motion in three dimensions, which is described using six independent variables. These six variables are termed degrees of freedom.

Active knee flexion leads to approximately 130° flexion. The active motion is limited by apposition of the posterior soft tissue masses (thigh and calf). Passive flexion may reach 160°. This is required in people who habitually kneel as part of daily life, and is a challenge for designers of knee prostheses. It can be observed that such deep flexion is often accompanied by tibial internal rotation, so that when kneeling the buttocks can rest on the feet. This movement carries the lateral tibial plateau anteriorly, so that it does not engage with the femoral lateral condyle in deep knee flexion. The femoral condyle passes posteriorly and rides over the horn of the lateral meniscus.

The most frequently employed knee movement occurs when walking (Fig. 82.19). When the leg is swinging past the supporting leg, the knee must be flexed in order to avoid dragging the toes on the ground; this requires approximately 67° knee flexion. When the swinging leg approaches the first contact with the ground, the knee extends, to move the foot forwards for heel strike. If the knee remained extended, this would then cause the body to move in a circular arc, centred at the ankle, causing the centre of gravity to move upwards and then back down again, leading to more energy expenditure. It would also increase the forces on the knee, because the leg would act more like a rigid strut unable to dissipate the impact forces when the foot hit the ground. All these problems are overcome by the knee flexing 15° in the mid stance phase: the centre of gravity of the body can move forwards at approximately constant height, and the impact energy is absorbed by stretching the quadriceps (Fig. 82.19).

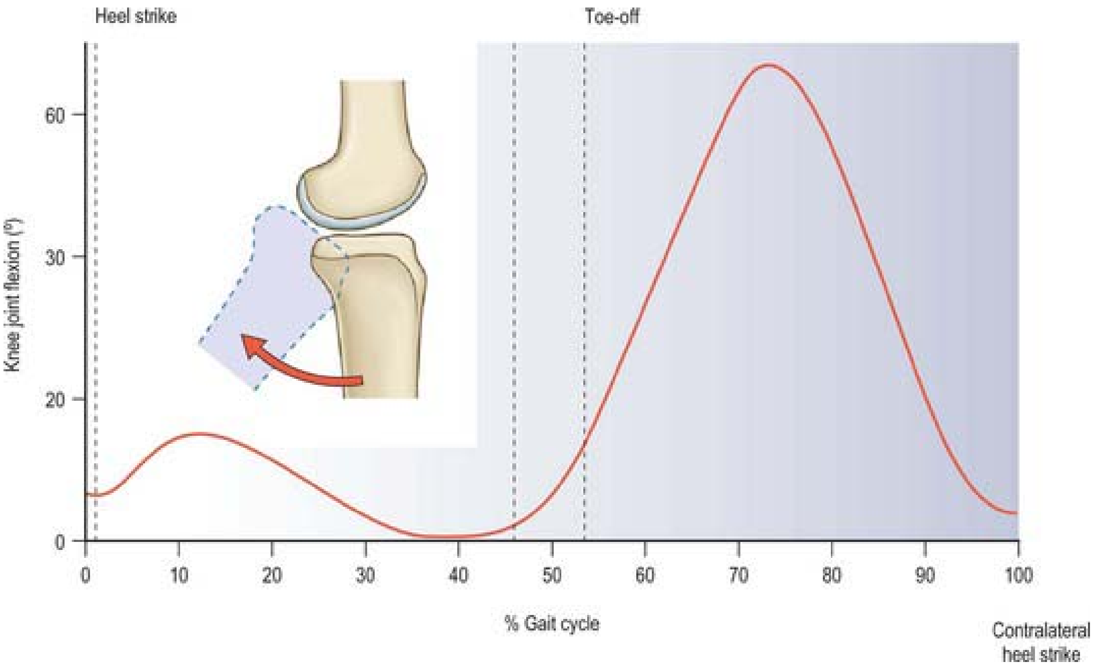


Fig. 82.19 Knee flexion–extension motion during gait.

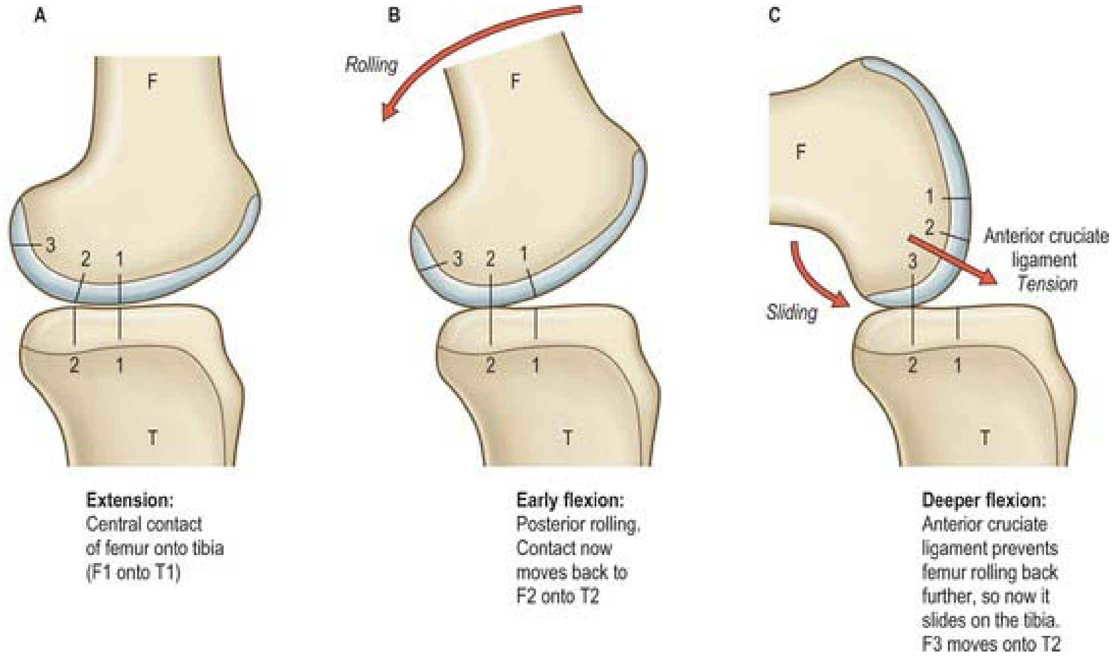
Tibial internal-external rotation also occurs during gait: the tibia rotates externally during terminal extension, a phenomenon known as ‘screw home’ (Fig. 82.20). It is surmised that this rotation helps to lock the geometry and tighten the soft tissues, thereby maintaining the knee in a stable position prior to the impact load of weight bearing. The knee acts as one link in a chain of limb segments, and this screw-home relates to rotation of both foot and hip. When the foot is swung forwards for heel strike, the pelvis rotates so that the hip is moved forwards, a movement that entails external rotation of the hip. During stance, the femur is internally rotated against the locked knee. Tibial external rotation also causes inversion of the foot at the subtalar joint, raising the arch and locking the structure of the foot. The knee flexion that occurs after the impact on the ground allows the tibia to rotate internally so that the foot everts, softening its structure and allowing it to deform and absorb energy. Conversely, towards toe-off, the knee extends, rotating the tibia externally, so the foot is again a rigid lever with which to push the body forwards.



Extension: Central contact of femur onto tibia (F1 onto T1)

Early flexion: Posterior rolling. Contact now moves back to F2 onto T2

Deeper flexion: Anterior cruciate ligament prevents femur rolling back further, so now it slides on the tibia. F3 moves onto T2

Fig. 82.20 Knee joint kinematics during gait: rolling and gliding (flexion, anterior translation).

Articular kinematics

We now consider knee motion at a smaller scale, within the joint. This, of course, is difficult to separate from the actions of the ligaments that act as passive restraints to tibiofemoral joint movements, and are discussed below.

Sagittal sections of the knee reveal that the arcs of the femoral condyles are much longer than the anterior–posterior length of the tibial plateau. This means that if the knee flexed with a purely rolling motion, then the femur would roll off of the back of the tibia long before the knee reaches full flexion (Fig. 82.20). This does not happen because the femur slides anteriorly at the same time as it rolls posteriorly, and thus remains in correct articulation. If the knee were to possess a fully conforming roller-in-trough geometry, as in the humeroulnar joint, then flexion would occur by pure sliding movement between the joint surfaces. This conformity is not possible at the knee because it would inhibit the tibial internal-external rotation that is needed during locomotion.

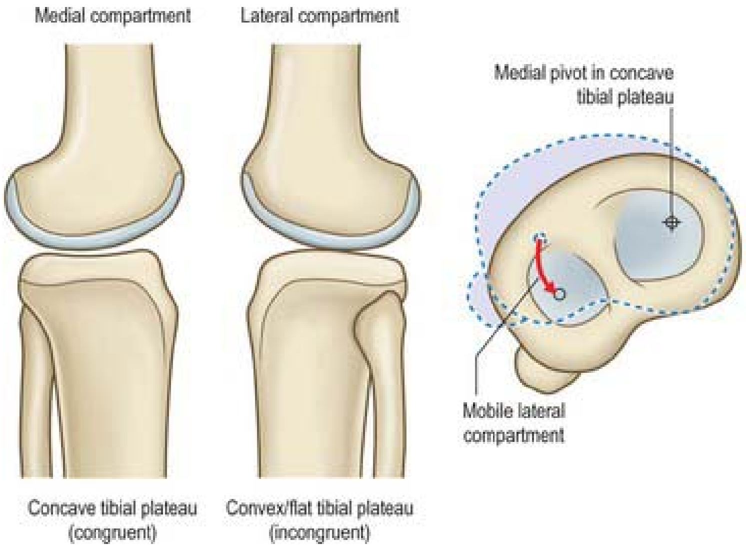
In the locked, fully-extended knee, the anterodistal femoral articular surfaces press onto the anterior horns of the menisci. This tends to cause the femur to slide posteriorly, tensing the ACL and slackening the PCL. With knee flexion, the femur lifts off of the anterior horns of the menisci, leading to contact between the smaller radii of the posterior parts of the femoral condyles, and the tibial plateau plus posterior horns of the menisci. This means that the centre of contact moves posteriorly in early knee flexion. After this, the femoral condyles have approximately circular sagittal sections. The femur is now prevented from rolling back any further by tension in the ACL. The action of the ACL is similar to that of a rope attaching the back of a car to the ground: when the car tries to drive away, the wheels roll until the rope tightens, and then spin in one position (sliding motion).

Articular mechanics

The combined effect of the external and internal loads on the knee is to impose considerable forces on the articular cartilage. This may be analysed into a vertical (compressive) component and a horizontal (shear or friction) component. The friction component is a combination of the compressive force and the friction characteristics of the joint surfaces.

Compression

The compressive force is distributed over an area to produce a contact pressure (contact stress). The contact pressure is, therefore, dependent on the area of contact as well as the load itself. Fully-conforming articular surface geometry would allow the greatest area of contact, and thus would minimize contact pressure, however, this is not present in the knee. The medial compartment of the knee is semi-conforming with a convex femoral condyle articulating over a concave medial tibial plateau. The lateral compartment has less conformity: the lateral tibial plateau is flat or slightly convex in sagittal sections. These different shapes reflect the differential movement of the medial and lateral compartments. In normal movement, the screw home rotation of the tibia occurs about a medial axis which means that most of the rotation of the tibia is due to an anterior–posterior translation of the lateral compartment (Fig. 82.21).



Medial compartment
Lateral compartment
Medial pivot in concave tibial plateau
Mobile lateral compartment
Concave tibial plateau (congruent)
Convex/flat tibial plateau (incongruent)

Fig. 82.21 The shape of the articular surfaces providing mobility of the lateral compartment.

In order to maintain some degree of conformity, and thus minimize contact pressure, the menisci have wedge-shaped cross-sections that fit between the femur and tibia around the bones. This serves to increase the area over which the compressive force on the knee is distributed. In the absence of the menisci, the load is carried by a much smaller area of cartilage, resulting in higher contact stresses on the articular cartilage. This explains the prevalence of osteoarthrosis following meniscectomy (Fig. 82.22).

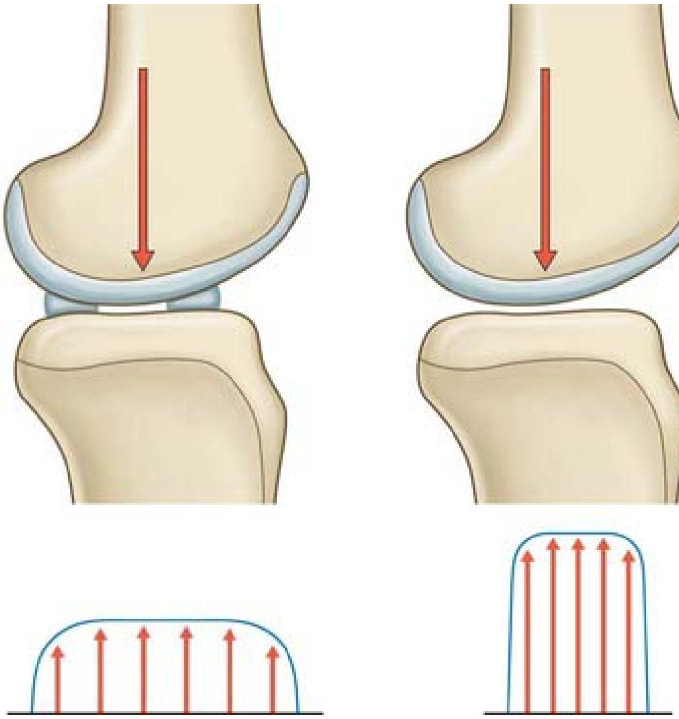


Fig. 82.22 The function of the menisci in increasing articular conformity, with increased peak pressure after meniscectomy.

The menisci are most firmly attached at the tibial intercondylar eminence and so they can translate anteriorly and posteriorly to ‘follow’ the femoral rollback. The lateral meniscus is more mobile, because it is attached to the capsule less tightly than the medial meniscus. The anterior–posterior movement of the menisci is approximately half the magnitude of the anterior–posterior movement of the femur, suggesting that the conformity of the joint changes during knee joint flexion.

The distal aspect of the femur, resting on the menisci in the extended knee, has a large radius of curvature, and so it fits against the entire area of the menisci. However, as the knee flexes, the smaller radii of the posterior parts of the femoral condyles cause the femur to lift off the anterior horns of the menisci, and the femoral contact is now solely on the posterior horns in the flexed knee. This, combined with the large joint forces that are generated when arising from a seated position, explains why there are often spontaneous tears of the posterior horns in older patients, when standing up from a squatting position.

The load-carrying mode of the menisci is shown in Fig. 82.23. When the femoral condyle presses down on the meniscus, it tends to squeeze the meniscus out of the joint, because of its tapered cross-section. This causes the diameter of the circular shape of the meniscus (and therefore the meniscal circumference) to increase. This is resisted by ‘hoop tension’ in strong fibres that pass around the periphery of the meniscus, and transmit the tension to the tibial plateau via strong insertional ligaments. Because the tissue is adapted to resist hoop stresses, it has much greater hoop strength (approximately 100 MPa) than radial strength (approximately 3 MPa), which explains why bucket handle tears occur. It also explains why a circumferential tear does not have such a serious effect on meniscal function, because the circumferential fibres can still transmit the loads, whereas a radial tear breaks the load-carrying fibres.

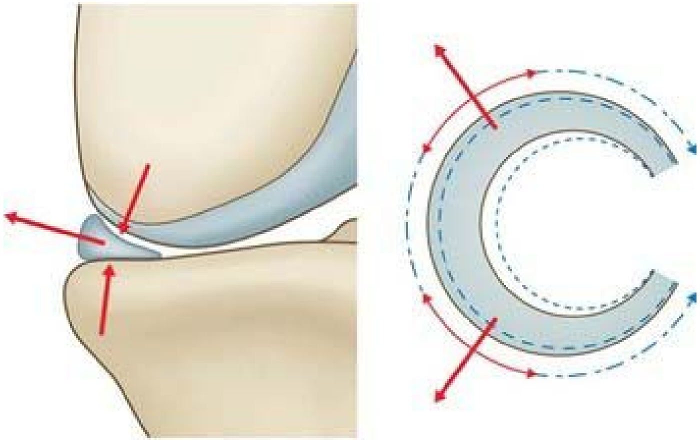

Fig. 82.23 The load-carrying mode of the menisci – conversion of axial load into meniscal hoop stresses.

Friction

The knee acts as a bearing that transmits forces and movements between the limb segments. Load-bearing synovial joints move with remarkably little friction, and their surfaces must withstand many millions of impact loads which tend to cause fatigue failure and breakdown of the surfaces.

During walking, every step involves phases of action that vary the loading and velocity conditions at the knee joint. A variety of lubrication mechanisms normally prevent joint surface damage. Thus, in the swing phase, when the foot is off the ground, the joint surfaces are loaded lightly, and have high relative velocity while the knee flexes and extends. This allows the synovial fluid to separate the surfaces, giving fluid film lubrication, with very low friction and no wear (Fig. 82.24). At the time of heel strike, a large impact load acts to compress the surfaces together. At a microscopic level, the surfaces do not come into contact, because of the squeeze film effect: in essence, the impact occurs so rapidly (less than 0.1 sec) that the synovial fluid cannot all be squeezed out of the joint space, because of its viscosity and the narrowness of the space. In the mid stance phase, the flexion–extension motion again entrains the synovial fluid in between the joint surfaces, producing what is known as a hydrodynamic effect: the fluid is trapped between the surfaces by the motion, and therefore it acts to separate them. Finally, when the foot is pushing off the body weight, there is little motion, and the thin fluid film diminishes under the compressive load. If the squeeze-film effect is insufficient, then the joint surfaces would now come into direct contact, were it not for the fact that the synovial fluid contains large protein molecules that are trapped on the cartilage surfaces when the fluid is expelled. This molecular layer acts as a boundary lubricant, protecting the cartilage in the same way that grease protects a synthetic bearing.

Many aspects of the arthritic breakdown of the cartilage can be explained on the basis of lubrication biomechanics. Thus, in joints affected by osteoarthrosis, synovial fluid is known to have a lower viscosity than that in normal joints. The viscosity is lower still in rheumatoid joints, and unable to prevent attritional damage to the cartilage surfaces.

SOFT-TISSUE MECHANICS

The knee joint relies on active (musculotendinous) and passive (ligamentous) restraints to maintain its stability. The muscles provide the loading to move the joint. The quadriceps, hamstrings and gastrocnemius control both flexion/extension and internal–external rotation. However, they also cause anterior–posterior shear forces that are resisted primarily by the cruciate ligaments. This tethering effect is critical in allowing the joint to move physiologically, maintaining congruency and stability.

The passive stabilizers of the joint act by resisting unwanted displacements between the bones. This may be to control the path of motion, or to limit the range of motion. When the muscles or some other external force (due to bodyweight or impact) cause the bones to displace, the ligaments are stretched, and so develop tensile forces that resist the displacement and allow the joint to maintain its stability. Disruption of any of these passive restraints may cause a mechanical instability, which is an abnormally increased displacement due to an applied force (in biomechanical terms this is called excess laxity).

Primary and secondary restraints

On testing the laxity in any of the degrees of freedom of the joint (e.g. in the anterior drawer test, a bedside clinical test in which the subject is placed in the supine position with the knee to be tested flexed to 80–90° before passive forward traction is applied to the tibia), there are usually combinations of ligaments that are tensed. Some of these are better aligned to resist the applied load or displacement. These are termed primary restraints, and are exemplified by the cruciate ligaments and the medial and lateral collateral ligaments. Secondary restraints are less well-aligned, but still have a significant restraining effect. These are exemplified by the menisci, and by the meniscofemoral ligaments. In the example in Fig. 82.25, the ACL is well-aligned to resist the applied anterior drawer force. With an absent ACL, the superficial MCL can resist the applied force, however, it does so by being loaded to a much higher level than the original loading on the ACL. The size of the lines in the vector diagram demonstrate this principle: although joint laxity may remain normal initially following rupture of a primary restraint, it may subsequently result in the overload of a secondary restraint, and ultimately, in further soft-tissue failure.

Fig. 82.25 Primary and secondary restraints to anteroposterior forces – example of the ACL and superficial MCL.

The patellofemoral joint is most heavily loaded during weight-bearing activities when the knee is flexed. Analyses of rising from a chair have predicted that the patellar tendon tension at 90° flexion may then be 2.9 BW, and so the joint force will be 5.5 BW. This is higher than the tibiofemoral joint, which is loaded to 3.3 BW at the same time (Amis & Farahmand 1996).

In the frontal plane the quadriceps muscles and patellar tendon tensions combine to cause a lateralizing force vector termed the Q-angle effect. The Q angle is defined as the difference between the resultant force vector of the quadriceps, which is normally parallel to the femoral shaft, and the patellar tendon (Fig. 82.26). Clinically, the Q angle is changed by the position of hip rotation, tibial rotation, and quadriceps tension. The clinical Q-angle is 12–15° (males) and 15–18° (females), which means that there is a greater lateralizing force vector on the patellofemoral joint in females. Contraction of the quadriceps, therefore, tends to displace the patella laterally; this is resisted by the geometry of the joint and by the passive stabilizers. Vastus medialis obliquus (VMO) acts medially and posteriorly as much as it acts proximally, and so its tension helps to resist the Q angle effect.

MUSCLES

The majority of muscles that act on the knee joint are described in either Chapter 80 (quadriceps femoris, semimembranosus, biceps femoris, semitendinosus, articularis genu) or Chapter 83 (gastrocnemius). Popliteus is described below.

Popliteus

Attachments

Popliteus is a flat muscle that forms the floor of the lower part of the popliteal fossa. It arises within the capsule of the knee joint by a strong tendon, 2.5 cm long, which is attached to a depression at the anterior end of the groove on the lateral aspect of the lateral condyle of the femur. Medially this tendon is joined by collagenous fibres from the arcuate popliteal ligament, from the fibrous capsule adjacent to the lateral meniscus, and from the outer margin of the meniscus.

Popliteus is attached to the medial aspect of the fibular head by the popliteofibular ligament, which passes laterally and inferiorly from the popliteus tendon in a sheet of tissue that is normally about 2 cm^2. This ligament is the single most important stabilizer of the posterolateral region of the knee and resists external rotation of the tibia on the femur. Failure to recognize and reconstruct damage to this ligament and to the related ligamentous structures is the most common reason for a poor result from an otherwise well-performed operation for repair of ruptured cruciate ligaments.

Fleshy fibres expand from the inferior limit of the tendon to form a somewhat triangular muscle that descends medially to be inserted into the medial two-thirds of the triangular area above the soleal line on the posterior surface of the tibia, and into the tendinous expansion that covers its surface.

An additional head may arise from the sesamoid in the lateral head of gastrocnemius. Very rarely, two other muscles may be found deeply situated behind the knee. Popliteus minor runs from the posterior surface of the lateral tibial condyle, medial to plantaris, to the oblique popliteal ligament.

Peroneotibialis runs deep to popliteus from the medial side of the fibular head to the upper end of the soleal line.

Relations

Popliteus is covered posteriorly by a dense aponeurotic expansion, which is largely derived from the tendon of semimembranosus. Gastrocnemius, plantaris, the popliteal vessels and the tibial nerve all lie posterior to the expansion. The popliteal tendon is intracapsular and is deep to the fibular collateral ligament of the knee and the tendon of biceps femoris. It is invested on its deep surface by synovial membrane, and grooves the posterior border of the lateral meniscus and the adjoining part of the tibia before it emerges inferior to the posterior band of the arcuate ligament. This region is called the ‘popliteus hiatus’: the lateral meniscus has no peripheral bony attachment here, and is therefore rather mobile.

Vascular supply

The arterial supply of popliteus is derived mainly from the medial and lateral inferior genicular arteries. The latter may cross superficial or deep to the muscle. There are additional contributions from the nutrient artery to the tibia, the proximal part of the tibial artery and from the posterior tibial recurrent artery.

Innervation

Popliteus is innervated by a branch of the tibial nerve (L4 and 5 and S1) which winds around the distal border of popliteus and enters the anterior surface of the muscle; this nerve also innervates the superior tibiofibular joint and the crural interosseous membrane.

Actions

Popliteus rotates the tibia medially on the femur or, when the tibia is fixed, rotates the femur laterally on the tibia. It is usually regarded as the muscle that ‘unlocks’ the joint at the beginning of flexion of the fully extended knee: electromyography supports this view. Its connection with the arcuate popliteal ligament, fibrous capsule and lateral meniscus has led to the suggestion that popliteus may retract the posterior horn of the lateral meniscus during lateral rotation of the femur and flexion of the knee joint, thus protecting the meniscus from being crushed between the femur and the tibia during these movements. The muscle is markedly active in crouching, perhaps to provide stability as the tibia rotates internally during flexion of the knee. However, the main function is likely to be provision of dynamic stability to the posterolateral part of the knee by preventing excessive external rotation of the tibia, partly by its direct action, but more significantly by tensing the popliteofibular ligament.

Testing

Popliteus plays a part in medially rotating the leg when the knee is flexed and non-weightbearing, but its individual actions cannot be isolated clinically. Damage to the popliteus complex of ligament and tendon is manifest as excessive external rotation of the tibia on the femur at 90° and especially at 30° of knee flexion., reflecting the function of the popliteus complex as a ‘static tether’.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIES

There is an intricate arterial anastomosis around the patella and femoral and tibial condyles. A superficial network spreads between the fascia and skin around the patella and in the fat deep to the patellar tendon. A deep network lies on the femur and tibia near the adjoining articular surfaces, and supplies the bone and marrow, the articular capsule, synovial membrane and the cruciate ligaments (Fig. 82.1). The vessels involved are the superior, middle and inferior genicular branches of the popliteal artery, descending genicular branches of the femoral artery, the descending branch of the lateral circumflex femoral artery, the circumflex fibular artery and the anterior and posterior tibial recurrent arteries. For details consult Scapinelli (1968).

Popliteal artery

The popliteal artery is the continuation of the femoral artery and crosses the popliteal fossa (Fig. 82.4). It descends laterally from the opening in adductor magnus to the femoral intercondylar fossa, inclining obliquely to the distal border of popliteus, where it divides into the anterior and posterior tibial arteries. This division usually occurs at the proximal end of the asymmetrical crural interosseous space between the wide tibial metaphysis and the slender fibular metaphysis. The artery is relatively tethered at the adductor magnus hiatus and again distally by the fascia related to soleus, and is therefore susceptible to traction damage in knee injuries, e.g. dislocation.

Variations in arterial anatomy of lower limb

Most anatomical variations in the arterial pattern of the lower limb arteries are apparently symptomless and cause no clinically detectable functional impairment. They are usually incidental findings in the dissection room, or may come to light in the course of angiographic examination. However, some variations in vascular anatomy may be the cause of symptoms and may necessitate surgical correction, and other variations, while asymptomatic, may influence technical considerations in vascular surgical procedures.

Anatomical variations in the femoral, profunda femoris, anterior tibial, posterior tibial and fibular arteries have been described elsewhere in this section.

Variations in the popliteal artery

Several cadaveric studies have shown that the pattern and level of termination of the popliteal artery described above occurs in the majority (90%) of subjects. However, the artery may occasionally (5%) show a high bifurcation, and divide into its terminal branches proximal to popliteus, or it may trifurcate into anterior and posterior tibial and fibular arteries. Either the anterior tibial or the posterior tibial artery may be reduced or increased in size. The size of the fibular artery is usually inversely related to the size of the anterior and posterior tibial arteries, either of whose functions the fibular artery may assume. Rarely, the anterior tibial artery is the source of the fibular artery; almost always this is associated with a high bifurcation of the popliteal artery.

The popliteal artery may be a continuation, not of the femoral artery, but of the sciatic artery (a branch of the inferior gluteal artery). When this occurs, the popliteal artery usually has an abnormal relationship to popliteus, running deep to the muscle before dividing into its terminal branches. The popliteal artery may pass medially beneath the medial head of gastrocnemius, or may pass beneath an aberrant band of muscle in the popliteal fossa: in either case, contraction of the muscles may occlude the artery. This condition, known as popliteal artery entrapment, may present with claudication on exercise in a young male patient. The popliteal vein is usually superficial and adjacent to the artery, but it may run deep to the artery, or be separated from it by a slip of muscle derived from the medial head of gastrocnemius.

Relations

Anteriorly, from proximal to distal, are fat covering the femoral popliteal surface, the capsule of the knee joint, and the fascia of popliteus. Posteriorly are semimembranosus (proximally) and gastrocnemius and plantaris (distally). In between, the artery is separated from the skin and fasciae by fat and crossed from its lateral to its medial side by the tibial nerve and popliteal vein: the vein lies between the nerve and artery and is adherent to the latter. Laterally are biceps femoris, the tibial nerve, popliteal vein and lateral femoral condyle (all proximal), and plantaris and the lateral head of gastrocnemius (distal). Medially are semimembranosus and the medial femoral condyle (proximal), and the tibial nerve, popliteal vein and medial head of gastrocnemius (distally). The relations of the popliteal lymph nodes are described below.

Branches (other than terminal)

Genicular anastomosis

There is an intricate arterial anastomosis around the patella and femoral and tibial condyles (Fig. 82.1). A superficial network spreads between the fascia and skin around the patella and in the fat deep to the patellar tendon. A deep network lies on the femur and tibia near the adjoining articular surfaces, and supplies the bone and marrow, articular capsule and synovial membrane. The vessels involved are the medial and lateral superior genicular, the medial and lateral inferior genicular, the descending genicular, the descending branch of the lateral circumflex femoral, the circumflex fibular and the anterior and posterior tibial recurrent arteries.

Superior genicular arteries

The superior genicular arteries branch from the popliteal artery, curving round proximal to both femoral condyles to reach the anterior aspect of the knee. The medial superior genicular artery lies under semimembranosus and semitendinosus, proximal to the medial head of gastrocnemius and deep to the tendon of adductor magnus. It divides into a branch to vastus medialis that anastomoses with the descending genicular and medial inferior genicular arteries, and a branch that ramifies on the femur and anastomoses with the lateral superior genicular artery. Its size varies inversely with that of the descending genicular artery. The lateral superior genicular artery passes under the tendon of biceps femoris and divides into superficial and deep branches. The superficial branch supplies vastus lateralis and anastomoses with the descending branch of the lateral circumflex femoral and lateral inferior genicular arteries, while the deep branch anastomoses with the medial superior genicular artery, forming an anterior arch across the femur with the descending genicular artery. The superficial branch is vulnerable if the lateral patellar retinaculum is divided surgically.

Middle genicular artery

The middle genicular artery is small. It arises from the popliteal artery near the midpoint of the posterior aspect of the knee joint. It pierces the oblique popliteal ligament to supply the cruciate ligaments and synovial membrane.

Inferior genicular arteries

The medial and lateral inferior genicular arteries arise from the popliteal artery deep to gastrocnemius. The medial is deep to the medial head of gastrocnemius. It descends along the proximal margin of popliteus, which it supplies, passes inferior to the medial tibial condyle, under the medial collateral ligament, and then ascends anteromedial to the joint at the anterior border of the medial collateral ligament. It supplies the joint and the tibia, and anastomoses with the lateral inferior and medial superior genicular arteries and with the anterior tibial recurrent artery and saphenous branch of the descending genicular artery. The lateral inferior genicular artery runs laterally across popliteus and forwards over the fibular head to the front of the knee joint, passing under the lateral head of gastrocnemius, the fibular collateral ligament and the tendon of biceps femoris. Its branches anastomose with the medial inferior and lateral superior genicular, anterior and posterior tibial recurrent and circumflex fibular arteries.

Cutaneous branches: the superficial sural arteries

The superficial sural arteries are three vessels which leave the popliteal artery, or its side branches, descend between the heads of gastrocnemius and perforate the deep fascia to supply the skin on the back of the leg. The central or median vessel is usually larger than the medial and lateral, and usually accompanies the sural nerve.

Fasciocutaneous free and pedicled flaps may be raised on the superficial sural arteries.

Superior muscular branches

The superior muscular branches are two or three vessels that arise proximally and pass to adductor magnus and the hamstrings. They anastomose with the termination of the profunda femoris artery.

Sural arteries

The two sural arteries are large and arise behind the knee joint to supply gastrocnemius, soleus and plantaris. They are used in gastrocnemius musculocutaneous flaps.

VEINS

The veins draining the knee correspond in name to the arteries and run with them; the named smaller veins drain into the popliteal and femoral veins.

Popliteal vein

The popliteal vein ascends through the popliteal fossa to the opening in adductor magnus where it becomes the femoral vein (see Fig. 79.9B). Its relationship to the popliteal artery changes as the vein ascends. Distally it is medial to the artery, between the heads of gastrocnemius it is superficial (posterior) to it, and proximal to the knee joint it is posterolateral to the artery. Its tributaries are the short saphenous vein, veins corresponding to branches of the popliteal artery, and muscular veins, including a large branch from each head of gastrocnemius. There are usually four or five valves in the popliteal vein.

Long saphenous vein

The course of the long saphenous vein is described in Chapter 80.

Short saphenous vein

The short saphenous vein (small saphenous vein) begins posterior to the lateral malleolus as a continuation of the lateral marginal vein (see Fig. 79.9B). In the lower third of the calf it ascends lateral to the calcaneal tendon, lying on the deep fascia and covered only by superficial fascia and skin. Inclining medially to reach the midline of the calf, it penetrates the deep fascia, within which it ascends on gastrocnemius, only emerging between the deep fascia and gastrocnemius gradually at about the junction of the intermediate and proximal thirds of the calf (usually well below the lower limit of the popliteal fossa). Continuing its ascent, it passes between the heads of gastrocnemius then proceeds to its termination in the popliteal vein in the popliteal fossa, 3–7.5 cm above the knee joint.

Tributaries

The short saphenous vein connects with deep veins on the dorsum of the foot, receives many cutaneous tributaries in the leg, and sends several communicating branches proximally and medially to join the long saphenous vein. Sometimes a communicating branch ascends medially to the accessory saphenous vein: this may be the main continuation of the short saphenous vein. In the leg the short saphenous vein lies near the sural nerve. It has 7–13 valves, one near its termination. Its mode of ending is variable: it may join the long saphenous vein in the proximal thigh or it may bifurcate, one branch joining the long saphenous, the other the popliteal or deep posterior femoral veins. Sometimes it ends distal to the knee in the long saphenous or deep sural muscular veins.

LYMPHATIC DRAINAGE

Lymphatic drainage is to the popliteal lymph nodes. Most of the lymph vessels accompany the genicular arteries; some vessels from the joint drain directly into a node between the popliteal artery and the posterior capsule.

Popliteal lymph nodes

There are usually six small lymph nodes embedded in the fat of the popliteal fossa. One, near the termination of the short saphenous vein, drains the superficial region served by the vein. Another lies between the popliteal artery and the posterior aspect of the knee joint, receiving direct vessels from the knee joint and those accompanying the genicular arteries. The remainder flank the popliteal vessels, receiving trunks that accompany the anterior and posterior tibial vessels. Popliteal efferents ascend close to the femoral vessels to reach the deep inguinal nodes; some may accompany the long saphenous vein to the superficial inguinal nodes.

Inflammation of the popliteal nodes is often caused by lateral lesions of the heel.

INNERVATION

The knee joint is innervated by branches from the obturator, femoral, tibial and common fibular nerves (Freeman & Wyke 1967). The genicular branch of the obturator nerve is the terminal branch of its posterior division. Muscular branches of the femoral nerve, especially to vastus medialis, supply terminal branches to the joint. Genicular branches from the tibial and common fibular nerves accompany the genicular arteries: those from the tibial nerve run with the medial and middle genicular arteries, while those from the common fibular nerve run with the lateral genicular and anterior tibial recurrent arteries.

The femoral and obturator nerves are described on page 1382–1383, and the tibial and common fibular nerves are described on page 1427).

Saphenous nerve

The saphenous nerve is the largest and longest cutaneous branch of the femoral nerve. It descends lateral to the femoral artery in the femoral triangle and enters the adductor canal, where it crosses in front of the artery to lie medial to the artery. At the distal end of the canal it leaves the artery and emerges through the aponeurotic covering with the saphenous branch of the descending genicular artery. As it leaves the adductor canal it gives off an infrapatellar branch that contributes to the peripatellar plexus (p. 1393) and then pierces the fascia lata between the tendons of sartorius and gracilis, becoming subcutaneous to supply the prepatellar skin. It descends along the medial tibial border with the long saphenous vein and divides distally into a branch which continues along the tibia to the ankle and a branch which passes anterior to the ankle to supply the skin on the medial side of the foot, often as far as the first metatarsophalangeal joint. The saphenous nerve connects with the medial branch of the superficial fibular nerve. Near midthigh, it gives a branch to the subsartorial plexus. The nerve may be subject to an entrapment neuropathy as it leaves the adductor canal.

CHAPTER 83

Leg

This chapter describes the shafts of the tibia and fibula, the soft tissues that surround them and the interosseous membrane between them. The superior (proximal) and inferior (distal) tibiofibular joints are described in Chapters 82 and 84 respectively.

SKIN AND SOFT TISSUE

SKIN

Vascular supply and lymphatic drainage

The cutaneous arterial supply is derived from branches of the popliteal, anterior tibial, posterior tibial and fibular vessels (see Fig. 79.5). Multiple fasciocutaneous perforators from each vessel pass along intermuscular septa to reach the skin; musculocutaneous perforators traverse muscles before reaching the skin. In some areas there is an additional direct cutaneous supply from vessels that accompany cutaneous nerves, e.g. the descending genicular artery (saphenous artery) and superficial sural arteries. Fasciocutaneous and direct cutaneous branches have a longitudinal orientation in the skin, whereas the musculocutaneous branches are more radially oriented. For further details consult Cormack & Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic vessels running on the medial side of the leg accompany the long saphenous vein, and drain to the superficial inguinal nodes, while those from the lateral and posterior sides of the leg accompany the short saphenous vein and pierce the deep fascia to drain into the popliteal nodes.

Innervation

The skin of the leg is supplied by branches of the saphenous, common fibular and tibial nerves (see below and Figs 79.17; 79.20).

SOFT TISSUE

Deep fascia

The deep fascia of the leg, the fascia cruris, is continuous with the fascia lata and is attached around the knee to the patellar margin, the patellar tendon, the tuberosity and condyles of the tibia, and the head of the fibula. Posteriorly, where it covers the popliteal fossa as the popliteal fascia, it is strengthened by transverse fibres and often perforated by the short saphenous vein and sural nerve. It receives lateral expansions from the tendon of biceps femoris and multiple medial expansions from the tendons of sartorius, gracilis, semitendinosus and semimembranosus. The deep fascia blends with the periosteum on the subcutaneous surface of the tibia and the subcutaneous surfaces of the fibular head and malleolus, and is continuous below with the extensor and flexor retinacula. It is thick and dense in the proximal and anterior part of the leg, where fibres of tibialis anterior and extensor digitorum longus are attached to its deep surface, and is thinner posteriorly where it covers gastrocnemius and soleus. On the lateral side it is continuous with the anterior and posterior crural intermuscular septa, which are attached to the anterior and posterior borders of the fibula respectively. A broad transverse intermuscular septum, the deep transverse fascia of the leg, passes between the superficial and deep muscles in the calf.

Deep transverse fascia

The deep transverse fascia of the leg is a fibrous stratum between the superficial and deep muscles of the calf. It extends transversely from the medial margin of the tibia to the posterior border of the fibula. Proximally, where it is thick and dense, it is attached to the soleal ridge of the tibia and to the fibula, inferomedial to the fibular attachment of soleus. Between these bony attachments it is continuous with the fascia covering popliteus which is, in effect, an expansion from the tendon of semimembranosus. At intermediate levels it is thin, but distally, where it covers the tendons behind the malleoli, it is thick and continuous with the flexor and superior fibular retinacula.

Interosseous membrane

The interosseous membrane connects the interosseous borders of the tibia and fibula (Fig. 83.1). It is interposed between the anterior and posterior groups of crural muscles; some members of each group are attached to the corresponding surface of the interosseous membrane. The anterior tibial artery passes forwards through a large oval opening near the proximal end of the membrane, and the perforating branch of the fibular artery pierces it distally. Its fibres are predominantly oblique and most descend laterally; those which descend medially include a bundle at the proximal border of the proximal opening. The membrane is continuous distally with the interosseous ligament of the distal tibiofibular joint. Tibialis anterior, extensor digitorum longus, extensor hallucis longus, fibularis tertius, the anterior tibial vessels and deep fibular nerve are all anterior to the membrane, and tibialis posterior and flexor hallucis longus are posterior.

Retinacula

The retinacula at the ankle joint are described in Chapter 84.

Osteofascial compartments

The compartments of the leg are particularly well defined and are the most common sites at which osteofascial compartment syndromes occur. The three main compartments are anterior (extensor), lateral (fibular) and posterior (flexor). They are enclosed by the unyielding deep fascia (fascia cruris) and separated from each other by the bones of the leg and interosseous membrane and by the anterior and posterior intermuscular septa that pass from the deep fascia to the fibula. The anterior compartment, the least expansile of the three, is bounded by the deep fascia, the interosseous surfaces of the tibia and fibula, the interosseous membrane and the anterior intermuscular septum. The lateral compartment lies between the anterior and posterior intermuscular septa, and is bordered laterally by the deep fascia and medially by the lateral surface of the fibula. The posterior compartment is bounded by the deep fascia, the posterior intermuscular septum, the fibula and tibia and the interosseous membrane. Its relatively expansile superficial component is separated from the compacted deep component by the deep transverse fascia, reinforced by the deep aponeurosis of soleus.

The nerve supply of the muscles in the compartments follows the ‘one compartment – one nerve’ principle: the deep fibular nerve supplies the anterior compartment, the superficial fibular nerve supplies the lateral compartment, and the tibial nerve supplies the posterior compartment. Most of the muscles in the anterior compartment are supplied by the anterior tibial artery, with an additional contribution from the fibular artery to extensor hallucis longus. Muscles in the posterior compartment are supplied by the popliteal, posterior tibial and fibular arteries. Muscles in the lateral compartment are supplied by the anterior tibial and fibular arteries, and to a small extent proximally by a branch from the popliteal system.

Trauma and soft tissues of the leg

The relative paucity of soft tissue in the shin region and the subcutaneous position of the medial surface of the tibia means that even trivial soft tissue injury may lead to serious problems such as ulceration and osteomyelitis. In the elderly these soft tissues are often especially thin and unhealthy, reflecting the effects of ageing and venous stasis (see below). Tibial fractures are common in the young and, partly as a result of poor soft tissue coverage, they are often open injuries. Diminished blood supply to the bone, caused by traumatic stripping of attached soft tissues, and the risk of contamination add greatly to the risk of non-union and infection of the fracture. Healing of fractures at the junction of the middle and lower thirds of the tibia is compromised by the relatively poor blood supply to this region.

BONE

TIBIA

The tibia lies medial to the fibula and is exceeded in length only by the femur (Figs 83.2, 83.3). Its shaft is triangular in section and has expanded ends; a strong medial malleolus projects distally from the smaller distal end. The anterior border of the shaft is sharp and curves medially towards the medial malleolus. Together with the medial and lateral borders it defines the three surfaces of the bone. The exact shape and orientation of these surfaces show individual and racial variations.

Proximal end

The expanded proximal end is a bearing surface for body weight, which is transmitted through the femur. It consists of medial and lateral condyles, an intercondylar area and the tibial tuberosity.

Condyles

The tibial condyles overhang the proximal part of the posterior surface of the shaft. Both condyles have articular facets on their superior surfaces that are separated by an irregular, non-articular intercondylar area. The condyles are visible and palpable at the sides of the patellar tendon, the lateral being more prominent. In the passively flexed knee the anterior margins of the condyles are palpable in fossae that flank the patellar tendon.

The fibular facet on the posteroinferior aspect of the lateral condyle faces distally and posterolaterally. The angle of inclination of the superior tibiofibular joint varies between individuals, and may be horizontal or oblique. Superomedial to it the condyle is grooved on its posterolateral aspect by the tendon of popliteus; a synovial recess intervenes between the tendon and bone. The anterolateral aspect of the condyle is separated from the lateral surface of the shaft by a sharp margin for the attachment of deep fascia. The distal attachment of the iliotibial tract makes a flat but definite marking, Gerdy's tubercle, on its anterior aspect. This tubercle, which is triangular and facet-like, is usually palpable.

The anterior condylar surfaces are continuous with a large triangular area whose apex is distal and formed by the tibial tuberosity. The lateral edge is a sharp ridge between the lateral condyle and lateral surface of the shaft. The condyles, their articular surfaces and the intercondylar area are described in Chapter 82.

Tibial tuberosity

The tibial tuberosity is the truncated apex of a triangular area where the anterior condylar surfaces merge. It projects only a little, and is divided into a distal rough and a proximal smooth region. The distal region is palpable and is separated from skin by the subcutaneous infrapatellar bursa. A line across the tibial tuberosity marks the distal limit of the proximal tibial growth plate (Fig. 83.2). The patellar tendon is attached to the smooth bone proximal to this, its superficial fibres reaching a rough area distal to the line. The deep infrapatellar bursa and fibroadipose tissue intervene between the bone and tendon proximal to its site of attachment. The latter may be marked distally by a somewhat oblique ridge, onto which the lateral fibres of the patellar tendon are inserted more distally than the medial fibres. (This knowledge is necessary to avoid damaging the tendon when sawing the tibia transversely just above the tibial tuberosity in a lateral to medial direction, e.g. in performing an osteotomy.) In habitual squatters a vertical groove on the anterior surface of the lateral condyle is occupied by the lateral edge of the patellar tendon in full flexion of the knee.

Shaft

The shaft is triangular in section and has (antero)medial, lateral and posterior surfaces separated by anterior, lateral (interosseous) and medial borders. It is narrowest at the junction of the middle and distal thirds, and expands gradually towards both ends. The anterior border descends from the tuberosity to the anterior margin of the medial malleolus and is subcutaneous throughout. Except in its distal fourth, where it is indistinct, it is a sharp crest. It is slightly sinuous, and turns medially in the distal fourth. The interosseous border begins distal and anterior to the fibular facet and descends to the anterior border of the fibular notch; it is indistinct proximally. The interosseous membrane is attached to most of its length, connecting tibia to fibula. The medial border descends from the anterior end of the groove on the medial condyle to the posterior margin of the medial malleolus. Its proximal and distal fourths are ill defined but its central region is sharp and distinct.

The anteromedial surface, between the anterior and medial borders, is broad, smooth and almost entirely subcutaneous. The lateral surface, between the anterior and interosseous borders, is also broad and smooth. It faces laterally in its proximal three-fourths and is transversely concave. Its distal fourth swerves to face anterolaterally, on account of the medial deviation of the anterior and distal interosseous borders. This part of the surface is somewhat convex. The posterior surface, between the interosseous and medial borders, is widest above, where it is crossed distally and medially by an oblique, rough soleal line. A faint vertical line descends from the centre of the soleal line for a short distance before becoming indistinct. A large vascular groove adjoins the end of the line and descends distally into a nutrient foramen. Deep fascia and, proximal to the medial malleolus, the medial end of the superior extensor retinaculum, are attached to the anterior border. Posterior fibres of the medial collateral ligament and slips of semimembranosus and the popliteal fascia are attached to the medial border proximal to the soleal line, and some fibres of soleus and the fascia covering the deep calf muscles are attached distal to the line. The distal medial border runs into the medial lip of a groove for the tendon of tibialis posterior. The interosseous membrane is attached to the lateral border, except at either end of this border. It is indistinct proximally where a large gap in the membrane transmits the anterior tibial vessels. Distally the border is continuous with the anterior margin of the fibular notch, to which the anterior tibiofibular ligament is attached.

The anterior part of the medial collateral ligament is attached to an area approximately 5 cm long and 1 cm wide near the medial border of the proximal medial surface. The remaining medial surface is subcutaneous and crossed obliquely by the long saphenous vein. Tibialis anterior is attached to the proximal two-thirds of the lateral surface. The distal third, devoid of attachments, is crossed in mediolateral order by the tendons of tibialis anterior (lying just lateral to the anterior border), extensor hallucis longus, the anterior tibial vessels and deep fibular nerve, extensor digitorum longus and fibularis tertius.

On the posterior surface, popliteus is attached to a triangular area proximal to the soleal line, except near the fibular facet. The popliteal aponeurosis, soleus and its fascia, and the deep transverse fascia are all attached to the soleal line: the proximal end of the line does not reach the interosseous border, and is marked by a tubercle for the medial end of the tendinous arch of soleus. Lateral to the tubercle, the posterior tibial vessels and tibial nerve descend on tibialis posterior. Distal to the soleal line, a vertical line separates the attachments of flexor digitorum longus and tibialis posterior. Nothing is attached to the distal quarter of this surface, but the area is crossed medially by the tendon of tibialis posterior travelling to a groove on the posterior aspect of the medial malleolus. Flexor digitorum longus crosses obliquely behind tibialis posterior; the posterior tibial vessels and nerve and flexor hallucis longus contact only the lateral part of the distal posterior surface.

Distal end

The slightly expanded distal end of the tibia has anterior, medial, posterior, lateral and distal surfaces. It projects inferomedially as the medial malleolus. The distal end of the tibia, when compared to the proximal end, is laterally rotated (tibial torsion). The torsion begins to develop *in utero* and progresses throughout childhood and adolescence till skeletal maturity is attained. Tibial torsion is approximately 30° in Caucasian and Asian populations, but is significantly greater in people of African origin (Eckhoff et al 1994). Some of the femoral neck anteversion seen in the newborn may persist in adult females: this causes the femoral shaft and knee to be internally rotated, and the tibia may develop a compensatory external torsion to counteract the tendency of the feet to turn inwards.

The smooth anterior surface projects beyond the distal surface, from which it is separated by a narrow groove. The capsule of the ankle joint is attached to an anterior groove near the articular surface. The medial surface is smooth and continuous above and below with the medial surfaces of the shaft and medial malleolus respectively: it is subcutaneous and visible. The posterior surface is smooth except where it is crossed near its medial end by a nearly vertical but slightly oblique groove, which is usually conspicuous and extends to the posterior surface of the malleolus. The groove is adapted to the tendon of tibialis posterior, which usually separates the tendon of flexor digitorum longus from the bone. More laterally, the posterior tibial vessels and nerve and flexor hallucis longus contact this surface. The lateral surface is the triangular fibular notch; its anterior and posterior edges project and converge proximally to the interosseous border. The floor of the notch is roughened proximally by a substantial interosseous ligament but is smooth distally and sometimes covered by articular cartilage. The anterior and posterior tibiofibular ligaments are attached to the corresponding edges of the notch. The distal surface articulates with the talus and is wider in front, concave sagittally and slightly convex transversely, i.e. it is saddle-shaped. Medially it continues into the malleolar articular surface which may extend into the groove that separates it from the anterior surface of the shaft. Such extensions, medial or lateral or both, are squatting facets, and they articulate with reciprocal talar facets in extreme dorsiflexion. These features have been used in the field of forensic medicine to identify the racial origins of skeletal material.

Medial malleolus

The short thick medial malleolus has a smooth lateral surface with a crescentic facet that articulates with the medial surface of the talus. Its anterior aspect is rough and its posterior aspect features the continuation of the groove from the posterior surface of the tibial shaft for the tendon of tibialis posterior. The distal border is pointed anteriorly, posteriorly depressed, and gives attachment to the deltoid ligament. The tip of the medial malleolus does not project as far distally as the tip of the lateral malleolus; the latter also being the more posteriorly located of the two malleoli. The capsule of the ankle joint is attached to the anterior surface of the medial malleolus, and the flexor retinaculum to its prominent posterior border.

Muscle attachments

The patellar tendon is attached to the proximal half of the tibial tuberosity. Semimembranosus is attached to the distal edge of the groove on the posterior surface of the medial condyle; a tubercle at the lateral end of the groove is the main attachment of the tendon of this muscle. Slips from the tendon of biceps femoris are attached to the lateral tibial condyle anteroproximal to the fibular facet. Proximal fibres of extensor digitorum longus and (occasionally) fibularis longus are attached distal to this area. Slips of semimembranosus are attached to the medial border of the shaft posteriorly, proximal to the soleal line. Some fibres of soleus attach to the posteromedial surface distal to the line. Semimembranosus is attached to the medial surface proximally, near the medial border, behind the attachment of the anterior part of the medial collateral ligament. Anterior to this area (in anteroposterior sequence), are the linear attachments of the tendons of sartorius, gracilis and semitendinosus: these rarely mark the bone. Tibialis anterior is attached to the proximal two-thirds of the lateral (extensor) surface. Popliteus is attached to the posterior surface in a triangular area proximal to the soleal line, except near the fibular facet. Soleus and its associated fascia are attached to the soleal line itself. Flexor digitorum longus and tibialis posterior are attached to the posterior surface distal to the soleal line, medial and lateral respectively to the vertical line (see above).

Vascular supply

The proximal end of the tibia is supplied by metaphysial vessels from the genicular arterial anastomosis. The nutrient foramen usually lies near the soleal line and transmits a branch of the posterior tibial artery; the nutrient vessel may also arise at the level of the popliteal bifurcation or as a branch from the anterior tibial artery. On entering the bone the nutrient artery divides into ascending and descending branches. The periosteal supply to the shaft arises from the anterior tibial artery and from muscular branches. The distal metaphysis is supplied by branches from the anastomosis around the ankle.

Innervation

The proximal and distal ends of the tibia are innervated by branches from the nerves that supply the knee joint and ankle joint respectively. The periosteum of the shaft is supplied by branches from the nerves that innervate the muscles attached to the tibia.

Ossification

The tibia ossifies from three centres, one in the shaft and one in each epiphysis. Ossification (Figs 83.2, 83.3, 83.4; see Fig. 82.6) begins in midshaft at about the seventh intrauterine week. The proximal epiphysial centre is usually present at birth: at approximately 10 years a thin anterior process from the centre descends to form the smooth part of the tibial tuberosity. A separate centre for the tuberosity may appear at about the twelfth year and soon fuses with the epiphysis. Distal strata of the epiphysial plate are composed of dense collagenous tissue in which the fibres are aligned with the patellar tendon. Exaggerated traction stresses may account for Osgood–Schlatter disease, where fragmentation of the epiphysis of the tuberosity occurs during adolescence and produces a painful swelling in the region of the tuberosity. Healing occurs once the growth plate fuses, leaving a bony protrusion. Prolonged periods of traction with the knee extended, both in children and adolescents, can lead to growth arrest of the anterior part of the proximal epiphysis, which results in bowing of the proximal tibia as the posterior tibia continues to grow. The proximal epiphysis fuses in the 16th year in females and the 18th in males. The distal epiphysial centre appears early in the first year and joins the shaft at about the 15th year in females and the 17th in males. The medial malleolus is an extension from the distal epiphysis and starts to ossify in the seventh year: it may have its own separate ossification centre. In 47% of females and 17% of males, an accessory ossification centre appears at the tip of the medial malleolus which fuses during the eighth year in females and the ninth in males: it should not be confused with an os subtibiale, which is a rare accessory bone found on the posterior aspect of the medial malleolus.

FIBULA

The fibula (Figs 83.2, 83.3) is much more slender than the tibia and is not directly involved in transmission of weight. It has a proximal head, a narrow neck, a long shaft and a distal lateral malleolus. The shaft varies in form, being variably moulded by attached muscles: these variations may be confusing.

Head

The head of the fibula is irregular in shape and projects anteriorly, posteriorly, and laterally. A round facet on its proximomedial aspect articulates with a corresponding facet on the inferolateral surface of the lateral tibial condyle. It faces proximally and anteromedially and has an inclination which may vary among individuals from almost horizontal to an angle of up to 45°. A blunt apex (styloid process) projects proximally from the posterolateral aspect of the head and is often palpable approximately 2 cm distal to the knee joint. The fibular collateral ligament is attached in front of the apex, embraced by the main attachment of biceps femoris. The tibiofibular capsular ligament is attached to the margins of the articular facet. The common fibular nerve crosses posterolateral to the neck and can be rolled against bone at this location.

Shaft

The shaft has three borders and surfaces, each associated with a particular group of muscles. The anterior border ascends proximally from the apex of an elongated triangular area that is continuous with the lateral malleolar surface, to the anterior aspect of the fibular head. The posterior border, continuous with the medial margin of the posterior groove on the lateral malleolus, is usually distinct distally but often rounded in its proximal half. The interosseous border is medial to the anterior border and somewhat posterior. Over the proximal two-thirds of the fibular shaft the two borders approach each other, with the surface between the two being narrowed to 1 mm or less.

The lateral surface, between the anterior and posterior borders and associated with the fibular muscles, faces laterally in its proximal three-fourths. The distal quarter spirals posterolaterally to become continuous with the posterior groove of the lateral malleolus. The anteromedial (sometimes simply termed anterior, or medial) surface, between the anterior and interosseous borders, usually faces anteromedially but often directly anteriorly. It is associated with the extensor muscles. Though wide distally, it narrows in its proximal half and may become a mere ridge. The posterior surface, between the interosseous and posterior borders, is the largest and is associated with the flexor muscles. Its proximal two-thirds is divided by a longitudinal medial crest, separated from the interosseous border by a grooved surface that is directed medially. The remaining surface faces posteriorly in its proximal half; its distal half curves onto the medial aspect. Distally this area occupies the fibular notch of the tibia, which is roughened by the attachment of the principal interosseous tibiofibular ligament. The triangular area proximal to the lateral surface of the lateral malleolus is subcutaneous; muscles cover the rest of the shaft.

The anterior border is divided distally into two ridges that enclose a triangular subcutaneous surface. The anterior intermuscular septum is attached to its proximal three-fourths. The lateral end of the superior extensor retinaculum is attached distally on the anterior border of the triangular area and the lateral end of the superior fibular retinaculum is attached distally on the posterior margin of the triangular area. The interosseous border ends at the proximal limit of the rough area for the interosseous ligament. The interosseous membrane attached to this border does not reach the fibular head, which leaves a gap through which the anterior tibial vessels pass. The posterior border is proximally indistinct, and the posterior intermuscular septum is attached to all but its distal end. The medial crest is related to the fibular artery. A layer of deep fascia separating the tendon of tibialis posterior from flexor hallucis longus and flexor digitorum longus is attached to the medial crest.

Lateral malleolus

The distal end forms the lateral malleolus which projects distally and posteriorly (Figs 83.2, 83.3, 83.5). Its lateral aspect is subcutaneous while its posterior aspect has a broad groove with a prominent lateral border. Its anterior aspect is rough, round and continuous with the tibial inferior border. The medial surface has a triangular articular facet, vertically convex, its apex distal, which articulates with the lateral talar surface. Behind this facet is a rough malleolar fossa pitted by vascular foramina. The posterior tibiofibular ligament and, more distally, the posterior talofibular ligament, are attached in the fossa. The anterior talofibular ligament is attached to the anterior surface of the lateral malleolus; the calcaneofibular ligament is attached to the notch anterior to its apex. The tendons of fibularis brevis and longus groove its posterior aspect: the latter is superficial and covered by the superior fibular retinaculum.

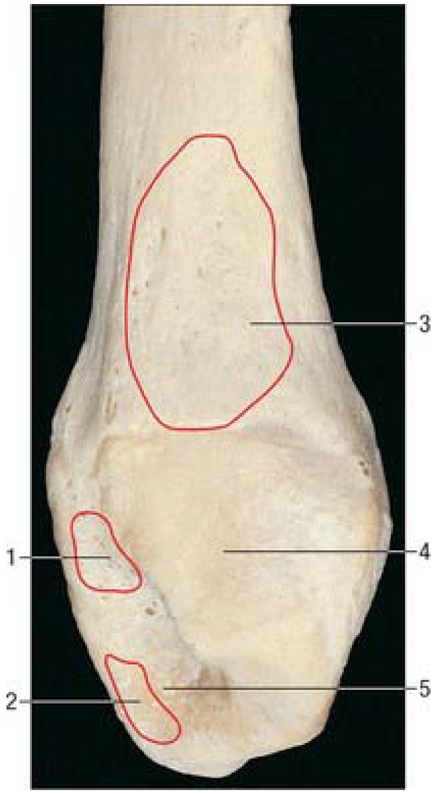

Fig. 83.5 Distal end of left fibula: medial aspect. **1**. Attachment of posterior tibiofibular ligament. **2**. Attachment of posterior talofibular

ligament. **3**. Area for attachment of interosseous tibiofibular ligament. **4**. Articular facet for talus. **5**. Malleolar fossa.

Muscle attachments

The main attachments of biceps femoris embrace the fibular collateral ligament in front of the apex (styloid process) of the fibular head. Extensor digitorum longus is attached to the head anteriorly, fibularis longus anterolaterally, and soleus posteriorly. Extensor digitorum longus, extensor hallucis longus and fibularis tertius are attached to the anteromedial (extensor) surface. Fibularis longus is attached to the whole width of the lateral (fibular) surface in its proximal third, but in its middle third only to its posterior part, behind fibularis brevis. The latter continues its attachment almost to the distal end of the shaft.

Muscle attachments to the posterior surface, which is divided longitudinally by the medial crest, are complex. Between the crest and interosseous border the posterior surface is concave. Tibialis posterior is attached throughout most (the proximal three-fourths) of this area; an intramuscular tendon may ridge the bone obliquely. Soleus is attached between the crest and the posterior border on the proximal fourth of the posterior surface; its tendinous arch is attached to the surface proximally. Flexor hallucis longus is attached distal to soleus on the posterior surface and almost reaches the distal end of the shaft.

Vascular supply

A little proximal to the midpoint of the posterior surface (14–19 cm from the styloid process), the fibular shaft is characterized by a nutrient foramen, directed distally, which receives a branch of the fibular artery. An appreciation of the detailed anatomy of the fibular artery in relation to the fibula is fundamental to the raising of osteofasciocutaneous free flaps incorporating segments of the bone. Free vascularized diaphysis grafts may also be taken on a fibular arterial pedicle. The proximal and distal ends receive metaphysial vessels from the arterial anastomoses at the knee and ankle respectively.

Innervation

The proximal and distal ends of the bone are supplied by branches of nerves that innervate the knee and superior tibiofibular joint and the ankle and inferior tibiofibular joints respectively. The periosteum of the shaft is supplied by branches from the nerves that innervate the muscles attached to the fibula.

Ossification

The fibula ossifies from three centres, one each for the shaft and the extremities (Fig. 83.6). The process begins in the shaft at about the eighth intrauterine week, in the distal end in the first year, and in the proximal end at about the third year in females and the fourth in males. The distal epiphysis unites with the shaft at about the 15th year in females and the 17th in males, whereas the proximal epiphysis does not unite until about the 17th year in females and the 19th in males.. An os subfibulare is an occasional and separate entity and lies posterior to the tip of the fibula, whereas the distal fibular apophysis lies anteriorly. An os retinaculi is rarely encountered; if present, it overlies the bursa of the distal fibula within the fibular retinaculum.

view. Note the trabecular pattern in the calcaneus. **1**. Tibial growth plate. **2**. Posterior growth plate of calcaneus.

MUSCLES

The muscles of the leg consist of an anterior group of extensor muscles, which produce dorsiflexion (extension) of the ankle; a posterior group of flexor muscles, which produce plantar flexion (flexion); and a lateral group of muscles, the fibulares, derived, embryologically, from the extensors. The greater bulk of the muscles in the calf is commensurate with the powerful propulsive role of the plantar flexors in walking and running.

ANTERIOR OR EXTENSOR COMPARTMENT

The anterior compartment contains muscles that dorsiflex the ankle when acting from above (Figs 83.7, 83.8, 83.9). When acting from below they pull the body forward on the fixed foot during walking. Two of the muscles, extensor digitorum longus and extensor hallucis longus, also extend the toes, and two muscles, tibialis anterior and fibularis tertius, have the additional actions of inversion and eversion respectively.

Tibialis anterior

Attachments

Tibialis anterior is a superficial muscle and is therefore readily palpable lateral to the tibia. It arises from the lateral condyle and proximal half to two-thirds of the lateral surface of the tibial shaft; the adjoining anterior surface of the interosseous membrane; the deep surface of the deep fascia; and the intermuscular septum between itself and extensor digitorum longus. The muscle descends vertically and ends in a tendon on its anterior surface in the lower third of the leg. The tendon passes through the medial compartments of the superior and inferior retinacula, inclines medially, and is inserted into the medial and inferior surfaces of the medial cuneiform and the adjoining part of the base of the first metatarsal bone.

Attachments to the talus, first metatarsal head, base of the proximal phalanx of the hallux, and extensor retinaculum have been recorded.

Relations

Tibialis anterior overlaps the anterior tibial vessels and deep fibular nerve in the upper part of the leg. It lies on the tibia and interosseous membrane. Extensor digitorum longus and extensor hallucis longus lie laterally.

Vascular supply

The main body of tibialis anterior is supplied by a series of medial and anterior branches of the anterior tibial artery: the branches may occur in two columns. There is a proximal accessory supply from the anterior tibial recurrent artery. The tendon is supplied by the anterior medial malleolar artery and network, dorsalis pedis artery, medial tarsal arteries, and by the medial malleolar and calcaneal branches of the posterior tibial artery.

Innervation

Tibialis anterior is innervated by the deep fibular nerve, L4 and 5.

Actions

Tibialis anterior is a dorsiflexor of the ankle joint and invertor of the foot. It is most active when both movements are combined, as in walking. Its tendon can be seen through the skin lateral to the anterior border of the tibia and can be traced downwards and medially across the front of the ankle to the medial side of the foot. Tibialis anterior elevates the first metatarsal base and medial cuneiform and rotates their dorsal aspects laterally.

The muscle is usually quiescent in a standing subject, since the weight of the body acts through a vertical line that passes anterior to the ankle joints. Acting from below, it helps to counteract any tendency to overbalance backwards by flexing the leg forwards at the ankle. It has a role in supporting the medial longitudinal arch of the foot: although electromyographically detectable activity is minimal during standing, it is manifest during any movement that increases the arch, such as toe-off in walking and running.

Testing

Tibialis anterior can be seen to act when the foot is dorsiflexed against resistance.

Extensor hallucis longus

Attachments

Extensor hallucis longus lies between, and partly overlapped by, tibialis anterior and extensor digitorum longus. It arises from the middle two-fourths of the medial surface of the fibula, medial to extensor digitorum longus, and from the adjacent anterior surface of the interosseous membrane. Its fibres run distally and end in a tendon that forms on the anterior border of the muscle. The tendon passes deep to the superior extensor retinaculum and through the inferior extensor retinaculum, crosses anterior to the anterior tibial vessels to lie on their medial side near the ankle, and is inserted into the dorsal aspect of the base of the distal phalanx of the hallux. At the metatarsophalangeal joint a thin prolongation from each side of the tendon covers the dorsal surface of the joint. An expansion from the medial side of the tendon to the base of the proximal phalanx is usually present.

Extensor hallucis longus is sometimes united with extensor digitorum longus and may send a slip into the second toe.

Relations

The anterior tibial vessels and deep fibular nerve lie between extensor hallucis longus and tibialis anterior. Extensor hallucis longus lies lateral to the artery proximally, crosses it in the lower third of the leg, and is medial to it on the foot.

Vascular supply

Extensor hallucis longus is supplied by the anterior tibial artery via obliquely running branches, with a variable contribution from the perforating branch of the fibular artery. More distally, the tendon is supplied via the anterior medial malleolar artery and network, the dorsalis pedis artery, and the plantar arteries of the first ray via perforating branches.

Innervation

Extensor hallucis longus is innervated by the deep fibular nerve, L5.

Actions

Extensor hallucis longus extends the phalanges of the hallux and dorsiflexes the foot. When the hallux is actively extended, relatively little external force is required to overcome the extension of the distal phalanx, whereas considerable force is needed to overcome the extension of the proximal phalanx.

Testing

When the hallux is extended (dorsiflexed) against resistance, the tendon of extensor hallucis longus can be seen and felt on the lateral side of the tendon of tibialis anterior. This is a useful and very specific test of the integrity of the L5 spinal nerve.

Extensor digitorum longus

Attachments

Extensor digitorum longus arises from the inferior surface of the lateral condyle of the tibia, proximal three-quarters of the medial surface of the fibula, adjacent anterior surface of the interosseous membrane, deep surface of the deep fascia, anterior crural intermuscular septum, and from the fascial septum between itself and tibialis anterior. These origins form the walls of an osseo-aponeurotic tunnel. Extensor digitorum longus becomes tendinous at about the same level as tibialis anterior, and the tendon passes deep to the superior extensor retinaculum and within a loop of the inferior extensor retinaculum with fibularis tertius (see Figs 83.7, 84.2). It divides into four slips which run forward on the dorsum of the foot and are attached in the same way as the tendons of extensor digitorum in the hand. At the metatarsophalangeal joints the tendons to the second, third and fourth toes are each joined on the lateral side by a tendon of extensor digitorum brevis. The dorsal digital expansions thus formed on the dorsal aspects of the proximal phalanges, as in the fingers, receive contributions from the appropriate lumbrical and interosseous muscles. The expansion narrows as it approaches a proximal interphalangeal joint, and divides into three slips. These are a central (axial) slip, attached to the base of the middle phalanx, and two collateral (coaxial) slips, which reunite on the dorsum of the middle phalanx and are attached to the base of the distal phalanx.

The tendons to the second and fifth toes are sometimes duplicated, and accessory slips may be attached to metatarsals or to the hallux.

Relations

Extensor digitorum longus lies on the lateral tibial condyle, fibula, lower end of the tibia, ankle joint and extensor digitorum brevis. Tibialis anterior and extensor hallucis longus lie medially in the leg, and the fibular muscles lie laterally. In the upper part of the leg the anterior tibial vessels and deep fibular nerve lie between extensor digitorum longus and tibialis anterior; the nerve runs obliquely and medially beneath its upper part.

Vascular supply

The main blood supply to extensor digitorum longus is derived from anteriorly and laterally placed branches of the anterior tibial artery, supplemented distally from the perforating branch of the fibular artery. Proximally there may also be a supply from the lateral inferior genicular, popliteal or anterior tibial recurrent arteries. At the ankle and in the foot, the tendons are supplied by the anterior lateral malleolar artery and malleolar network, and by lateral tarsal, metatarsal, plantar and digital arteries.

Innervation

Extensor digitorum longus is innervated by the deep fibular nerve, L5, S1.

Actions

Extensor digitorum longus extends the lateral four toes. Acting synergistically with tibialis anterior, extensor hallucis longus and fibularis tertius, it is a dorsiflexor of the ankle. Acting with extensor hallucis longus it helps tighten the plantar aponeurosis.

Testing

The tendons of extensor digitorum longus can be seen when the toes are extended (dorsiflexed) against resistance.

Fibularis tertius

Attachments

Fibularis tertius (peroneus tertius) is a muscle unique to humans. It often appears to be part of extensor digitorum longus, and might be described as its ‘fifth tendon’. The muscle fibres of fibularis tertius arise from the distal third or more of the medial surface of the fibula, the adjoining anterior surface of the interosseous membrane, and the anterior crural intermuscular septum. The tendon passes deep to the superior extensor retinaculum and within the loop of the inferior extensor retinaculum alongside the extensor digitorum longus (see Figs 83.7, 84.2). It is inserted into the medial part of the dorsal surface of the base of the fifth metatarsal bone; a thin expansion usually extends forwards along the medial border of the shaft of the bone.

Relations

Fibularis tertius lies lateral to extensor digitorum longus.

Vascular supply

Fibularis tertius is supplied by the same vessels as extensor digitorum longus. In the foot it receives an additional supply from the termination of the arcuate artery and the fourth dorsal metatarsal artery.

Innervation

Fibularis tertius is innervated by the deep fibular nerve, L5, S1.

Actions

Electromyographic studies show that during the swing phase of gait (see Fig. 84.26), fibularis tertius acts with extensor digitorum longus and tibialis anterior to produce dorsiflexion of the foot, and with fibularis longus and fibularis brevis to effect eversion of the foot (Jungers et al 1993). This levels the foot and helps the toes to clear the ground, an action that improves the efficiency and enhances the economy of bipedal locomotion. Fibularis tertius is not active during the stance phase, a finding that is at variance with the suggestion that the muscle acts primarily to support the lateral longitudinal arch and to transfer the centre of pressure of the foot medially.

Testing

Fibularis tertius cannot be tested in isolation, but its tendon can sometimes be seen and felt when the foot is dorsiflexed against resistance.

LATERAL (FIBULAR OR PERONEAL) COMPARTMENT

The lateral compartment contains fibularis (peroneus) longus and fibularis (peroneus) brevis (Figs 83.7, 83.8). Both muscles evert the foot and are plantar flexors of the ankle, and both probably play a part in balancing the leg on the foot in standing and walking.

Fibularis longus

Attachments

Fibularis longus is the more superficial of the two muscles of the lateral compartment. It arises from the head and proximal two-thirds of the lateral surface of the fibula, the deep surface of the deep fascia, the anterior and posterior crural intermuscular septa, and occasionally by a few fibres from the lateral condyle of the tibia. The muscle belly ends in a long tendon that runs distally behind the lateral malleolus in a groove it shares with the tendon of fibularis brevis. The groove is converted into a canal by the superior fibular retinaculum, so that the tendon of fibularis longus, and that of fibularis brevis which lies in front of the longus tendon, are contained in a common synovial sheath. If the fibular retinaculum is ruptured by injury and fails to heal, the tendons can dislocate from the groove. The fibularis longus tendon runs obliquely forwards on the lateral side of the calcaneus, below the fibular trochlea and the tendon of fibularis brevis, and deep to the inferior fibular retinaculum. It crosses the lateral side of the cuboid and then runs under the cuboid in a groove that is converted into a canal by the long plantar ligament (see Fig. 84.19). It crosses the sole of the foot obliquely and is attached by two slips, one to the lateral side of the base of the first metatarsal bone and one to the lateral aspect of the medial cuneiform; occasionally a third slip is attached to the base of the second metatarsal bone. The tendon changes direction below the lateral malleolus and on the cuboid bone. At both sites it is thickened and at the second a sesamoid fibrocartilage (sometimes a bone, the os peroneum) is usually present. A second synovial sheath invests the tendon as it crosses the sole of the foot.

Relations

Proximally fibularis longus lies posterior to extensor digitorum longus and anterior to soleus and flexor hallucis longus. Distally in the leg it lies posterior to fibularis brevis. Between its attachments to the head and shaft of the fibula there is a gap through which the common fibular nerve passes.

Vascular supply of lateral compartment

Usually the predominant supply of the lateral compartment muscles is derived from superior and inferior branches of the anterior tibial artery; the superior is commonly the larger. There is also a lesser, variable, contribution from the fibular artery in the distal part of the leg. A fibular branch may replace the inferior branch of the anterior tibial artery; less commonly the fibular artery provides the main supply to the whole compartment. The upper part of fibularis longus is also supplied by the circumflex fibular artery, which is usually a branch of the anterior tibial artery. The companion artery to the common fibular nerve, a branch of the popliteal artery, provides a minor contribution proximally. Distally the tendons are supplied by the fibular perforating, anterior lateral malleolar, lateral calcaneal, lateral tarsal, arcuate, lateral and medial plantar arteries (see Fig. 84.9).

Innervation

Fibularis longus is innervated by the superficial fibular nerve, L5, S1.

Actions

There is little doubt that fibularis longus can evert the foot and plantar flex the ankle, and possibly act on the leg from its distal attachments. The oblique direction of its tendon across the sole would also enable it to support the longitudinal and transverse arches of the foot. With the foot off the ground, eversion is visually and palpably associated with increased prominence of both tendon and muscle. It is not clear to what extent this helps to maintain plantigrade contact of the foot in normal standing, but electromyographic records show little or no fibular activity under these conditions. Fibular activity is necessary to stand plantigrade with the legs crossed. Fibularis longus and brevis come strongly into action to maintain the concavity of the foot during toe-off and tip-toeing. If the subject deliberately sways to one side, the fibulares contract on that side, but their involvement in influencing postural interactions between the foot and leg remains uncertain.

Testing

Fibularis longus and brevis are tested together by eversion of the foot against resistance: the tendons can be identified laterally at the ankle and in the foot.

Fibularis brevis

Attachments

Fibularis brevis arises from the distal two-thirds of the lateral surface of the fibula, anterior to fibularis longus, and from the anterior and posterior crural intermuscular septa. It passes vertically downwards and ends in a tendon that passes behind the lateral malleolus together with, and anterior to, that of fibularis longus. The two tendons run deep to the superior fibular retinaculum in a common synovial sheath. The tendon of fibularis brevis then runs forwards on the lateral side of the calcaneus above the fibular trochlea and the tendon of fibularis longus, and is inserted into a tubercle on the lateral side of the base of the fifth metatarsal bone.

Relations

Anteriorly lie extensor digitorum longus and fibularis tertius. Fibularis longus and flexor hallucis longus are posterior. On the lateral surface of the calcaneus the tendons of fibularis longus and fibularis brevis occupy separate osteofascial canals formed by the calcaneus and the inferior fibular retinaculum; each tendon is enveloped in a separate distal prolongation of the common synovial sheath (see Fig. 84.2).

Vascular supply

See under fibularis longus.

Innervation

Fibularis brevis is innervated by the superficial fibular nerve, L5, S1.

Actions

Fibularis brevis may limit inversion of the foot and so relieve strain on the ligaments that are tightened by this movement (lateral part of interosseous talocalcaneal, lateral talocalcaneal and calcaneofibular ligaments). It participates in eversion of the foot and may help to steady the leg on the foot. See also under fibularis longus.

Testing

See under fibularis longus.

Variants of fibular muscles

Tendinous slips from fibularis longus may extend to the base of the third, fourth or fifth metatarsal bone, or to adductor hallucis. Fusion of fibularis longus and brevis has been reported, but is rare. Fibularis tertius is highly variable in its form and bulk but is seldom completely absent; its distal attachment may be to the fourth metatarsal rather than the fifth. Two other variant fibular muscles, arising from the fibula between fibularis longus and fibularis brevis, have been described. These are fibularis accessorius, whose tendon joins that of fibularis longus in the sole, and fibularis quartus, which arises posteriorly and inserts into the calcaneus or into the cuboid.

POSTERIOR (FLEXOR) COMPARTMENT

The muscles in the posterior compartment of the lower leg form superficial and deep groups, separated by the deep transverse fascia.

Superficial flexor group

The superficial flexors gastrocnemius, plantaris and soleus (Figs 83.8, 83.10; see Figs 82.2, 80.25) form the bulk of the calf. Gastrocnemius and soleus, collectively known as the triceps surae, constitute a powerful muscular mass whose main function is plantar flexion of the foot, although soleus in particular has an important postural role (see below). Their large size is a defining human characteristic, and is related to the upright stance and bipedal locomotion of the human. Gastrocnemius and plantaris act both on the knee and ankle joints; soleus on the latter alone.

(From Sobotta 2006.)

Gastrocnemius

Attachments

Gastrocnemius is the most superficial muscle of the group and forms the ‘belly’ of the calf. It arises by two heads, connected to the condyles of the femur by strong, flat tendons. The medial, larger, head is attached to a depression at the upper and posterior part of the medial condyle behind the adductor tubercle, and to a slightly raised area on the popliteal surface of the femur just above the medial condyle. The lateral head is attached to a recognizable area on the lateral surface of the lateral condyle and to the lower part of the corresponding supracondylar line. Both heads also arise from subjacent areas of the capsule of the knee joint. The tendinous attachments expand to cover the posterior surface of each head with an aponeurosis, from the anterior surface of which the muscle fibres arise. The fleshy part of the muscle extends to about midcalf. The muscle fibres of the larger medial head extend lower than those of the lateral head. As the muscle descends, the muscle fibres begin to insert into a broad aponeurosis that develops on its anterior surface; up to this point the muscular masses of the two heads remain separate. The aponeurosis gradually narrows and receives the tendon of soleus on its deep surface to form the calcaneal tendon (for a detailed description of the calcaneal tendon see Ch. 84).

On occasion the lateral head, or the whole muscle, is absent. A third head, arising from the popliteal surface of the femur, is sometimes present.

Relations

Proximally, the two heads of gastrocnemius form the lower boundaries of the popliteal fossa. The lateral head is partially overlaid by the tendon of biceps femoris, the medial head by semimembranosus. Over the rest of its length the muscle is superficial, and the two heads can easily be seen in the living subject. The superficial surface of the muscle is separated by the deep fascia from the short saphenous vein and the fibular communicating and sural nerves. The common fibular nerve crosses behind the lateral head of the muscle, partly under cover of biceps femoris. The deep surface lies posterior to the oblique popliteal ligament, popliteus, soleus, plantaris, popliteal vessels and the tibial nerve. A bursa, which communicates with the knee joint, is located anterior to the tendon of the medial head; if the bursa expands into the popliteal fossa it does so in the plane between the medial head of gastrocnemius and semimembranosus. The tendon of the lateral head frequently contains a fibrocartilaginous or bony sesamoid, the fabella, where it moves over the lateral femoral condyle. A sesamoid may occasionally occur in the tendon of the medial head. These can be seen on radiographs and may be mistaken for loose bodies in the knee joint.

Vascular supply

Each head of gastrocnemius is supplied by its own sural artery. These arteries are branches of the popliteal artery, and arise at variable levels, usually at the level of the tibiofemoral joint line. The medial sural artery almost always arises more proximally than the lateral: the medial may arise proximal to the joint line, the lateral sometimes distal to the line. Each sural artery enters the corresponding muscle head with its nerve of supply, the pedicle entering the muscle near its axial border at the level of the middle of the popliteal fossa. Medial or lateral gastrocnemius musculocutaneous flaps may be raised, each based on its neurovascular pedicle. Minor accessory sural arteries arise from the popliteal or from the superior genicular vessels.

The blood supply to the calcaneal tendon is described in Chapter 84.

Innervation

Gastrocnemius is innervated by the tibial nerve, S1 and 2.

Actions

The action of gastrocnemius is considered with soleus.

Testing

Gastrocnemius is tested by plantar flexion of the foot against resistance, in the supine position and with the knee extended.

Plantaris

Attachments

Plantaris arises from the lower part of the lateral supracondylar line and the oblique popliteal ligament. Its small fusiform belly is 7–10 cm long and ends in a long slender tendon which crosses obliquely, in an inferomedial direction, between gastrocnemius and soleus, then runs distally along the medial border of the calcaneal tendon and inserts on to the calcaneus just medial to the calcaneal tendon. Occasionally it ends by fusing with the tendon.

The muscle is sometimes double, and is absent in approximately 10% of cases. Occasionally, its tendon merges with the flexor retinaculum or with the fascia of the leg.

Vascular supply

Plantaris is supplied superficially by the lateral sural and popliteal arteries, and deeply by the lateral superior genicular artery. The distal tendon shares a blood supply with the calcaneal tendon.

Innervation

Plantaris is innervated by the tibial nerve, often from the ramus that supplies the lateral head of gastrocnemius, S1 and 2.

Actions

Plantaris is the lower limb equivalent of palmaris longus, and in many mammals is well developed and inserts directly or indirectly into the plantar aponeurosis. In man the muscle is almost vestigial and is normally inserted well short of the plantar aponeurosis, usually into the calcaneus. It is therefore presumed to act with gastrocnemius.

Soleus

Attachments

Soleus is a broad flat muscle situated immediately deep (anterior) to gastrocnemius. It arises from the posterior surface of the head and proximal quarter of the shaft of the fibula; the soleal line and the middle third of the medial border of the tibia; and from a fibrous band between the tibia and fibula (the soleal arch) that arches over the popliteal vessels and tibial nerve. This origin is aponeurotic: most of the muscular fibres arise from its posterior surface and pass obliquely to the tendon of insertion on the posterior surface of the muscle. Other muscle fibres arise from the anterior surface of the aponeurosis. They are short, oblique and bipennate in arrangement, and converge on a narrow, central intramuscular tendon that merges distally with the principal tendon. The latter gradually becomes thicker and narrower, and joins the tendon of gastrocnemius to form the calcaneal tendon. The muscle is covered proximally by gastrocnemius, but below midcalf it is broader than the tendon of gastrocnemius and is readily accessible on either side of the tendon.

An accessory part of the muscle is sometimes present distally and medially. It may be inserted into the calcaneal tendon, the calcaneus or the flexor retinaculum.

Relations

The superficial surface of soleus is in contact with gastrocnemius and plantaris. Its deep surface is related to flexor digitorum longus, flexor hallucis longus, tibialis posterior and the posterior tibial vessels and tibial nerve, from all of which it is separated by the deep transverse fascia of the leg.

Vascular supply

Soleus is supplied by two main arteries: the superior arises from the popliteal artery at about the level of the soleal arch, and the inferior from the proximal part of the fibular artery or sometimes from the posterior tibial artery. A secondary supply is derived from the lateral sural, fibular or posterior tibial vessels.

There is a venous plexus within the muscle belly that is important physiologically as part of the muscle pump complex (see below). Pathologically, it is a common site of deep vein thrombosis.

Innervation

Soleus is innervated by two branches from the tibial nerve, S1 and 2.

Actions

See under triceps surae.

Testing

Soleus is tested by plantar flexion of the foot against resistance in the supine position, with hip and knee flexed: the muscle belly can be palpated separately from those of gastrocnemius.

Actions of triceps surae

Gastrocnemius and soleus are the chief plantar flexors of the foot; gastrocnemius is also a flexor of the knee. The muscles are usually large and correspondingly powerful. Gastrocnemius provides force for propulsion in walking, running and leaping. Soleus, acting from below, is said to be more concerned with steadying the leg on the foot in standing. This postural role is also suggested by its high content of slow, fatigue-resistant (type 1) muscle fibres. In many adult mammals the proportion of this type of fibre in soleus approaches 100%. However, such a rigid separation of functional roles seems unlikely in man: soleus probably participates in locomotion, and gastrocnemius in posture. Nevertheless, the ankle joint is loose-packed in the erect posture, and since the weight of the body acts through a vertical line that passes anterior to the joint, a strong brace is required behind the joint to maintain stability. Electromyography shows that these forces are supplied mainly by soleus: during symmetrical standing, soleus is continuously active, whereas gastrocnemius is recruited only intermittently. The relative contributions of soleus and gastrocnemius to phasic activity of the triceps surae in walking have yet to be satisfactorily analysed.

Deep flexor group

The deep flexor group (Fig. 83.8, Fig. 83.11), lies beneath (anterior to) the deep transverse fascia, and consists of popliteus, which acts on the knee joint, and flexor digitorum longus, flexor hallucis longus and tibialis posterior, which all produce plantar flexion at the ankle in addition to their specific actions on joints of the foot and digits.

(From Sobotta 2006.)

Popliteus

Popliteus is described in Chapter 82.

Flexor digitorum longus

Attachments

Flexor digitorum longus is thin and tapered proximally, but widens gradually as it descends. It arises from the posterior surface of the tibia medial to tibialis posterior from just below the soleal line to within 7 or 8 cm of the distal end of the bone; it also arises from the fascia covering tibialis posterior. The muscle ends in a tendon that extends along almost the whole of its posterior surface. The tendon gradually crosses tibialis posterior on its superficial aspect and passes behind the medial malleolus where it shares a groove with tibialis posterior, from which it is separated by a fibrous septum, i.e. each tendon occupies its own compartment lined by a synovial sheath. The tendon of flexor digitorum longus then curves obliquely forwards and laterally, in contact with the medial side of the sustentaculum tali, passes deep to the flexor retinaculum, and enters the sole of the foot on the medial side of the tendon of flexor hallucis longus (see Fig. 84.18). It crosses superficial to that tendon and receives a strong slip from it (and may also send a slip to it). The tendon of flexor digitorum longus then passes forward as four separate tendons, one each for the second to fifth toes, deep to the tendons of flexor digitorum brevis. After giving off the lumbricals, it passes through the fibrous sheaths of the lateral four toes. The tendons of flexor accessorius insert into the long flexor tendons of the second, third and fourth digits; flexor hallucis longus makes a variable contribution through the connecting slip mentioned above. The long flexor tendons of the lateral four digits are attached to the plantar surfaces of the bases of their distal phalanges; each passes between the slips of the corresponding tendon of flexor digitorum brevis at the base of the proximal phalanx.

A supplementary head of the muscle, flexor accessorius longus, with its own tendon, may arise from the fibula, tibia or deep fascia and insert into the main tendon or into flexor accessorius in the foot. It may send communicating slips to tibialis anterior or to flexor hallucis longus.

Relations

Flexor digitorum longus lies medial to flexor hallucis longus. In the leg its superficial surface is in contact with the deep transverse fascia, which separates it from soleus, and distally from the posterior tibial vessels and tibial nerve. Its deep surface is related to the tibia and to tibialis posterior. In the foot it is covered by abductor hallucis and flexor digitorum brevis and it crosses superficial to flexor hallucis longus.

Vascular supply

A series of transversely running branches of the posterior tibial artery enters the lateral border of flexor digitorum longus. There may be a secondary supply from fibular branches to flexor hallucis longus. The tendons are supplied by the vessels of the ankle and sole.

Innervation

Flexor digitorum longus is innervated by branches of the tibial nerve, L5, S1 and S2.

Actions

See under flexor hallucis longus.

Testing

Flexor digitorum longus is tested by flexing the toes against resistance. Aberrant function of flexor digitorum longus is implicated in toe deformities such as hammer toe, claw toe and mallet toe. It may be used in tendon transfer procedures for the surgical treatment of tibialis posterior tendon dysfunction.

Flexor hallucis longus

Attachments

Flexor hallucis longus arises from the distal two-thirds of the posterior surface of the fibula (except for the lowest 2.5 cm of this surface); the adjacent interosseous membrane and the posterior crural intermuscular septum; and from the fascia covering tibialis posterior, which it overlaps to a considerable extent. Its fibres pass obliquely down to a tendon that occupies nearly the whole length of the posterior aspect of the muscle. This tendon grooves the posterior surface of the lower end of the tibia, then, successively, the posterior surface of the talus and the inferior surface of the sustentaculum tali of the calcaneus (see Fig. 84.2B). Fibrous bands convert the grooves on the talus and calcaneus into a canal lined by a synovial sheath. In dancers, overuse causes thickening of the tendon in this region, and pain and even ‘triggering’ can occur (hallux saltans). In the sole of the foot, the tendon of flexor hallucis longus passes forward in the second layer (Ch. 84) like a bowstring. It crosses the tendon of flexor digitorum longus from lateral to medial, curving obliquely superior to it. At the crossing point (knot of Henry) it gives off two strong slips to the medial two divisions of the tendons of flexor digitorum longus and then crosses the lateral part of flexor hallucis brevis to reach the interval between the sesamoid bones under the head of the first metatarsal. It continues on the plantar aspect of the hallux, and runs in an osseo-aponeurotic tunnel to be attached to the plantar aspect of the base of the distal phalanx. The tendon is retained in position over the lateral part of flexor hallucis brevis by the diverging stems of the distal band of the medial intermuscular septum.

The distal extent of the muscle belly is a distinctive characteristic: in the posteromedial surgical approach to the ankle, flexor hallucis longus is readily identifiable by the fact that muscle fibres are evident almost to calcaneal level. In athletes the muscle fibres may be present so far inferiorly into the tendon as to be susceptible to impingement when pulled into the tunnel at the talus.

The connecting slip to flexor digitorum longus varies in size: it usually continues into the tendons for the second and third toes but is sometimes restricted to the second and occasionally extends to the fourth.

Relations

Soleus and the calcaneal tendon lie superficial (i.e. posterior) to flexor hallucis longus, separated by the deep transverse fascia. Deeply situated are the fibula, tibialis posterior, fibular vessels, distal part of the interosseous membrane and the talocrural joint. Laterally lie fibularis longus and fibularis brevis; medially are tibialis posterior, posterior tibial vessels and the tibial nerve. Flexor hallucis longus is an important surgical landmark at the ankle: staying lateral to it prevents injury to the neurovascular bundle.

Vascular supply

Flexor hallucis longus is supplied by numerous branches of the fibular artery. The tendon is supplied by arteries of the ankle and foot.

Innervation

Flexor hallucis longus is innervated by branches of the tibial nerve, L5, S1 and 2 (mainly S1).

Testing

Flexor hallucis longus is tested by flexion of the hallux against resistance.

Actions of deep digital flexors

Both flexor hallucis longus and flexor digitorum longus can act as plantar flexors but this action is weak compared with that of gastrocnemius and soleus. When the foot is off the ground, both muscles flex the phalanges of the toes, acting primarily on the distal phalanges. When the foot is on the ground and under load, they act synergistically with the small muscles of the foot and, especially in the case of flexor digitorum longus, with the lumbricals and interossei to maintain the pads of the toes in firm contact with the ground, enlarging the weightbearing area and helping to stabilize the heads of the metatarsal bones, which form the fulcrum on which the body is propelled forwards. Activity in the long digital flexors is minimal during quiet standing, so they apparently contribute little to the static maintenance of the longitudinal arch, but they become very active during toe-off and tip-toe movements.

Tibialis posterior

Attachments

Tibialis posterior is the most deeply placed muscle of the flexor group. At its origin it lies between flexor hallucis longus and flexor digitorum longus, and is overlapped by both, but especially by the former. Its proximal attachment consists of two tapered processes, separated by an angular interval that is traversed by the anterior tibial vessels. The medial process arises from the posterior surface of the interosseous membrane, except at its most distal part, and from a lateral area on the posterior surface of the tibia between the soleal line above and the junction of the middle and lower thirds of the shaft below. The lateral part arises from a medial strip of the posterior fibular surface in its upper two-thirds. The muscle also arises from the deep transverse fascia, and from the intermuscular septa that separate it from adjacent muscles. In the distal quarter of the leg its tendon passes deep to that of flexor digitorum longus, with which it shares a groove behind the medial malleolus, each enclosed in a separate synovial sheath. It then passes deep to the flexor retinaculum and superficial to the deltoid ligament to enter the foot. In the foot it is at first inferior to the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage. The tendon then divides into two. The more superficial and larger division, which is a direct continuation of the tendon, is attached to the tuberosity of the navicular, from which fibres continue to the inferior surface of the medial cuneiform. A tendinous band also passes laterally and a little proximally to the tip and distal margin of the sustentaculum tali. The deeper lateral division gives rise to the tendon of origin of the medial limb of flexor hallucis brevis, and then continues between this muscle and the navicular and medial cuneiform to end on the intermediate cuneiform and the bases of the second, third and fourth metatarsals; the slip to the fourth metatarsal is the strongest.

The slips to the metatarsals vary in number. Slips to the cuboid and lateral cuneiform may also occur. An additional muscle, the tibialis secundus, has been described running from the back of the tibia to the capsule of the ankle joint.

Relations

The superficial surface of tibialis posterior is separated from soleus by the deep transverse fascia, and is related to flexor digitorum longus, flexor hallucis longus, the posterior tibial vessels, the tibial nerve and the fibular vessels. The deep surface is in contact with the interosseous membrane, tibia, fibula and talocrural joint.

Vascular supply

Tibialis posterior is supplied by numerous branches of small calibre arising from the posterior tibial and fibular arteries. The tendon is supplied by arteries of the medial malleolar network and by the medial plantar artery.

Innervation

Tibialis posterior is innervated by the tibial nerve, L4 and 5.

Actions

Tibialis posterior is a powerful muscle which, on contraction, describes an excursion of only 1–2 cm. It is the principal invertor of the foot and also initiates elevation of the heel: it is responsible for the hindfoot varus that occurs during a single heel raise. By reason of its insertions into the cuneiform bones and the bases of the metatarsals, it has long been thought to assist in elevating the longitudinal arch of the foot, although electromyography shows that it is actually quiescent in standing. It is phasically active in walking, during which it probably acts with the intrinsic foot musculature and the lateral calf muscles to control the degree of pronation of the foot and the distribution of weight through the metatarsal heads. It is said that when the body is supported on one leg, the invertor action of tibialis posterior, exerted from below, helps to maintain balance by resisting any tendency to sway laterally.

Tibialis posterior is also important in the maintenance of the medial longitudinal arch. In overweight individuals with pes planus, unaccustomed activity can result in inflammation and degeneration of the terminal portion of the tendon, which leads to elongation of the tendon, attenuation of the spring ligament and progressive collapse of the medial longitudinal arch. As the excursion is so short, the muscle cannot compensate for the lengthening of its tendon, a failure that results in tibialis posterior tendon dysfunction.

Testing

Tibialis posterior is tested by asking the individual to perform a single heel raise and by moving the foot into a position of maximal plantar flexion and inversion against the resistance of the examiner’s hand: the tendon can be seen and felt just proximal to the medial malleolus.

VASCULAR SUPPLY

ARTERIES

Anterior tibial artery

The anterior tibial artery arises at the distal border of popliteus (Figs 83.9, 83.12, 83.13; see Figs 82.1, 82.4, 84.9). At first in the flexor compartment, it passes between the heads of tibialis posterior and through the oval aperture in the proximal part of the interosseous membrane to reach the extensor (anterior) compartment, passing medial to the fibular neck: it is vulnerable here during tibial osteotomy. Descending on the anterior aspect of the membrane it approaches the tibia and, distally, lies anterior to it. At the ankle the anterior tibial artery is midway between the malleoli, and it continues on the dorsum of the foot as the dorsalis pedis artery.

The anterior tibial artery may, on occasion, be small but it is rarely absent. Its function may be replaced by perforating branches from the posterior tibial artery or by the perforating branch of the fibular artery. It occasionally deviates laterally, regaining its usual position at the ankle. It may also be larger than normal, in which case its territory of supply in the foot may be increased to include the plantar surface.

Relations

In its proximal two-thirds the anterior tibial artery lies on the interosseous membrane, and in its distal third it is anterior to the tibia and ankle joint. Proximally it lies between tibialis anterior and extensor digitorum longus, then between tibialis anterior and extensor hallucis longus. At the ankle it is crossed superficially from the lateral side by the tendon of extensor hallucis longus and then lies between this tendon and the first tendon of extensor digitorum longus. Its proximal two-thirds are covered by adjoining muscles and deep fascia, its distal third by the skin, fasciae and extensor retinacula. It is accompanied by venae comitantes. The deep fibular nerve, curling laterally round the fibular neck, reaches the lateral side of the artery where it enters the extensor region, is then anterior to the artery in the middle third of the leg, and becomes lateral again distally.

Branches

The named branches of the anterior tibial artery are the posterior and anterior recurrent tibial, muscular, perforating, and anterior medial and lateral malleolar arteries.

Posterior tibial recurrent artery

The posterior tibial recurrent artery is an inconstant branch that arises before the anterior tibial reaches the extensor compartment. It ascends anterior to popliteus with the recurrent nerve to that muscle, anastomosing with the inferior genicular branches of the popliteal artery. It supplies the superior tibiofibular joint.

Anterior tibial recurrent artery

The anterior tibial recurrent artery arises near the posterior tibial recurrent artery. It ascends in tibialis anterior, ramifies on the front and sides of the knee joint and joins the patellar network, anastomosing with the genicular branches of the popliteal and circumflex fibular arteries.

Muscular branches

Numerous branches supply the adjacent muscles. Some then pierce the deep fascia to supply the skin, while others traverse the interosseous membrane to anastomose with branches of the posterior tibial and fibular arteries.

Perforating branches

Most of the fasciocutaneous perforators pass along the anterior fibular fascial septum behind extensor digitorum longus before penetrating the deep fascia to supply the skin.

Anterior medial malleolar artery

The anterior medial malleolar artery arises approximately 5 cm proximal to the ankle. It passes posterior to the tendons of extensor hallucis longus and tibialis anterior medial to the joint, where it joins branches of the posterior tibial and medial plantar arteries.

Anterior lateral malleolar artery

The anterior lateral malleolar artery runs posterior to the tendons of extensor digitorum longus and fibularis tertius to the lateral side of the ankle and anastomoses with the perforating branch of the fibular artery and ascending branches of the lateral tarsal artery.

Posterior tibial artery

The posterior tibial artery begins at the distal border of popliteus, between the tibia and fibula (Fig. 83.13; see Figs 82.1, 82.4). It descends medially in the flexor compartment and divides under abductor hallucis, midway between the medial malleolus and the medial tubercle of the calcaneus, into the medial and lateral plantar arteries. The artery may be much reduced in length or in calibre: the fibular artery then takes over its distal territory of supply and may consequently be increased in size.

Relations

The posterior tibial artery is successively posterior to tibialis posterior, flexor digitorum longus, the tibia and the ankle joint. Proximally, gastrocnemius, soleus and the deep transverse fascia of the leg are superficial to the artery, and distally it is covered only by skin and fascia. It is parallel with and approximately 2.5 cm anterior to the medial border of the calcaneal tendon; terminally it is deep to the flexor retinaculum and abductor hallucis. The artery is accompanied by two veins and the tibial nerve. The nerve is at first medial to the artery but soon crosses behind it and subsequently becomes largely posterolateral.

Branches

The named branches of the posterior tibial artery are the circumflex fibular, nutrient, muscular, perforating, communicating, medial malleolar, calcaneal, lateral and medial plantar, and fibular arteries.

Circumflex fibular artery

The circumflex fibular artery, which sometimes arises from the anterior tibial artery, passes laterally round the neck of the fibula through the soleus to anastomose with the lateral inferior genicular, medial genicular and anterior tibial recurrent arteries. It supplies bone and articular structures.

Nutrient artery of the tibia

The nutrient artery of the tibia arises from the posterior tibial near its origin. After giving off a few muscular branches it descends into the bone immediately distal to the soleal line. It is one of the largest of the nutrient arteries.

Muscular branches

Muscular branches are distributed to the soleus and deep flexors of the leg.

Perforating branches

Approximately five fasciocutaneous perforators emerge between flexor digitorum longus and soleus and pass through the deep fascia, often accompanying the perforating veins that connect the deep and superficial venous systems. The arterial perforators then divide into anterior and posterior branches to supply periosteum and skin. These vessels are utilized in raising medial fasciocutaneous perforator flaps in the leg.

Communicating branch

The communicating branch runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, to join a communicating branch of the fibular artery.

Medial malleolar branches

The medial malleolar branches pass round the tibial malleolus to the medial malleolar network, which supplies the skin.

Calcaneal branches

Calcaneal branches arise just proximal to the terminal division of the posterior tibial artery. They pierce the flexor retinaculum to supply fat and skin behind the calcaneal tendon and in the heel, and muscles on the tibial side of the sole; the branches anastomose with medial malleolar arteries and calcaneal branches of the fibular artery.

Medial plantar artery

The medial plantar artery is the smaller terminal branch of the posterior tibial artery and passes distally along the medial side of the foot, medial to the medial plantar nerve (see Fig. 84.24). At first deep to abductor hallucis, it runs distally between this muscle and flexor digitorum brevis, and supplies both. Near the first metatarsal base, its size, already diminished by muscular branches, is further reduced by a superficial stem that divides to form three superficial digital branches. These accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries. The main trunk of the medial plantar artery then runs on to reach the medial border of the hallux, where it anastomoses with a branch of the first plantar metatarsal artery.

Lateral plantar artery

The lateral plantar artery is the larger terminal branch of the posterior tibial artery (see Fig. 84.24). It passes distally and laterally to the fifth metatarsal base, lateral to the lateral plantar nerve. (The medial and lateral plantar nerves lie between the corresponding plantar arteries.) Turning medially with the deep branch of the lateral plantar nerve, it reaches the interval between the first and second metatarsal bases, and unites with the dorsalis pedis artery to complete the plantar arch. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi and is covered by the plantar aponeurosis, superficial fascia and skin.

Branches

Muscular branches supply the adjoining muscles. Superficial branches emerge along the lateral intermuscular septum to supply the skin and subcutaneous tissue lateral in the sole. Anastomotic branches run to the lateral border of the foot, joining branches of the lateral tarsal and arcuate arteries. A calcaneal branch sometimes pierces abductor hallucis to supply the skin of the heel.

Fibular artery

The fibular artery arises from the posterior tibial artery approximately 2.5 cm distal to popliteus and passes obliquely to the fibula, descending along its medial crest either in a fibrous canal between tibialis posterior and flexor hallucis longus or within flexor hallucis longus (Figs 83.9, 83.12, 83.13; see Fig. 82.4). Reaching the inferior tibiofibular syndesmosis, it divides into calcaneal branches that ramify on the lateral and posterior surfaces of the calcaneus. Proximally it is covered by soleus and the deep transverse fascia between soleus and the deep muscles of the leg, and distally it is overlapped by flexor hallucis longus.

The fibular artery may branch high from the posterior tibial artery or may even branch from the popliteal artery separately, giving a true ‘trifurcation’. It may also branch more distally from the posterior tibial artery, sometimes 7 or 8 cm distal to popliteus. Its size tends to be inversely related to the size of the other arteries of the leg. It may be reduced in size but is more often enlarged, when it may join, reinforce or even replace the posterior tibial artery in the distal leg and foot. An enlarged perforating branch may replace the dorsalis pedis artery: the dorsalis pedis pulse will then be absent.

Branches

The fibular artery has muscular, nutrient, perforating, communicating and calcaneal branches.

Muscular branches

Multiple short branches supply soleus, tibialis posterior, flexor hallucis longus and the fibular muscles.

Nutrient artery

The nutrient artery branches from the main trunk approximately 7 cm from its origin and enters the fibula 14–19 cm from the styloid process.

Perforating branches

The main perforating branch traverses the interosseous membrane approximately 5 cm proximal to the lateral malleolus to enter the extensor compartment, where it anastomoses with the anterior lateral malleolar artery. Descending anterior to the inferior tibiofibular syndesmosis, it supplies the tarsus and anastomoses with the lateral tarsal artery. This branch is sometimes enlarged and may replace the dorsalis pedis artery.

Fasciocutaneous perforators from the lateral muscular branches pass along the posterior fibular fascial septum to penetrate the deep fascia and reach the skin. These vessels are utilized in raising fasciocutaneous posterolateral leg flaps (see below).

Communicating branch

The communicating branch connects to a communicating branch of the posterior tibial artery approximately 5 cm proximal to the ankle.

Calcaneal branches

Calcaneal (terminal) branches anastomose with the anterior lateral malleolar and calcaneal branches of the posterior tibial artery.

Perforator flaps in the knee and leg

The perforators which arise from the rich vascular anastomosis around the patella generally traverse the quadriceps tendon to supply the skin over the patella and the peri-patellar region (see Fig. 79.7). The skin flaps based on these perforators may be used as distally based or proximally based flaps to cover defects over the knee and popliteal region. The direct cutaneous branch of the popliteal artery and a superficial sural artery which accompanies the sural nerve provide additional perforators to the skin over the back of the knee. The posterior tibial artery gives out an average of ten perforators to the skin covering the anteromedial and posterior parts of the leg. In the upper third of the leg the perforating vessels are predominantly muscular and periosteocutaneous, while in the lower third, the perforating vessels are mainly direct subcutaneous types. They anastomose with the perforating branches of the anterior tibial artery anteriorly and fibular artery posteriorly. Inferiorly, the posterior tibial artery forms a rich anastomotic circle around the ankle joint with the fibular and anterior tibial arteries. Perforators from these vessels supply the calcaneal tendon and the overlying skin. The posterior tibial artery gives off three direct cutaneous perforators in the lower part of the leg: a distally based skin or adipo-fascial flap based on one of these perforators may be used to reconstruct a defect over the anterior or the posterior aspect of the lower leg. The anterior tibial artery gives off an average of six perforators which supply the antero-lateral part of the leg. They emerge in two longitudinal rows; one perforator is fairly large and accompanies the superficial fibular nerve. A small skin flap based on any one of these perforators may be used to cover small defects over the tibia and a neurocutaneous flap that includes the superficial fibular nerve may be used.

The fibular artery has an average of five perforators. A constant perforator pierces the deep fascia approximately 5 cm above the lateral malleolus and divides into an ascending and descending branch. A vascularized fibula graft based on the fibular artery is now the standard graft used in reconstruction of the mandible, while small fascio-cutaneous and adipo-fascial flaps based on the perforators of the fibular artery are useful in covering soft tissue defects over the heel and proximal part of the foot region.

DEEP AND SUPERFICIAL VENOUS SYSTEM

Posterior tibial veins

The posterior tibial veins accompany the posterior tibial artery (see Fig. 79.8). They receive tributaries from the calf muscles (especially from the venous plexus in the soleus) and connections from superficial veins and the fibular veins.

Fibular veins

The fibular veins, running with their artery, receive tributaries from soleus and from superficial veins.

Anterior tibial veins

The anterior tibial veins, continuations of the venae comitantes of the dorsalis pedis artery, leave the anterior compartment between the tibia and fibula and pass through the proximal end of the interosseous membrane. They unite with the posterior tibial veins to form the popliteal vein at the distal border of popliteus.

Long and short saphenous vein

The long and short saphenous veins are described on pages 1381 and 1409.

Venous disease

Chronic venous disease is common. Sustained overdistension of the superficial veins of the lower limb may result in the development of short, dilated venous segments or varicosities. Varicose veins can occur as a consequence of venous valve failure at the proximal end of the long saphenous vein at the saphenofemoral junction, or in the perforating veins that pass from the superficial system to the high-pressure deep veins. Varicose veins have thin walls and ‘leak’ red blood cells into adjacent soft tissues. As these cells are broken down haemosiderin is deposited in the soft tissues causing a brown pigmentation. This phenomenon, together with the fact that venous stasis produces oedema, renders the soft tissues of the leg unhealthy and prone to ulceration, particularly after minor trauma.

Acute venous disease occurs most commonly in the posterior compartment of the leg. This is attributed to the sluggish blood flow that occurs, at times, in the deep veins of the calf. This relative stasis predisposes to the formation of venous thrombi. Fragments of these thrombi may become dislodged and carried in the circulation to cause life-threatening pulmonary embolism. Blockage of the normal venous system may contribute to increased local venous pressure and oedema.

INNERVATION

Tibial nerve

The tibial nerve, the larger component of the sciatic nerve (see Chs 79 & 80), is derived from the ventral branches (anterior divisions) of the fourth and fifth lumbar and first to third sacral ventral rami. It descends along the back of the thigh and popliteal fossa to the distal border of popliteus. It then passes anterior to the arch of soleus with the popliteal artery and continues into the leg. In the thigh it is overlapped proximally by the hamstring muscles but it becomes more superficial in the popliteal fossa, where it is lateral to the popliteal vessels. At the level of the knee the tibial nerve becomes superficial to the popliteal vessels and crosses to the medial side of the artery. In the distal popliteal fossa it is overlapped by the junction of the two heads of gastrocnemius.

In the leg the tibial nerve descends with the posterior tibial vessels to lie between the heel and the medial malleolus. Proximally it is deep to soleus and gastrocnemius, but in its distal third is covered only by skin and fasciae, overlapped sometimes by flexor hallucis longus. At first medial to the posterior tibial vessels, it crosses behind them and descends lateral to them until it bifurcates. It lies on tibialis posterior for most of its course except distally, where it adjoins the posterior surface of the tibia. The tibial nerve ends under the flexor retinaculum by dividing into the medial and lateral plantar nerves.

Branches

The branches of the tibial nerve are articular, muscular, sural, medial calcaneal and medial and lateral plantar nerves. The medial and lateral plantar nerves are described in Chapter 84.

Articular branches

Articular branches to the knee joint accompany the superior, and inferior medial genicular arteries, and the middle genicular artery. They form a plexus with a branch from the obturator nerve and supply the oblique popliteal ligament. The branches accompanying the superior and inferior genicular arteries also supply the medial part of the capsule. Just before the tibial nerve bifurcates it supplies the ankle joint.

Muscular branches

Proximal muscular branches arise between the heads of gastrocnemius and supply gastrocnemius, plantaris, soleus and popliteus. The nerve to soleus enters its superficial aspect. The branch to popliteus descends obliquely across the popliteal vessels, curling round the distal border of the muscle to its anterior surface. It also supplies tibialis posterior, the proximal tibiofibular joint and the tibia, and gives off an interosseous branch that descends near the fibula to reach the distal tibiofibular joint.

Muscular branches in the leg, either independently or by a common trunk, supply soleus (on its deep surface), tibialis posterior, flexor digitorum longus and flexor hallucis longus. The branch to flexor hallucis longus accompanies the fibular vessels.

Sural nerve

The sural nerve descends between the heads of gastrocnemius, pierces the deep fascia proximally in the leg, and is joined at a variable level by the sural communicating branch of the common fibular nerve. Some authors term this branch the lateral sural cutaneous nerve, and the main trunk (from the tibial nerve) the medial sural cutaneous nerve. The sural nerve descends lateral to the calcaneal tendon, near the short saphenous vein, to the region between the lateral malleolus and the calcaneus and supplies the posterior and lateral skin of the distal third of the leg. It then passes distal to the lateral malleolus along the lateral side of the foot and little toe, supplying the overlying skin. It connects with the posterior femoral cutaneous nerve in the leg and with the superficial fibular nerve on the dorsum of the foot.

The surface marking at the ankle is a line parallel to the calcaneal tendon half-way between the tendon and the lateral malleolus. However, its position is variable and it is at risk from any surgery in this region. Rather like the radial nerve at the wrist, the sural nerve, when injured, has a tendency to form painful neuromas. The nerve is often used as an autologous peripheral nerve graft on the grounds that it is easily harvested, easily identified and exclusively sensory.

Lesions of the tibial nerve

The tibial nerve is vulnerable to direct injury in the popliteal fossa, where it lies superficial to the vessels at the level of the knee. It may be damaged in compartment syndrome that affects the deep flexor compartment of the calf. The nerve may be entrapped beneath the flexor retinaculum at the ankle, resulting in tarsal tunnel syndrome.

Common fibular nerve

The common fibular nerve (common fibular nerve) is approximately half the size of the tibial nerve and is derived from the dorsal branches of the fourth and fifth lumbar and first and second sacral ventral rami. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, medial to biceps femoris. It lies between the bicipital tendon, to which it is bound by fascia, and the lateral head of gastrocnemius. The nerve then passes into the anterolateral compartment of the leg through a tight opening in the thick fascia overlying tibialis anterior. It curves lateral to the fibular neck, deep to fibularis longus, and divides into superficial and deep fibular nerves.

The course of the common fibular nerve can be indicated by a line drawn from the apex of the popliteal fossa, passing distally, medial to the biceps tendon, to the back of the head of the fibula, where the nerve can be rolled against the bone.

Branches

The common fibular nerve has articular and cutaneous branches and terminates as the superficial and deep fibular nerves.

Articular branches

There are three articular branches. Two accompany the superior and inferior lateral genicular arteries, and may arise in common. The third, the recurrent articular nerve, arises near the termination of the common fibular nerve. It ascends with the anterior recurrent tibial artery through tibialis anterior and supplies the anterolateral part of the knee joint capsule and the proximal tibiofibular joint.

Cutaneous branches

The two cutaneous branches, often from a common trunk, are the lateral sural and sural communicating nerves. The lateral sural nerve (lateral cutaneous nerve of the calf) supplies the skin on the anterior, posterior and lateral surfaces of the proximal leg. The sural communicating nerve arises near the head of the fibula and crosses the lateral head of gastrocnemius to join the sural nerve. It may descend separately as far as the heel.

Lesions of the common fibular nerve

The common fibular nerve is relatively unprotected as it traverses the lateral aspect of the neck of the fibula and is easily compressed at this site, e.g. by plaster casts or ganglia. The nerve may also become entrapped between the attachments of fibularis longus to the head and shaft of the fibula. Traction lesions can accompany dislocations of the lateral compartment of the knee, and are most likely to occur if the distal attachments of biceps and the ligaments that insert into the fibular head are avulsed, possibly with a small part of the fibular head: because the nerve is tethered to the bicipital tendon by dense fascia, it is pulled proximally. Patients with such injury present with a foot drop which is usually painless. Examination reveals weakness of ankle dorsiflexion, extensor hallucis longus and eversion of the foot, but inversion and plantar flexion are normal and the ankle reflex is preserved. Since the common fibular nerve divides at the fibular neck into the superficial and deep fibular nerves, injuries to the nerve at this level may damage either the main trunk or its branches.

Superficial fibular nerve

The superficial fibular nerve (superficial fibular nerve) begins at the bifurcation of the common fibular nerve. It lies at first deep to fibularis longus, then passes anteroinferiorly between fibularis longus and brevis and extensor digitorum longus and pierces the deep fascia in the distal third of the leg. It divides into a large medial dorsal cutaneous nerve and a smaller, more laterally placed, intermediate dorsal cutaneous nerve, usually after piercing the crural fascia, but sometimes while it is still deep to the fascia. As the nerve lies between the muscles it supplies fibularis longus, fibularis brevis and the skin of the lower leg. The deep course, i.e. the compartmental localization, and the peripheral digital distribution of the superficial fibular nerve are subject to considerable variation (see Kosinksi's classification; Kosinski 1926; Solomon et al 2001).

Branches

The medial dorsal cutaneous nerve passes in front of the ankle joint, and divides into two dorsal digital branches, one of which supplies the medial side of hallux and the other supplies the adjacent side of the second and third toes. It communicates with the saphenous and deep fibular nerves. The smaller intermediate branch traverses the dorsum of the foot laterally. It divides into dorsal digital branches that supply the contiguous sides of the third to fifth toes and the skin of the lateral aspect of the ankle, where it connects with the sural nerve. Both branches, especially the intermediate, are at risk during the placement of portal incisions for arthroscopy and during surgical approaches to the lateral malleolus. Branches of the superficial fibular nerve supply the dorsal skin of all the toes except that of the lateral side of the fifth toe (supplied by the sural nerve) and the adjoining sides of the great and second toes (supplied by the medial terminal branch of the deep fibular nerve). Some of the lateral branches of the superficial fibular nerve are frequently absent and are replaced by sural branches.

Accessory fibular nerves

An accessory superficial fibular nerve and an accessory deep fibular nerve have been described as anomalous branches of the superficial fibular nerve;

both are probably the product of atypical branching of the parent nerve deep to the crural fascia (see above).

Lesions of the superficial fibular nerve

A lesion of the superficial fibular nerve causes weakness of foot eversion and sensory loss on the lateral aspect of the leg that extends onto the dorsum of the foot. The nerve can be subject to entrapment as it penetrates the deep fascia of the leg and it may also be involved in compartment syndrome that affects the lateral compartment of the leg.

Deep fibular nerve

The deep fibular nerve (deep fibular nerve) begins at the bifurcation of the common fibular nerve, between the fibula and the proximal part of fibularis longus. It passes obliquely forwards deep to extensor digitorum longus to the front of the interosseous membrane and reaches the anterior tibial artery in the proximal third of the leg. It descends with the artery to the ankle, where it divides into lateral and medial terminal branches. As it descends, the nerve is first lateral to the artery, then anterior, and finally lateral again at the ankle.

Branches

The deep fibular nerve supplies muscular branches to tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius, and an articular branch to the ankle joint.

The lateral terminal branch crosses the ankle deep to extensor digitorum brevis, enlarges as a pseudoganglion and supplies extensor digitorum brevis. From the enlargement three minute interosseous branches supply the tarsal and metatarsophalangeal joints of the middle three toes.

The medial terminal branch runs distally on the dorsum of the foot lateral to the dorsalis pedis artery, and connects with the medial branch of the superficial fibular nerve in the first interosseous space. It divides into two dorsal digital nerves which supply adjacent sides of the great and second toes. Before dividing, it gives off an interosseous branch which supplies the first metatarsophalangeal joint. The deep fibular nerve may end as three terminal branches.

Lesions of the deep fibular nerve

Damage to the deep fibular nerve, e.g. in compartment syndrome that affects the anterior compartment of the leg, results in weakness of ankle dorsiflexion and extension of all toes; sensory impairment is confined to the first interdigital cleft.

Saphenous nerve

The saphenous nerve is described on page 1409.

CHAPTER 84

Ankle and foot

The ankle joint (talocrural joint) is a diarthrodial articulation involving the distal tibia and fibula and the body of the talus: it is the only example in the human body of a true mortise joint. The human foot is a complex structure adapted to allow orthograde bipedal stance and locomotion and is the only part of the body which is in regular contact with the ground. There are 28 separate bones in the human foot, including the sesamoid bones of the first metatarsophalangeal joint and 31 joints, including the ankle joint.

SKIN AND SOFT TISSUE

SKIN

Vascular supply and lymphatic drainage

The skin around the ankle is supplied by anterior lateral and anterior medial malleolar arteries from the anterior tibial artery, medial malleolar branches from the posterior tibial artery, and fasciocutaneous perforators from the anterior and posterior tibial and fibular arteries. The main blood supply to the medial side of the heel is from the medial calcaneal branches of the lateral plantar artery passing through the flexor retinaculum; the skin of the lateral side of the heel is supplied by calcaneal branches of the fibular artery and the lateral tarsal artery. The arterial supply to the skin of the foot is rich and is derived from branches of the dorsalis pedis (the direct continuation of the anterior tibial artery), posterior tibial and fibular arteries. The skin covering the dorsum of the foot is supplied by the dorsalis pedis artery, and by its continuation, the first dorsal metatarsal artery, with smaller contributions from the anterior perforating branch of the fibular artery and the marginal anastomotic arteries on the medial and lateral borders of the foot. The plantar skin is supplied by perforating branches of the medial and lateral plantar arteries (the terminal branches of the posterior tibial artery). The skin of the forefoot is supplied by cutaneous branches of the common digital arteries.

Cutaneous venous drainage is via dorsal and plantar venous arches, which drain into medial and lateral marginal veins. On the plantar aspect, a superficial venous network forms an intradermal and subdermal mesh that drains to the medial and lateral marginal veins. Branches that accompany the medial and lateral plantar arteries arise from a deep venous network. Uniquely within the lower limb, venous flow in the foot is bidirectional. However, when valves are present, flow is from the plantar to the superficial dorsal system. From here, blood leaves the foot in the superficial and deep veins of the lower limb.

Superficial lymphatic drainage is via vessels that accompany the long saphenous vein medially and the short saphenous vein laterally and drain via the inguinal lymph nodes. Deep lymphatic vessels accompany the dorsalis pedis, posterior tibial and fibular arteries and pass via the popliteal lymph nodes.

Cutaneous innervation

The skin covering the ankle and foot is supplied by the fourth and fifth lumbar and first sacral spinal nerves (see Figs 79.18, 79.20). Innervation of the dorsum of the foot is provided medially by the saphenous nerve, centrally by the superficial fibular nerve and laterally by the sural nerve; the deep fibular nerve supplies the dorsum of the first web space. Dorsal branches of the medial and lateral plantar nerves supply the nail beds. The plantar aspect of the foot is supplied by the medial and lateral plantar nerves, which arise as terminal branches of the tibial nerve. The medial plantar nerve supplies sensation to the plantar aspect of the hallux, the second, the third and the medial half of the fourth toes. The lateral plantar nerve supplies the remaining lateral aspect of the fourth and the entire fifth toe. The heel is innervated by calcaneal branches of the tibial nerve. Injury to any of these nerves can lead to painful neuromata and loss of protective sensation. The sural nerve is especially prone to neuroma formation.

SOFT TISSUES

The tendons that cross the ankle joint are all deflected to some degree from a straight course, and must therefore be held down by retinacula and enclosed in synovial sheaths.

Retinacula at the ankle

In the vicinity of the ankle joint, the tendons of the muscles of the leg are bound down by localized, band-shaped thickenings of the deep fascia termed retinacula which collectively serve to prevent bowstringing of the underlying tendons. There are superior and inferior extensor retinacula, superior and inferior fibular retinacula, and a flexor retinaculum.

Extensor retinacula

Superior extensor retinaculum

The superior extensor retinaculum binds down the tendons of tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius immediately proximal to the anterior aspect of the talocrural joint (see Fig. 83.7; Fig. 84.1). The anterior tibial vessels and deep fibular nerve pass deep to the retinaculum and the superficial fibular nerve passes superficially. The retinaculum is attached laterally to the distal end of the anterior border of the fibula and medially to the anterior border of the tibia. Its proximal border is continuous with the fascia cruris, and dense connective tissue connects its distal border to the inferior extensor retinaculum. The tendon of tibialis anterior is the only extensor tendon that possesses a synovial sheath at the level of the superior extensor retinaculum.

(From Drake, Vogl and Mitchell 2005.)

Inferior extensor retinaculum

The inferior extensor retinaculum is a Y-shaped band lying anterior to the talocrural joint (see Fig. 83.7; Fig. 84.2A,B). The stem of the Y is at the lateral end, where it is attached to the upper surface of the calcaneus, in front of the sulcus calcanei. The band passes medially, forming a strong loop around the tendons of fibularis tertius and extensor digitorum longus (Fig. 84.2A). From the deep surface of the loop, a band passes laterally behind the interosseous talocalcaneal ligament and the cervical ligament and is attached to the sulcus calcanei. At the medial end of the loop, two diverging limbs extend medially to complete the ‘Y’ shape of the retinaculum. The proximal of the two limbs consists of two layers. The deep layer passes deep to the tendons of extensor hallucis longus and tibialis anterior, but superficial to the anterior tibial vessels and deep fibular nerve, to reach the medial malleolus. The superficial layer crosses superficial to the tendon of extensor hallucis longus and then adheres firmly to the deep one; in some cases it continues superficial to the tendon of tibialis anterior, before blending with the deep layer. The distal limb extends downwards and medially and blends with the plantar aponeurosis. It is superficial to the tendons of extensor hallucis longus and tibialis anterior, the dorsalis pedis artery and the terminal branches of the deep fibular nerve.

Flexor retinaculum

The flexor retinaculum is attached anteriorly to the tip of the medial malleolus, distal to which it is continuous with the deep fascia on the dorsum of the foot (Fig. 84.2B). From its malleolar attachment it extends posteroinferiorly to the medial process of the calcaneus and the plantar aponeurosis. Proximally, there is no clear demarcation between its border and the deep fascia of the lower leg, especially the deep transverse layer of the deep fascia. Distally, its border is continuous with the plantar aponeurosis, and many fibres of abductor hallucis are attached to it. The flexor retinaculum converts grooves on the tibia and calcaneus into canals for the tendons, and bridges over the posterior tibial vessels and tibial nerve. As these structures enter the sole they are, from medial to lateral, the tendons of tibialis posterior and flexor digitorum longus, the posterior tibial vessels, the tibial nerve and the tendon of flexor hallucis longus (see Fig. 84.14).

Fibular retinacula

The fibular retinacula are fibrous bands that retain the tendons of fibularis longus and brevis in position as these tendons cross the lateral aspect of the ankle region (Fig. 84.2A).

Superior fibular retinaculum

The superior fibular retinaculum is a short band which extends from the back of the lateral malleolus to the deep transverse fascia of the leg and the lateral surface of the calcaneus. Damage to the retinaculum can lead to instability of the fibular tendons.

Inferior fibular retinaculum

The inferior fibular retinaculum is continuous in front with the inferior extensor retinaculum, and is attached posteriorly to the lateral surface of the calcaneus. Some of its fibres are fused with the periosteum on the fibular trochlea (peroneal tubercle) of the calcaneus, forming a septum between the tendons of fibularis longus and brevis.

Synovial sheaths at the ankle

Anterior to the ankle, the sheath for tibialis anterior extends from the proximal margin of the superior extensor retinaculum to the interval between the diverging limbs of the inferior retinaculum (Figs 84.1, 84.2A,B). A common sheath encloses the tendons of extensor digitorum longus and fibularis tertius, starting just above the level of the malleoli, and reaching to the level of the base of the fifth metatarsal bone (Figs 84.1, 84.2A). The sheath for extensor hallucis longus starts at a level just distal to that for extensor digitorum longus and extends as far as the base of the first metatarsal bone (Figs 84.1, 84.2A,B).

Posteromedial to the ankle, the sheath for tibialis posterior starts approximately 4 cm above the medial malleolus and ends just proximal to the attachment of the tendon to the tuberosity of the navicular (Fig. 84.2B). The sheath for flexor hallucis longus starts at the level of the medial malleolus, and extends distally as far as the base of the first metatarsal bone (Fig. 84.2B). Occasionally, as a result of overuse, particularly in ballet dancers where balance on the tips of the toes en pointe involves sustained extreme plantar flexion of the ankle and first toe in the weight-bearing position, a fibrous nodule may develop in the tendon, just proximal to the tendon sheath.

This may result in the thickened tendon being caught intermittently in the sheath, causing pain and ‘triggering’ of the great toe, a condition referred to as hallux saltans. Surgical opening of the sheath may be required. In athletes, the muscle belly of flexor hallucis longus may be abnormally large and may extend more distally than usual; it can also catch at the opening of the sheath. The sheath for flexor digitorum longus starts slightly above the level of the medial malleolus and ends at the level of the navicular (Fig. 84.2B).

Posterolateral to the ankle, the tendons of fibularis longus and brevis are enclosed in a sheath that is single proximally but double distally (Fig. 84.2A). From the tip of the lateral malleolus it extends for about 4 cm both proximally and distally.

Plantar fascia

The plantar fascia or aponeurosis is composed of densely compacted collagen fibres orientated mainly longitudinally, but also transversely (Fig. 84.3). Its medial and lateral borders overlie the intrinsic muscles of the hallux and fifth toe respectively, while its dense central part overlies the long and short flexors of the digits.

Medial malleolus
Plantar aponeurosis
Abductor hallucis
Lateral malleolus
Subcutaneous calcaneal bursa

Fig. 84.3 The plantar aponeurosis.

(From Sobotta 2006.)

The central part is the strongest and thickest. The fascia is narrow posteriorly, where it is attached to the medial process of the calcaneal tuberosity proximal to flexor digitorum brevis, and traced distally it becomes broader and somewhat thinner. Just proximal to the level of the metatarsal heads it divides into five bands, one for each toe. As these five digital bands diverge below the metatarsal shafts, they are united by transverse fibres (Fig. 84.3). Proximal, plantar and a little distal to the metatarsal heads and the metatarsophalangeal joints, the superficial stratum of each of the five bands is connected to the dermis by skin ligaments (retinacula cutis). These ligaments reach the skin of the ball of the foot proximal to, and in the floors of, the furrows that separate the toes from the sole: Dupuytren’s disease may involve these ligaments resulting in contractures of the affected digits. The deep stratum of each digital band of the aponeurosis yields two septa that flank the digital flexor tendons and separate them from the lumbricals and the digital vessels and nerves. These septa pass deeply to fuse with the interosseous fascia, the deep transverse metatarsal ligaments (which run between the heads of adjacent metatarsals), the plantar ligaments of the metatarsophalangeal joints, and the periosteum and fibrous flexor sheaths at the base of each proximal phalanx. Pads of fat develop in the webs between the metatarsal heads and the bases of the proximal phalanges; they cushion the digital nerves and vessels from adjoining tendinous structures and extraneous plantar pressures. Just distal to the metatarsal heads, a plantar interdigital ligament (superficial transverse metatarsal ligament) blends progressively with the deep aspect of the superficial stratum of the plantar aponeurosis where it enters the toes (Fig. 84.3). The central part of the plantar aponeurosis thus provides an intermediary structure between the skin and the osteoligamentous framework of the foot via numerous cutaneous retinacula and deep septa that extend to the metatarsals and phalanges. The central part is also continuous with the medial and lateral parts: at the junctions, two intermuscular septa, medial and lateral, extend in oblique vertical planes between the medial, intermediate and lateral groups of plantar muscles to reach bone. Thinner horizontal intermuscular septa, derived from the vertical intermuscular septa, pass between the muscle layers.

The lateral part of the plantar aponeurosis, which covers abductor digiti minimi, is thin distally and thick proximally, where it forms a strong band, sometimes containing muscle fibres, between the lateral process of the calcaneal tuberosity and the base of the fifth metatarsal bone. It is continuous medially with the central part of the aponeurosis, and with the fascia on the dorsum of the foot around its lateral border. The medial part of the plantar aponeurosis, which covers abductor hallucis, is thin. It is continuous proximally with the flexor retinaculum, medially with the fascia dorsalis pedis, and laterally with the central part of the plantar aponeurosis.

Fascial compartments of the foot

There are four main compartments of the plantar aspect of the foot (Jones 1949) (Fig. 84.4). The medial compartment contains abductor hallucis and flexor hallucis brevis, and is bounded inferiorly and medially by the medial part of the plantar aponeurosis and its medial extension, laterally by an intermuscular septum, and dorsally by the first metatarsal. The central compartment contains flexor digitorum brevis, the lumbricals, flexor accessorius and adductor hallucis, and is bounded by the plantar aponeurosis inferiorly, the osseofascial tarsometatarsal structures dorsally and intermuscular septa medially and laterally. The lateral compartment contains abductor digiti minimi and flexor digiti minimi brevis, and its boundaries are the fifth metatarsal dorsally, the plantar aponeurosis inferiorly and laterally, and an intermuscular septum medially. The interosseous compartment contains the seven interossei and its boundaries are the interosseous fascia and the metatarsals.

Fig. 84.4 Transverse section through the midfoot showing the main fascial compartments.

The dorsal aspect of the foot effectively contains a single compartment which is occupied by the extensor tendons and extensor digitorum brevis, and which is roofed by the deep dorsal fascia (see below).

Lateral intermuscular septum

The lateral intermuscular septum is incomplete, especially at its proximal end. Distally, its deep attachments are to the fibrous sheath of fibularis longus and to the fifth metatarsal bone.

Medial intermuscular septum

The medial intermuscular septum is incomplete and divides into three bands, proximal, intermediate and distal, each of which displays lateral and medial divisions as it approaches its deep attachment. The proximal band is attached laterally to the cuboid and blends medially with the tendon of tibialis posterior. The middle band is attached laterally to the cuboid and the long plantar ligament and medially to the medial cuneiform bone. The distal band divides to enclose the tendon of flexor hallucis longus and is attached to the fascia over flexor hallucis brevis.

Deep dorsal fascia

The deep fascia on the dorsum of the foot (fascia dorsalis pedis) is a thin layer, continuous above with the inferior extensor retinaculum; it covers the dorsal extensor tendons and extensor digitorum brevis.

Compartment syndrome in the foot

A compartment syndrome results from an increase in intracompartmental pressure sufficient to impair venous outflow from that compartment. As blood enters at arterial pressure, the compartment pressure increases further until it exceeds arterial pressure, at which point inflow of arterial blood ceases, leading to muscle and nerve ischaemia. Failure to relieve the increased pressure in the compartment surgically results in necrosis of the soft tissues within the compartment. The most common cause of compartment syndrome in the foot is trauma, usually of high-energy (high impact) type: crush injuries, calcaneal fractures and disruption of the tarsometatarsal joints are the usual antecedents associated with compartment syndrome in the foot.

Specialized adipose tissue (heel and metatarsal pad)

The heel pad is subject to repeated high impacts and is anatomically adapted to withstand these pressures. The adult heel pad has an average thickness of 18 mm and a mean epidermal thickness of 0.64 mm (dorsal epidermal thickness averages 0.069 mm). The heel pad contains elastic adipose tissue organized as spiral fibrous septa anchored to each other, to the calcaneus and to the skin. The septa are U-shaped fat-filled columns designed to resist compressive loads and are reinforced internally with elastic diagonal and transverse fibres, which separate the fat into compartments.

In the forefoot, the subcutaneous tissue consists of fibrous lamellae arranged in a complex whorl containing adipose tissue attached via vertical fibres to the dermis superficially and the plantar aponeurosis deeply. The fat is particularly thick in the region of the metatarsophalangeal joints, which cushions the foot during the toe-off phase of gait (see below). Like the heel pad, the metatarsal fat pad is designed to withstand compressive and shearing forces. Atrophy of either may be a cause of persistent pain in the distal plantar region.

BONE

Functionally, the skeleton of the foot may be divided into tarsus, metatarsus and phalanges. With regard to nomenclature of the surfaces of the foot, the terms ‘plantar’ and ‘dorsal’ are used, to denote the inferior and superior surfaces respectively. The terms ‘proximal’ and ‘distal’ are used with the same significance as in limbs generally. Rotation of the limb buds that occurs in the early stages of the development of the limbs results in a laterally directed thumb in the hand, and a medially directed great toe in the foot.

DISTAL TIBIA

The distal end of the tibia has anterior, medial, posterior, lateral and distal surfaces, and projects inferomedially as the medial malleolus (see Figs 83.2A,B; 83.3A,B). The distal surface articulates with the talus and is wider anteriorly than posteriorly. It is concave sagittally and slightly convex transversely and continues medially into the malleolar articular surface. The medial malleolus is short and thick and has a smooth lateral surface with a crescentic facet that articulates with the medial surface of the talar body. The distal end of the tibia, including its ossification, is described in detail in Chapter 83.

Attachments

No muscles are attached to the distal tibia. The interosseous ligament, the deltoid ligament, and the anterior and posterior tibiofibular ligaments are attached to the distal tibia.

Vascular supply

The distal tibia is supplied by an arterial network formed by branches of the dorsalis pedis, posterior tibial and fibular arteries.

Innervation

The distal tibia is innervated by branches from the deep fibular, posterior tibial, saphenous and sural nerves.

DISTAL FIBULA

The distal end of the fibula or lateral malleolus projects distally and posteriorly relative to the medial malleolus (see Figs 83.2A,B; 83.3A,B). Its lateral aspect is subcutaneous, the posterior surface has a broad groove with a prominent lateral border, and the anterior surface is rough and somewhat rounded and articulates with the anteroinferior aspect of the tibia. The medial surface has a triangular articular facet, vertically convex with its apex directed distally. It articulates with the lateral talar surface. Behind the facet is a rough malleolar fossa. The distal end of the fibula, including its ossification, is described in detail in Chapter 83.

Attachments

No muscles are attached to the distal fibula below the level of the interosseous ligament. The ligamentous attachments are those of the lateral ligament complex, i.e. the anterior talofibular, the calcaneofibular and the posterior talofibular ligaments. The interosseous ligament is attached on its medial aspect.

Vascular supply

The distal fibula is supplied by an arterial network made up of branches of the dorsalis pedis, posterior tibial and fibular arteries.

Innervation

The distal fibula is innervated by the deep fibular, tibial, saphenous and sural nerves.

TARSUS

The seven tarsal bones occupy the proximal half of the foot (Figs 84.5A,B; 84.6). The tarsus and carpus are homologous, but the tarsal elements are larger, reflecting their role in supporting and distributing body weight. As in the carpus, tarsal bones are arranged in proximal and distal rows, but medially there is an additional single intermediate tarsal element, the navicular. The proximal row is made up of the talus and calcaneus; the long axis of the talus is inclined anteromedially and inferiorly, its distally directed head is medial to the calcaneus and at a higher level. The distal row contains, from medial to lateral, the medial, intermediate and lateral cuneiforms and the cuboid. Collectively these bones display an arched transverse alignment that is dorsally convex. Medially, the navicular is interposed between the head of the talus and the cuneiforms. Laterally, the calcaneus articulates with the cuboid.

The tarsus and metatarsus are arranged to form intersecting longitudinal and transverse arches. Hence thrust and weight are not transmitted from the tibia to the ground (or *vice versa*) directly through the tarsus, but are distributed through the tarsal and metatarsal bones to the ends of the longitudinal arches. For the purposes of description, each tarsal bone is arbitrarily considered to be cuboidal in form, with six surfaces. The ossification sites and dates are summarized in Fig. 84.7.

Head

Directed distally and somewhat inferomedially, the head has a distal surface which is ovoid and convex; its long axis is also inclined inferomedially to articulate with the proximal navicular surface. The plantar surface of the head has three articular areas, separated by smooth ridges. The most posterior and largest is oval, slightly convex and rests on a shelf-like medial calcaneal projection, the sustentaculum tali. Anterolateral to this and usually continuous with it, a flat articular facet rests on the anteromedial part of the dorsal (proximal) calcaneal surface; distally it continues into the navicular surface. Between the two calcaneal facets, a part of the talar head, covered with articular cartilage, is in contact with the plantar calcaneonavicular ligament, which is covered here, superiorly, by fibrocartilage (see Fig. 84.15A,B). When the foot is inverted passively, the dorsolateral aspect of the head is visible and palpable approximately 3 cm distal to the tibia; it is hidden by extensor tendons when the toes are dorsiflexed.

Neck

The neck is the narrow, medially inclined region between the head and body. Its rough surfaces are for ligaments. The medial plantar surface has a deep sulcus tali which, when the talus and calcaneus are articulated, forms a roof to the sinus tarsi, which is occupied by inter-osseous talocalcaneal and cervical ligaments.

The long axis of the neck, inclined downwards, distally and medially, makes an angle of approximately 150° with that of the body; it is smaller (130–140°) at birth, accounting in part for the inverted foot in young children. The dorsal talonavicular ligament and ankle articular capsule are attached distally to its dorsal surface. Thus the proximal part of this surface lies within the capsule of the ankle joint. The medial articular facet of the talar body and part of the trochlear surface may extend onto the neck. The anterior talofibular ligament is attached on the lateral aspect of the neck, spreading along the adjacent anterior border of the lateral surface. The interosseous talocalcaneal and cervical ligaments are attached to the inferior surface of the neck. A dorsolateral, so-called ‘squatting facet’ is commonly present on the talar neck in those individuals who habitually adopt the squatting position: it articulates with the anterior tibial margin in extreme dorsiflexion and may be double.

Body

The body is cuboidal, covered dorsally by a trochlear surface articulating with the distal end of the tibia. It is anteroposteriorly convex, gently concave transversely, widest anteriorly and, therefore, sellar. The triangular lateral surface is smooth and vertically concave for articulation with the lateral malleolus. Superiorly, it is continuous with the trochlear surface; inferiorly its apex is a lateral process. Proximally, the medial surface is (posterosuperiorly) covered by a comma-shaped facet, which is deeper in front and articulates with the medial malleolus. Distally, this surface is rough and contains numerous vascular foramina. The small posterior surface features a rough projection termed the posterior process. The process is marked by an oblique groove between two tubercles which lodges the tendon of flexor hallucis longus. The lateral tubercle is usually larger; the medial is less prominent and immediately behind the sustentaculum tali (Fig. 84.8A). The plantar surface articulates with the middle one-third of the dorsal calcaneal surface by an oval concave facet, its long axis directed distolaterally at an angle of approximately 45° with the median plane. The medial edge of the trochlear surface is straight, but its lateral edge inclines medially in its posterior part and is often broadened into a small elongated triangular area which is in contact with the posterior tibiofibular ligament in dorsiflexion.

(From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)

The posterior talofibular ligament is attached to the lateral tubercle of the posterior process. Its attachment extends up to the groove, or depression, between the process and posterior trochlear border. The posterior talocalcaneal ligament is attached to the plantar border of the posterior process. The groove between the tubercles of the process contains the tendon of flexor hallucis longus and continues distally into the groove on the plantar aspect of the sustentaculum tali. The medial talocalcaneal ligament is attached below to the medial tubercle, whereas the most posterior superficial fibres of the deltoid ligament are attached above the tubercle. The deep fibres of the deltoid ligament are attached still higher to the rough area immediately below the comma-shaped articular facet on the medial surface (Fig. 84.8A,C).

Muscle attachments

No muscles are attached to the talus. However, many ligaments are attached to the bone, and these confer stability to the ankle, subtalar and talocalcaneonavicular joints (Fig. 84.8A–C).

Vascular supply

The talar blood supply is rather tenuous because of the lack of muscle attachments. The first comprehensive account of talar blood supply was provided by Wildenauer in 1950. The extraosseous blood supply is via the posterior tibial, dorsalis pedis and fibular arteries (Fig. 84.9). The ‘artery of the tarsal canal’ arises from the posterior tibial artery approximately 1cm proximal to the origin of the medial and lateral plantar arteries (Fig. 84.10) and passes anteriorly between the sheaths of flexor digitorum longus and flexor hallucis longus to enter the tarsal canal in which it lies anteriorly, close to the talus. (The ‘tarsal canal’ is the term that is commonly used to describe the tunnel-shaped medial end of the sinus tarsi.) Branches from the arterial network in the tarsal canal enter the talus. The artery continues through the tarsal canal into the lateral part of the tarsal sinus, where it anastomoses with the artery of the tarsal sinus, forming a vascular sling under the talar neck. A branch of the artery of the tarsal canal known as the deltoid branch passes deep to the deltoid ligament and supplies part of the medial aspect of the talar body. Sometimes it arises from the posterior tibial artery; rarely, it arises from the medial plantar artery. In talar fractures it may be the only remaining arterial supply to the talus to maintain the viability of the talar body. The dorsalis pedis artery supplies branches to the superior aspect of the talar neck and also gives off the artery of the tarsal sinus. This large vessel is always present and anastomoses with the artery of the tarsal canal. The artery of the tarsal sinus receives a contribution from the anterior perforating branch of the fibular artery and supplies direct branches to the talus. The fibular artery provides small branches which form a plexus of vessels posteriorly with branches of the posterior tibial artery, however, the contribution that the fibular artery makes to the talar blood supply is thought to be insignificant.

The intraosseous blood supply of the talar head comes medially from branches of the dorsalis pedis and laterally via vessels that arise from the anastomosis between the arteries of the tarsal canal and tarsal sinus. The middle one-third of the talar body, other than its most superior aspect, and the lateral one-third, other than its posterior aspect, are supplied mainly by the anastomotic arcade in the tarsal canal. The medial one-third of the talar body is supplied by the deltoid branch of the artery of the tarsal canal.

Innervation

The talus is innervated by branches from the deep fibular, posterior tibial, saphenous and sural nerves.

Ossification

A single ossification centre appears prenatally at 6 months (Fig. 84.7). The posterior process (Stieda’s process) is a separate bone in 5% of individuals and arises from a separate ossification centre, which appears between 8 and 11 years. In athletes and dancers, it may be susceptible to impingement against the posterior tibia, resulting in pain and sometimes requires surgical removal. Another accessory bone (although rare) is the os supratalare, which lies on the dorsal aspect of the talus; it rarely measures more than 4 mm in length.

Talar fractures

The talus has no muscular attachments and 70% of its surface is covered by articular cartilage: displaced talar neck fractures, where the blood supply to the talar body is interrupted, can therefore result in avascular necrosis and non-union. In general, these complications do not occur in undisplaced fractures. If a subchondral lucency is seen in the talar dome on radiographs at 8 weeks after fracture of the talar neck (Hawkin's sign), it may be assumed that vascularity to the talar body is intact and that the fracture is likely to heal satisfactorily.

Calcaneus

The calcaneus is the largest tarsal bone and projects posterior to the tibia and fibula as a short lever for muscles of the calf attached to its posterior surface. It is irregularly cuboidal, its long axis being inclined distally upwards and laterally (Fig 84.8A,B). The superior or proximal surface is divisible into three areas. The posterior one-third is rough and concavo-convex; the convexity is transverse and supports fibroadipose tissue (Kager's fat pad) between the calcaneal tendon and ankle joint. The middle one-third carries the posterior talar facet, which is oval and convex anteroposteriorly. The anterior one-third is partly articular; distal (anterior) to the posterior articular facet, a rough depression, the sulcus calcanei, narrows into a groove on the medial side and completes the sinus tarsi with the talus. (The sinus tarsi is a conical hollow bounded by the talus medially, superiorly and laterally, with the superior surface of the calcaneus below. Its medial end is narrow and tunnel-shaped, and is often referred to as the tarsal canal.) Distal and medial to this groove, an elongated articular area covers the sustentaculum tali and extends distolaterally on the body of the bone. This facet is often divided into middle and anterior talar facets by a non-articular interval at the anterior limit of the sustentaculum tali (the incidence of this subdivision varies with sex, race and occupation). Rarely, all three facets on the upper surface of the calcaneus are fused into one irregular area. A detailed analysis of patterns of anterior talar articular facets in a series of 401 Indian calcanei revealed four types. Type I (67%) showed one continuous facet on the sustentaculum extending to the distomedial calcaneal corner; type II (26%) presented two facets, one sustentacular and one distal calcaneal; type III (5%) possessed only a single sustentacular facet; and type IV (2%) showed confluent anterior and posterior facets.

The anterior surface is the smallest, and is an obliquely set concavo-convex articular facet for the cuboid. The posterior surface is divided into three regions: a smooth proximal (superior) area separated from the calcaneal tendon by a bursa and adipose tissue; a middle area, which is the largest, limited above by a groove and below by a rough ridge for the calcaneal tendon; a distal (inferior) area inclined downwards and forwards, vertically striated, which is the subcutaneous weight-bearing surface.

The plantar surface is rough, especially proximally as the calcaneal tuberosity, the lateral and medial processes of which extend distally, separated by a notch. The medial process is longer and broader (Fig. 84.8B). Further distally, an anterior tubercle marks the distal limit of the attachment of the long plantar ligament.

The lateral surface is almost flat. It is proximally deeper and palpable on the lateral aspect of the heel distal to the lateral malleolus. Distally, it presents the fibular trochlea (Fig. 84.8A,B), which is exceedingly variable in size and palpable 2 cm distal to the lateral malleolus when well developed. It bears an oblique groove for the tendon of fibularis longus and a shallower proximal groove for the tendon of fibularis brevis. About 1 cm or more behind and above the fibular trochlea, a second elevation may exist for attachment of the calcaneofibular part of the lateral ligament.

The medial surface is vertically concave, and its concavity is accentuated by the sustentaculum tali, which projects medially from the distal part of its upper border (Fig. 84.8B). Superiorly, the process bears the middle talar facets and inferiorly a groove which is continuous with that on the talar posterior surface for the tendon of flexor hallucis longus (Fig. 84.8A,B). The medial aspect of the sustentaculum tali can be felt immediately distal to the tip of the medial malleolus; occasionally it is also grooved by the tendon of flexor digitorum longus.

Muscle and ligament attachments

The interosseous talocalcaneal and cervical ligaments and the medial root of the inferior extensor retinaculum are attached in the calcaneal sulcus. The non-articular area distal to the posterior talar facet is the site of attachment of extensor digitorum brevis (in part), the principal band of the inferior extensor retinaculum and the stem of the bifurcate ligament.

Abductor hallucis and the superficial part of the flexor retinaculum and, distally, the plantar aponeurosis and flexor digitorum brevis, are all attached to the medial process of the calcaneal tuberosity at its prominent medial margin. Abductor digiti minimi is attached to the lateral process, extending medially to the medial process. The long plantar ligament is attached to the rough region between the processes proximally, and extends to the anterior tubercle distally. The short plantar ligament is attached to the tubercle and the area distal to it. The lateral tendinous head of flexor accessorius is attached distal to the lateral process near the lateral margin of the long plantar ligament. Plantaris is attached to the posterior surface near the medial side of the calcaneal tendon. The anterior part of the lateral surface is crossed by the fibular tendons, but is largely subcutaneous. The calcaneofibular ligament is attached 1–2 cm proximal to the fibular trochlea, usually to a low, rounded elevation.

The dorsal surface of the sustentaculum tali is part of the talocalcaneonavicular joint; its plantar surface is grooved by the tendon of flexor hallucis longus and margins of the groove give attachment to the deep part of the flexor retinaculum. The plantar calcaneonavicular ligament is attached distally to the medial margin of the sustentaculum, which is narrow, rough and convex. A slip from the tendon of tibialis posterior, and superficial fibres of the deltoid ligament and medial talocalcaneal ligaments, are attached proximally. Distal to the attachment of the deltoid ligament, the tendon of flexor digitorum longus is related to the margin of the sustentaculum and may groove it. The large medial head of flexor accessorius is attached distal to the groove for flexor hallucis longus.

Vascular supply

The calcaneus receives its arterial supply from the medial and lateral calcaneal arteries (arising from the posterior tibial and fibular arteries, respectively), fibular artery, posterior calcaneal anastomosis (formed from the posterior tibial and fibular arteries), medial and lateral plantar arteries, artery of the tarsal sinus and tarsal canal, branches of the lateral tarsal artery and perforating fibular arteries.

Innervation

The calcaneus is innervated by branches of the tibial, sural and deep fibular nerves.

Ossification

The calcaneus is the only tarsal bone that always has two ossification centres (Fig. 84.7). In addition to the main ossification centre, there is a scale-like posterior apophysis that covers most of the posterior, and part of the plantar, surfaces. The main centre appears prenatally in the third month, whereas the posterior apophysis appears in the sixth year in females and the eighth in males, fusing in the 14th and 16th years, respectively.

An os calcaneus secondarius, an accessory bone rather than a secondary ossification centre, occurs in 2% of individuals. When present, it is located on the dorsal beak or anterior process of the calcaneus in an interval between the anteromedial aspect of the calcaneus, the proximal ends of the cuboid and navicular, and the head of the talus. Other rare accessory bones of the calcaneus include the calcaneus accessorius in the region of the fibular trochlea, the os sustentaculi on the posterior aspect of the sustentaculum, the os subcalcis on the plantar aspect of the calcaneus slightly posterior to the origin of the plantar aponeurosis, and the os aponeurosis plantaris, which lies within the plantar aponeurosis in close proximity to the medial process of the calcaneal tuberosity.

Navicular

The navicular articulates with the talar head proximally and with the cuneiform bones distally (Figs 84.8A,B; 84.11). Its distal surface is transversely convex and divided into three facets (the medial being the largest) for articulation with the cuneiforms. The proximal surface is oval and concave and articulates with the talar head. The dorsal surface is rough and convex. The medial surface is also rough and projects proximally as a prominent tuberosity, palpable approximately 2.5 cm distal and plantar to the medial malleolus. The plantar surface, rough and concave, is separated from the tuberosity medially by a groove. The lateral surface is rough, irregular and often bears a facet for articulation with the cuboid.

Fig. 84.11 Skeleton of the tarsals and metatarsals, dorsal aspect.

(From Sobotta 2006.)

The facet for articulation with the medial cuneiform is roughly triangular, its rounded apex is medial and its ‘base’, facing laterally, is often markedly curved; the articular facets for the intermediate and lateral cuneiforms are also triangular, with plantar facing apices. The facet for the lateral cuneiform may approach a wide crescent or a semicircle rather than a triangle (Fig. 84.11). Dorsal talonavicular, cuneonavicular and cubonavicular ligaments are attached to the dorsal navicular surface.

Muscle and ligament attachments

The navicular tuberosity is the main attachment of tibialis posterior and a groove lateral to it transmits part of the tendon distally to the cuneiforms and middle three metatarsal bases. The plantar calcaneonavicular ligament is attached to a slight projection lateral to the groove and adjacent to the proximal surface. The calcaneonavicular part of the bifurcate ligament is attached to the rough part of the lateral surface (Fig. 84.5B).

Vascular supply

The dorsal aspect of the navicular is supplied either from a branch of, or directly from, the dorsalis pedis artery. Its plantar aspect is supplied from the medial plantar artery, and the tuberosity is supplied by an anastomosis from the dorsalis pedis and medial plantar arteries.

Innervation

The navicular is innervated by the deep fibular and medial plantar nerves.

Ossification

The navicular ossification centre appears during the third year (Fig. 84.7). It is sometimes affected by avascular necrosis between the ages of 4 and 7 years (Köhler’s disease). An accessory navicular bone, which is considered an anatomic variant, occurs in approximately 5% of individuals. It arises from a separate ossification centre in the region of the navicular tuberosity. There are three distinct types of accessory navicular. Type I is probably a sesamoid bone within the plantar aspect of the tendon of tibialis posterior at the level of the inferior calcaneonavicular ligament. In type II, the accessory bone is separated from the body of the navicular by a synchondrosis. Type III is commonly called ‘the cornuate navicular,’ where the accessory bone is united to the navicular by a bony ridge, and may represent the possible end stage of type II. An accessory navicular may be the source of pain in athletes. Type II is the most commonly symptomatic variant: it has been suggested that the pull of the tendon of tibialis posterior, the degree of foot pronation, and the location of the accessory bone in relation to the undersurface of the navicular may produce tension, shear, and/or compression forces on the synchondrosis.

Rarely, the navicular is bipartite and it arises from two distinct centres of ossification. This can lead to premature degeneration within the talocalcaneonavicular joint (Muller–Weiss disease). Occasionally, a small bone is found within the talocalcaneonavicular joint on its dorsal aspect. Referred to as an os talonaviculare dorsale, it represents either a separate accessory bone or a fractured osteophyte of the proximal dorsal aspect of the navicular.

Cuboid

The cuboid, the most lateral bone in the distal tarsal row, lies between the calcaneus proximally and the fourth and fifth metatarsals distally (Fig. 84.11). Its dorsolateral surface is rough for the attachment of ligaments. The plantar surface is crossed distally by an oblique groove for the tendon of fibularis longus and bounded proximally by a ridge that ends laterally in the tuberosity of the cuboid, the lateral aspect of which is faceted for a sesamoid bone or cartilage that is frequently found in the tendon of fibularis longus. Proximal to its ridge, the rough plantar surface extends proximally and medially because of the obliquity of the calcaneocuboid joint, making its medial border much longer than the lateral. The lateral surface is rough; the groove for fibularis longus extends from a deep notch on its plantar edge. The medial surface, which is much more extensive and partly non-articular, bears an oval facet for articulation with the lateral cuneiform, and proximal to this another facet (sometimes absent) for articulation with the navicular: the two form a continuous surface separated by a smooth vertical ridge. The distal surface is divided vertically into a medial quadrilateral articular area for the fourth metatarsal base and a lateral triangular area, its apex lateral, for the fifth metatarsal base. The proximal surface, triangular and concavo-convex, articulates with the distal calcaneal surface; its medial plantar angle projects proximally and inferior to the distal end of the calcaneus.

Muscle (and ligament) attachments

The dorsal calcaneo-cuboid, cubonavicular, cuneocuboid and cubometatarsal ligaments are attached to the dorsal surface. Deep fibres of the long plantar ligament are attached to the proximal edge of the plantar ridge. Slips from the tendons of tibialis posterior and flexor hallucis brevis are attached to the projecting proximomedial part of the plantar surface. Interosseous, cuneocuboid and cubonavicular ligaments are attached to the rough part of the medial cuboidal surface. Proximally, the medial calcaneocuboid ligament, which is the lateral limb of the bifurcate ligament, is also attached to this surface.

Vascular supply

The cuboid is supplied by deep branches of the medial and lateral plantar arteries and by branches from the dorsal arterial network.

Innervation

The cuboid is innervated by branches from the lateral plantar, sural and deep fibular nerves.

Ossification

The cuboid frequently begins to ossify before birth, the primary ossification centre appearing just before birth (Fig. 84.7). An os cuboides secundarium is a rare accessory bone situated on the plantar aspect of the cuboid.

Cuneiforms

The wedge-like cuneiform bones articulate with the navicular proximally and with the bases of the first to third metatarsals distally; the medial cuneiform is the largest, the intermediate the smallest. The dorsal surfaces of the intermediate and lateral cuneiforms form the base of the wedge. The wedge is reversed in the medial cuneiform, which is a prime factor in shaping the transverse arch. The proximal surfaces of all three form a concavity for the distal surface of the navicular. The medial and lateral cuneiforms project distally beyond the intermediate cuneiform and so form a recess for the second metatarsal base.

Medial cuneiform

The medial cuneiform (Figs 84.5A,B; 84.11) articulates with the navicular and first metatarsal base. It has a rough, narrow dorsal surface. The distal surface is a reniform facet for the first metatarsal base, its ‘hilum’ being lateral. The proximal surface bears a piriform facet for the navicular, which is concave vertically and dorsally narrowed. The medial surface, rough and subcutaneous, is vertically convex; its distal plantar angle carries a large impression which receives the principal attachment of the tendon of tibialis anterior (Fig. 84.5B). The lateral surface is partly non-articular; there is a smooth right-angled strip along its proximal and dorsal margins for the intermediate cuneiform. Its distal dorsal area is separated by a vertical ridge from a small, almost square, facet for articulation with the dorsal part of the medial surface of the second metatarsal base. Plantar to this, the medial cuneiform is attached to the medial side of the second metatarsal base by a strong ligament. Proximally, an interosseous intercuneiform ligament connects this surface to the intermediate cuneiform. The distal and plantar area of the surface is roughened by attachment of part of the tendon of fibularis longus (Fig. 84.5B).

Muscle attachments

The plantar surface receives a slip from the tendon of tibialis posterior, in addition to part of the insertion of the tendon of fibularis longus. The medial surface receives the attachment of most of the tendon of tibialis anterior.

Vascular supply

The medial cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation

The medial cuneiform is supplied by the deep fibular and medial plantar nerves.

Ossification

The medial cuneiform may have two separate ossification centres, which appear during the second year of life (Fig. 84.7). Very rarely, the medial cuneiform is bipartite and there is a horizontal cleavage plane between the two moieties.

The os cuneo-1 metatarsale-I plantare is a rare accessory bone that occurs on the plantar aspect of the foot at the base of the first metatarsal and articulates with the plantar base of the first metatarsal and the medial cuneiform.

Intermediate cuneiform

The intermediate cuneiform articulates proximally with the navicular and distally with the second metatarsal base (Figs 84.5A; 84.11). It has a narrow, plantar surface that receives a slip from the tendon of tibialis posterior. The distal and proximal surfaces are both triangular articular facets and articulate with the second metatarsal base and the navicular, respectively. The medial surface is partly articular: it articulates via a smooth, angled strip that is occasionally double with the medial cuneiform along its proximal and dorsal margins. The lateral surface is also partly articular: along its proximal margin a vertical strip, usually indented, abuts the lateral cuneiform. Strong interosseous ligaments connect non-articular parts of both surfaces to the adjacent cuneiforms.

Muscle attachments

Part of the tendon of tibialis posterior is attached to the intermediate cuneiform.

Vascular supply

The intermediate cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation

The intermediate cuneiform is innervated by the deep fibular and medial plantar nerves.

Ossification

The ossification centre appears during the third year of life (Fig. 84.7). The os cuneo-2 metatarsale-II dorsale, a rare accessory bone, lies on the dorsal aspect of the joint between the intermediate cuneiform and the second metatarsal. It is wedge-shaped with its base orientated dorsally.

Lateral cuneiform

The lateral cuneiform is between the intermediate cuneiform and cuboid, and also articulates with the navicular and, distally, with the third metatarsal base (Figs 84.5A; 84.11). Like the intermediate cuneiform, its dorsal surface, which is rough and almost rectangular, is the base of a wedge. The plantar surface is narrow and receives a slip from tibialis posterior and sometimes part of flexor hallucis brevis. The distal surface is a triangular articular facet for the third metatarsal base. The proximal surface is rough on its plantar aspect, but its dorsal two-thirds articulate with the navicular by a triangular facet. The medial surface is partly non-articular and has a vertical strip, indented by the intermediate cuneiform, on its proximal margin; on its distal margin, a narrower strip (often two small facets) articulates with the lateral side of the second metatarsal base. The lateral surface, also partly non-articular, bears a triangular or oval proximal facet for the cuboid; a semilunar facet on its dorsal and distal margin articulates with the dorsal part of the medial side of the fourth metatarsal base. Non-articular areas of the medial and lateral surfaces receive intercuneiform and cuneocuboid ligaments, respectively, which are important in the maintenance of the transverse arch.

Muscle attachments

The plantar surface of the lateral cuneiform receives a slip from the tendon of tibialis posterior and, occasionally, part of flexor hallucis brevis.

Vascular supply

The lateral cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation

The lateral cuneiform is innervated by branches of the deep fibular and lateral plantar nerves.

Ossification

The lateral cuneiform ossifies during the first year of life (Fig. 84.7).

Tarsal coalition

Tarsal coalition is a hereditary condition in which there is a fibrous, cartilaginous or osseous union of two or more tarsal bones, and is believed to arise as a result of a failure of segmentation of primitive mesenchyme. Harris & Beath (1948) were the first to recognize an association between tarsal coalitions and ‘peroneal (fibular) spastic flat foot’. The two most common examples are talocalcaneal and calcaneonavicular coalitions, which usually present with symptoms early in the second decade of life. They are often, but not invariably, associated with flat feet (see below). A talonavicular coalition is rare, but when present is often associated with a ‘ball and socket’ ankle joint. Surgical resection of tarsal coalitions may eradicate associated pain but seldom improves the range of movement.

METATARSALS

The five metatarsal bones lie in the distal half of the foot and connect the tarsus and phalanges. Like the metacarpals, they are miniature long bones, and have a shaft, proximal base and distal head. Except for the first and fifth, the shafts are long and slender, longitudinally convex dorsally, and concave on their plantar aspects. Prismatic in section, they taper distally. Their bases articulate with the distal tarsal row and with adjacent metatarsal bases. The line of each tarsometatarsal joint, except the first, inclines proximally and laterally, metatarsal bases being oblique relative to their shafts. The heads articulate with the proximal phalanges, each by a convex surface that passes farther on to its plantar aspect, where it ends on the summits of two eminences. The sides of the heads are flat, with a depression surmounted by a dorsal tubercle for a collateral ligament of the metatarsophalangeal joint.

On occasion, an os intermetatarseum is encountered between the medial cuneiform and the bases of the first and second metatarsal bones and represents a rare accessory bone in this region.

Individual metatarsals

First metatarsal

The first metatarsal (Fig. 84.5A,B; 84.11) is the shortest and thickest, and has a strong shaft, of marked prismatic form. The base sometimes has a lateral facet or ill-defined smooth area as a result of contact with the second metatarsal. Its large proximal surface, usually indented on the medial and lateral margins, articulates with the medial cuneiform. Its circumference is grooved for tarsometatarsal ligaments and, medially, part of the tendon of tibialis anterior is attached; its plantar angle has a rough, oval, lateral prominence for the tendon of fibularis longus. The medial head of the first dorsal interosseous is attached to the flat lateral surface of the shaft. The large head has a plantar elevation, the crista, which separates two grooved facets (of which the medial is larger), on which sesamoid bones glide.

Muscle attachments

The first metatarsal receives attachments from the tendon of tibialis anterior medially, and the tendon of fibularis longus on its plantar aspect. It gives origin to the medial head of the first dorsal interosseus on the proximal aspect of the lateral surface.

Vascular supply

The first metatarsal is supplied by the first dorsal and first plantar metatarsal arteries and a superficial branch of the medial plantar artery, which together form a periosteal network. A nutrient artery enters the lateral surface of the mid-diaphysis. The head receives a medial, lateral and plantar supply from these arteries.

Innervation

The first metatarsal is innervated by the deep fibular and medial plantar nerves.

Ossification

The first metatarsal has two centres of ossification, one in the shaft, the other in the base (unlike the other metatarsals, in which the secondary ossification centre is distal). They appear during the tenth week of prenatal life and the third year of life, respectively (Fig. 84.7) and fuse between the 17th and 20th years. There may be a third centre in the first metatarsal head.

Second metatarsal

The second metatarsal is the longest (Figs 84.5A,B; 84.11). Its cuneiform base bears four articular facets. The proximal one, concave and triangular, is for the intermediate cuneiform. The dorsomedial one, for the medial cuneiform, is variable in size and usually continuous with that for the intermediate cuneiform. Two lateral facets, dorsal and plantar, are separated by non-articular bone, each divided by a ridge into distal demifacets, which articulate with the third metatarsal base, and a proximal pair (sometimes continuous) for the lateral cuneiform. The areas of these facets vary, particularly the plantar facet, which may be absent. An oval pressure facet, caused by contact with the first metatarsal, may appear on the medial side of the base, plantar to that for the medial cuneiform. Because of its length, its steep inclination, and the position of its base recessed in the tarsometatarsal joint, it is at risk of stress overload; perhaps this is why it is a common site for stress fractures in athletes and an avascular phenomenon in its head (Freiberg's infraction).

Muscle attachments

The lateral head of the first dorsal interosseous and the medial head of the second, are attached to the medial and lateral surfaces of the shaft, respectively.

Vascular supply

The blood supply of the second, third and fourth metatarsals follows the same pattern as that described for the first metatarsal, i.e. the bones are all supplied by branches of the dorsal and plantar metatarsal arteries. The nutrient artery enters the diaphysis on its lateral side near the metatarsal base. A constant plantar vessel supplies the head.

Innervation

The second metatarsal is innervated by branches of the deep fibular and branches of medial plantar nerve.

Ossification

There are two centres of ossification, one in the shaft and one distally in the metatarsal head (Fig. 84.7). Ossification of the shaft starts during the ninth prenatal week and ossification of the metatarsal head starts between the third and fourth years; fusion occurs between the 17th and 20th years.

Third metatarsal

The third metatarsal (Figs 84.5A,B; 84.11) has a flat triangular base, articulating proximally with the lateral cuneiform, medially with the second metatarsal, via dorsal and plantar facets, and laterally, via a single facet, with the dorsal angle of the fourth metatarsal. The medial plantar facet is frequently absent. The third tarsometatarsal joint is relatively immobile and predisposes the third metatarsal to stress fracture.

Muscle attachments

The lateral head of the second dorsal interosseous and first plantar are attached to the medial surface of the shaft. The medial head of the third dorsal interosseous is attached to its lateral surface.

Vascular supply

The blood supply of the third metatarsal is the same as that of the second metatarsal, described above.

Innervation

The third metatarsal is innervated by the deep fibular and lateral plantar nerves.

Ossification

There are two centres of ossification, one in the shaft and one distally in the metatarsal head (Fig. 84.7). Ossification of the shaft starts during the ninth prenatal week and ossification of the metatarsal head starts between the third and fourth years; fusion occurs between the 17th and 20th years.

Fourth metatarsal

The fourth metatarsal is smaller than the third (Figs 84.5A,B; 84.11). Its base has proximally, an oblique quadrilateral facet for articulation with the cuboid; laterally, a single facet for the fifth metatarsal; medially, an oval facet for the third metatarsal. The latter is sometimes divided by a ridge, in which case the proximal part articulates with the lateral cuneiform.

Muscle attachments

The lateral head of the third dorsal and second plantar interossei are attached to the medial surface. The medial head of the fourth dorsal interosseous is attached to the lateral surface.

Vascular supply

The blood supply of the fourth metatarsal is the same as that of the second and third metatarsals, described above.

Innervation

The fourth metatarsal is innervated by the deep fibular and lateral plantar nerves.

Ossification

There are two centres of ossification, one in the shaft and one distally in the metatarsal head (Fig. 84.7). Ossification of the shaft starts during the ninth prenatal week and ossification of the metatarsal head commences between the third and fourth years; fusion occurs between the 17th and 20th years.

Fifth metatarsal

The fifth metatarsal has a tuberosity (styloid process) on the lateral side of its base (Figs 84.5A,B; 84.11). The base articulates proximally with the cuboid by a triangular, oblique surface, and medially with the fourth metatarsal. The tuberosity can be seen and felt midway along the lateral border of the foot; in acute inversion it may be fractured. The metaphysial–diaphysial junction of the fifth metatarsal base is prone to traumatic or stress fractures, and these have a tendency to delayed and non-union, and often require surgical fixation. It is believed that fractures at this level damage the nutrient artery and the extraosseous plexus, resulting in compromised vascularity of the fracture site and consequent poor fracture healing.

Muscle attachments

The tendon of fibularis tertius is attached to the medial part of the dorsal surface and medial border of the shaft, and that of fibularis brevis to the dorsal surface of the tuberosity. A strong band of the plantar aponeurosis, sometimes containing muscle, connects the apex of the tuberosity to the lateral process of the calcaneal tuberosity. It is this attachment, and not that of fibularis brevis, which is responsible for avulsion fractures of the tuberosity.

The plantar surface of the base is grooved by the tendon of abductor digiti minimi, and flexor digiti minimi brevis is attached here. The lateral head of the fourth dorsal and the third plantar interossei are attached to the medial side of the shaft.

Vascular supply

The fifth metatarsal is supplied by dorsal and plantar metatarsal arteries and an inconstant fibular marginal artery. The nutrient artery enters the diaphysis proximally and medially.

Innervation

The fifth metatarsal is innervated by branches from the sural, superficial fibular and lateral plantar nerves.

Ossification

There are three centres of ossification, one at the base in the region of the tuberosity (an apophysis), one in the shaft and one distally in the metatarsal head. Ossification of the shaft starts during the tenth prenatal week and ossification of the metatarsal head starts between the third and fourth years (Fig. 84.7). Fusion of the distal and shaft centres occurs between the 17th and 20th years, the proximal apophysis fuses earlier. An os vesalianum is a rare variant that should not be confused with the basal apophysis. (Fig. 84.12)

PHALANGES OF THE FOOT

In general, the phalanges of the foot resemble those of the hand: there are two in the hallux, and three in each of the other toes (Fig. 84.5A,B). On occasion there are only two phalanges in the little toe and, rarely, this is the case with the other lesser toes. The phalanges of the toes are much shorter than their counterparts in the hand and their shafts, especially those of the proximal set, are compressed from side to side. In the proximal phalanges, the compressed shaft is convex dorsally, with a plantar concavity. The base is concave for articulation with a metatarsal head and the head is a trochlea for a middle phalanx. Middle phalanges are small and short, but broader than their proximal counterparts. Distal phalanges resemble those in the fingers, but are smaller and flatter. Each has a broad base for articulation with a middle phalanx and an expanded distal end. A rough tuberosity on the plantar aspect of the latter supports the pulp of the toe, and provides a weight-bearing area.

Muscle attachments

Tendons of the long digital flexors and extensors are attached to the plantar and dorsal aspects of the bases of the distal phalanges of the lateral four toes. Flexor hallucis longus and extensor hallucis longus are similarly attached to the hallux. The bases of the middle phalanges receive the tendons of flexor digitorum brevis and extensor digitorum brevis. The proximal phalanges of the second, third, fourth and fifth toes each receive a lumbrical on their medial side; those of the second, third and fourth toes also receive an interosseous muscle on both sides. For further details of muscular, capsular and ligamentous arrangements in the toes refer to Fig. 84.5A,B. The terminal phalanx of the hallux normally shows a small degree of valgus (lateral) deviation, as may the proximal phalanx. This is presumed to be unrelated to footwear, because this degree of. deviation has also been observed in fetal specimens.

Vascular supply

The proximal phalanges receive most of their blood supply from the dorsal digital arteries. The middle phalanges are supplied by plantar and dorsal digital arteries. The distal phalanges receive their supply mainly from plantar digital arteries.

Innervation

The phalanges are innervated by the plantar and dorsal digital nerves.

Ossification

Phalanges are ossified from a primary centre for the shaft and a basal epiphysis (Fig. 84.7). Primary centres for the distal phalanges appear between the ninth and twelfth prenatal weeks, somewhat later in the fifth digit. Primary centres for the proximal phalanges appear between the 11th and 15th weeks, and later for intermediate phalanges, but there is wide variation. Basal centres appear between the second and eighth years (usually second or third in the hallux), and union with the shaft occurs by the 18th year. There is considerable variation in ossification and fusion dates.

SESAMOIDS

Galen is believed to have been the first to use the term ‘sesamoid’ because of the resemblance of these bones to sesame seeds. Most sesamoid bones are only a few millimetres in diameter and their shape is variable. Some have a predictable location (see below), but many others vary in terms of location and frequency of occurrence (Fig. 84.12). Some sesamoids ossify, whereas others remain cartilaginous. Most sesamoid bones are embedded in tendons in close proximity to joints. Their precise role is not understood; it is believed that they may alter the direction of muscle pull, decrease friction and modify pressure.

Medial and lateral sesamoids of the first metatarsophalangeal joint

The two constant sesamoid bones within the foot are those of the first metatarsophalangeal articulation. The medial sesamoid is generally larger than the lateral sesamoid and lies slightly more distally. During dorsiflexion of the hallux, the sesamoids lie below the first metatarsal head, offering protection to the otherwise exposed plantar aspect of the first metatarsal head. The medial (tibial) sesamoid is approximately 10 mm wide and 14 mm long and the lateral (fibular) sesamoid is usually smaller (approximately 8 mm wide and 10 mm long): the overall sizes vary considerably.

The sesamoids are embedded within the double tendon of flexor hallucis brevis and articulate on their dorsal surfaces with the plantar facets of the first metatarsal head. They are separated by the crista or intersesamoidal ridge, which provides stability to the sesamoid complex. (This ridge can be eroded to the point of obliteration in severe cases of hallux valgus.) The sesamoids are connected to the plantar base of the proximal phalanx through the plantar plate, which is an extension of the tendon of flexor hallucis brevis. The plantar surface of each sesamoid is covered by a thin layer of the tendon of flexor hallucis brevis, whereas the dorsal or superior surface is covered by hyaline cartilage. The sesamoids are suspended by a sling-like mechanism made up of the collateral ligaments of the first metatarsophalangeal joint and the sesamoid ligaments on either side of the joint. The plantar aponeurosis also has an attachment to the sesamoids.

Approximately 30% of these sesamoid bones are bipartite. The medial is much more commonly affected and may have two, three or four parts, but the fibular sesamoid rarely has more than two. The condition may be bilateral. The sesamoids may be absent congenitally.

Muscle attachments

The medial sesamoid receives an attachment from abductor hallucis, which provides a medial stabilizing influence on the sesamoid complex. The lateral sesamoid receives some fibres from the tendon of adductor hallucis, and this provides lateral stabilization. The medial and lateral sesamoids are connected by the intersesamoid ligament, which forms the floor of the tendinous canal for the tendon of flexor hallucis longus.

Vascular supply

There are three patterns of blood supply to the sesamoid bones. In 50% of cases the arterial supply is derived from the medial plantar artery and the plantar arch, in 25% of cases it is predominantly from the plantar arch and in 25% of cases it is from the medial plantar artery alone. The major arterial blood supply to the sesamoids enters from the proximal and plantar aspects, and only a minor contribution enters through the distal pole. The pattern of vascular supply determines the vulnerability of a sesamoid to avascular necrosis after injury to the bone.

Innervation

The medial and lateral sesamoids are innervated by the plantar digital nerves.

Ossification

The ossification centres of the sesamoids can be multiple or single.

Other sesamoid and accessory bones

Accessory or inconstant sesamoid bones may occur under any weight-bearing surface of the foot, but are most common under the second to fifth metatarsal heads. They are extremely variable in size and their incidence is difficult to determine.

A true sesamoid occurs in the tendon of tibialis posterior in about 10% of individuals. It lies on the plantar aspect of the navicular tuberosity within the tendon at the level of the inferior border of the calcaneonavicular ligament (see above, accessory navicular bones). Very rarely, a sesamoid is found within the tendon of tibialis anterior near its insertion at the level of the anteroinferior corner of the medial cuneiform, where there is an articular facet. An os peroneum is a sesamoid bone within the tendon of fibularis longus that articulates with the lateral surface of the calcaneum, the calcaneocuboid joint or, more frequently, the plantar aspect of the cuboid where there is an articular facet. The bone is situated where the tendon of fibularis longus angles around the plantar aspect of the lateral border of the cuboid and is probably present in 95% of cases; it is usually cartilaginous.

JOINTS

ANKLE (TALOCRURAL) JOINT

The talocrural joint is a hinge joint, approximately uniaxial. The lower end of the tibia and its medial malleolus, together with the lateral malleolus of the fibula and inferior transverse tibiofibular ligament, form a deep recess (‘mortise’) for the body of the talus. Although it appears to be a simple hinge, its axis of rotation is dynamic, shifting during dorsi- and plantar flexion. Starting from the plantigrade position the normal range of dorsiflexion is 10° when the knee is straight, and 30° with the knee flexed (when the calcaneal tendon will be relaxed). The range of normal plantar flexion is 30°. (The values of these ranges are all approximate.) Dorsiflexion results in the joint adopting the ‘close-packed’ position, with maximal congruence and ligamentous tension; from this position, all major thrusting movements are exerted, in walking, running and jumping. The malleoli grip the talus, and even in relaxation no appreciable lateral movement can occur without stretch of the inferior tibiofibular syndesmosis and slight bending of the fibula. The superior talar surface is broader in front, and in dorsiflexion the malleolar gap is increased by slight lateral rotation of the fibula, by ‘give’ at the inferior tibiofibular syndesmosis and gliding at the superior tibiofibular joint.

Articulating surfaces

Articular surfaces are covered by hyaline cartilage. The talar trochlear surface, which is convex parasagittally and gently concave transversely, is wider in front; the distal tibial articular surface is reciprocally curved. The talar articular surface for the medial malleolus is a proximal area on the medial talar surface, and is fairly flat, comma-shaped and deeper anteriorly. The larger lateral talar articular surface is triangular and vertically concave, while the articular surface on the lateral malleolus is reciprocally curved. Posteriorly, the edge between the trochlear and fibular articular surfaces of the talus is bevelled to a narrow, flat triangular area that articulates with the inferior transverse tibiofibular ligament (Fig. 84.13A); all surfaces are contiguous. The bones are held together by a fibrous capsule, and by medial (deltoid), anterior and posterior talofibular and calcaneofibular ligaments.

Fig. 84.13 The left ankle and tarsal joints. **A**, Posterior aspect. **B**, Medial aspect. **C**. Lateral aspect.

Fibrous capsule

Around the joint, the fibrous capsule is thin in front and behind. It is attached proximally to the borders of the tibial and malleolar articular surfaces, and distally to the talus near the margins of its trochlear surface, except in front where it reaches the dorsum of the talar neck. The capsule is strengthened by strong collateral ligaments. Its posterior part consists mainly of transverse fibres. It blends with the inferior transverse ligament and is thickened laterally where it reaches the fibular malleolar fossa.

Ligaments

The ligaments of the talocrural joint are the medial and lateral collateral ligaments.

Medial collateral ligament (deltoid ligament)

The medial collateral ligament (deltoid ligament) is a strong, triangular band, attached to the apex and the anterior and posterior borders of the medial malleolus (Fig. 84.13B). Of its superficial fibres, the anterior (tibionavicular) pass forwards to the navicular tuberosity, behind which they blend with the medial margin of the plantar calcaneonavicular ligament; inter-mediate (tibiocalcaneal) fibres descend almost vertically to the entire length of the sustentaculum tali; posterior fibres (posterior tibiotalar) pass posterolaterally to the medial side of the talus and its medial tubercle. The deep fibres (anterior tibiotalar) pass from the tip of the medial malleolus to the non-articular part of the medial talar surface. The ligament is crossed by the tendons of tibialis posterior and flexor digitorum longus. It is rarely injured alone, and when torn, is commonly associated with a fracture of the distal fibula. Chronic instability is rare.

Lateral ligament

The lateral ligament has three discrete parts. The anterior talofibular ligament extends anteromedially from the anterior margin of the fibular malleolus to the talus, attached in front of its lateral articular facet and to the lateral aspect of its neck (Fig. 84.13C). The posterior talofibular ligament runs almost horizontally from the distal part of the lateral malleolar fossa to the lateral tubercle of the posterior talar process (Fig. 84.13A); a ‘tibial slip’ of fibres connects it to the medial malleolus. The calcaneofibular ligament, a long cord, runs from a depression anterior to the apex of the fibular malleolus to a tubercle on the lateral calcaneal surface and is crossed by the tendons of fibularis longus and brevis (Fig. 8.13A,C). The lateral ligament complex is injured most commonly with inversion sprains, often during sport; the posterior talofibular ligament is almost always spared. Although the resulting increased laxity is tolerated in most cases, some require surgical reconstruction.

Synovial membrane

The joint is lined by synovial membrane which projects into the inferior (distal) tibiofibular joint.

Vascular supply and lymphatic drainage

The talocrural joint is supplied by malleolar branches of the anterior and posterior tibial and fibular arteries. Lymphatic drainage is via vessels accompanying the arteries and via the long and short saphenous veins superficially.

Innervation

The talocrural joint is innervated by branches from the deep fibular, saphenous, sural and tibial nerves (or medial and lateral plantar nerves, depending on the level of division of the tibial nerve). Occasionally, the superficial fibular nerve also supplies the ankle joint.

For a comprehensive account of the innervation of the ankle joint (and other foot joints) see Gardner & Gray (1968).

Relations

Anteriorly, from medial to lateral, are tibialis anterior, extensor hallucis longus, the anterior tibial vessels, deep fibular nerve, extensor digitorum longus and fibularis tertius; posteromedially from medial to lateral, are tibialis posterior, flexor digitorum longus, the posterior tibial vessels, tibial nerve, flexor hallucis longus; in the groove behind the lateral malleolus are the tendons of fibularis longus and brevis. The tendon of fibularis brevis lies anterior to the tendon of fibularis longus at this level (Fig. 84.14). The long saphenous vein and saphenous nerve cross the ankle joint medial to the tendon of tibialis anterior and anterior to the medial malleolus, the nerve lying posterior to the vein.

All of the above structures are at risk during surgery on the ankle: the main structures at risk are the neurovascular structures anteriorly and posteromedially. Branches of the superficial fibular nerve are at risk on the anterolateral aspect of the ankle, particularly during ankle arthroscopy.

Factors maintaining stability

Passive stability is conferred upon the ankle mainly by the medial and lateral ligament complexes, the distal tibiofibular ligaments, the tendons crossing the joint, the bony contours and the capsular attachments. Dynamic stability is conferred by gravity, muscle action and ground reaction forces. Stability requires the continuous action of soleus assisted by gastrocnemius: it increases when leaning forward, and decreases when leaning backwards. If backward sway takes the projection of the centre of gravity (‘weight line’) posterior to the transverse axes of the ankle joints, the plantar flexors relax and the dorsiflexors contract.

Failure of the fibular muscles can lead progressively to varus instability, whereas long-standing failure of the tendon of tibialis posterior, which is relatively common in the elderly female, can result in valgus instability of the ankle and particularly a planovalgus foot deformity.

Muscles producing movement

Dorsiflexion is produced by tibialis anterior, assisted by extensors digitorum longus and hallucis longus, and fibularis tertius. Plantar flexion is produced by gastrocnemius and soleus, assisted by plantaris, tibialis posterior, flexors hallucis longus and digitorum longus.

Ankle fractures

Ankle fractures are common and of importance because failure to achieve accurate anatomical alignment in the treatment of ankle fractures often results in significant long term morbidity. Except for very simple and undisplaced fractures, most ankle fractures are associated with a ligamentous injury. The direction and nature of forces applied to the ankle correlate with the fracture pattern and concomitant ligament injury. The Lauge–Hansen classification, although slightly cumbersome, classifies injuries according to two components: the position of the foot at the time of injury and the direction of the force applied. In a supination/adduction type injury, the foot is supinated and an adduction force is applied, resulting in a transverse fracture of the distal fibula (stage 1), followed by an oblique fracture of the medial malleolus (stage 2). In a supination/external rotation type injury, the first structure to rupture is the anterior inferior tibiofibular ligament, followed in order by a spiral fibular fracture, a posterior malleolar fracture and then a medial malleolar fracture (or deltoid ligament rupture). In pronation/abduction injuries, a transverse medial malleolar fracture is followed by rupture of the anterior and posterior inferior tibiofibular ligaments and interosseous ligament, and then by an oblique fibular fracture. Pronation/external rotation injuries commence with a medial malleolar fracture (or deltoid ligament rupture), followed in turn by rupture of the anterior inferior tibiofibular ligament, the interosseous ligament, the interosseous membrane, a high fibular fracture and fracture of the posterior tibial plafond ('posterior malleolus').

Inferior (distal) tibiofibular joint

The inferior (distal) tibiofibular joint is usually considered a syndesmosis. It consists of the anterior and posterior tibiofibular ligaments and the interosseous ligament.

Articulating surfaces

The distal tibiofibular joint is between the rough, medial convex surface on the distal end of the fibula and the rough concave surface of the fibular notch of the tibia. These surfaces are separated distally for approximately 4 mm by a synovial prolongation from the ankle joint, and may be covered by articular cartilage in their lowest parts.

Fibrous capsule

The distal tibiofibular joint does not have a capsule.

Ligaments

The ligaments of the inferior (distal) tibiofibular joint are the anterior, interosseous and posterior ligaments.

Anterior tibiofibular ligament

The anterior tibiofibular ligament is a flat band which descends laterally between the adjacent margins of the tibia and fibula, anterior to the syndesmosis (Fig. 84.13C). Bassett's ligament is a variant that presents as a low lying slip of the ligament which is inserted so far distally on the fibula that it may cause irritation of the lateral dome of the talus: it is amenable to arthroscopic removal.

Interosseous tibiofibular ligament

The interosseous tibiofibular ligament is continuous with the interosseous membrane and contains many short bands between the rough adjacent tibial and fibular surfaces; it is the strongest bond between the bones.

Posterior tibiofibular ligament

The posterior tibiofibular ligament is stronger than the anterior, and is disposed similarly on the posterior aspect of the syndesmosis (Fig. 84.13A). Its distal, deep part is the inferior transverse ligament, a thick band of yellow fibres which crosses from the proximal end of the lateral malleolar fossa to the posterior border of the tibial articular surface almost to the medial malleolus. The ligament projects distal to the bones, in contact with the talus. Its colour reflects its content of yellow elastic fibres.

Synovial membrane

The synovial membrane of the ankle joint projects into the distal 4 mm or so of the inferior tibiofibular joint.

Vascular supply and lymphatic drainage

The inferior tibiofibular joint is supplied by the perforating branch of the fibular artery and the medial malleolar branches of the anterior and posterior tibial arteries. Lymphatic drainage is via vessels corresponding to the arteries, and via vessels that accompany the long and short saphenous veins.

Innervation

The inferior tibiofibular joint is innervated by branches from the deep fibular and sural nerves.

Relations

No significant structures pass anterior to the anterior aspect of the inferior tibiofibular joint, but the superficial fibular nerve is at risk during surgery to this area. Posteriorly, the fibular artery passes over the posterior tibiofibular ligament and is at risk in the posterolateral approach to the fibula.

Factors maintaining stability

Stability is maintained in part by the bone contours, but mainly by the dense anterior and posterior tibiofibular and the interosseous ligaments.

Muscles producing movement

No muscles act on the inferior tibiofibular joint, which moves only slightly. Because of the varying slope of the lateral surface of the body of talus, the fibula undergoes a small degree of lateral rotation during dorsiflexion at the ankle, and this results in slight widening of the interval between the bones. Testing for a significant disruption of this joint is usually carried out with the patient under anaesthetic and involves applying an external rotation and abduction force, looking for abnormal widening of the syndesmosis. Excessive anterior/posterior glide of the fibula relative to the tibia also indicates a disruption of the joint.

Talocalcaneal joint

Anterior and posterior articulations between the calcaneus and talus form a functional unit often termed the ‘subtalar joint’. The posterior articulation is referred to as the talocalcaneal joint and the anterior articulation is regarded as part of the talocalcaneonavicular joint. The talocalcaneal joint is modified multiaxial and its permitted movements are considered together with those at other tarsal joints. The bones are connected by a fibrous capsule, and by lateral, medial, interosseous talocalcaneal and cervical ligaments.

Articulating surfaces

The subtalar joint proper involves the concave posterior calcaneal facet on the posterior part of the inferior surface of the talus and the convex posterior facet on the superior surface of the calcaneus (Fig. 84.15A,B).

Fibrous capsule

The fibrous capsule envelops the joint, its fibres are short and attached to its articular margins.

Ligaments

The ligaments of the talocalcaneal joint are the lateral, medial and interosseous talocalcaneal ligaments and the cervical ligament.

Lateral talocalcaneal ligament

The lateral talocalcaneal ligament is a short flat fasciculus that descends obliquely back from the lateral talar process to the lateral calcaneal surface and is attached anterosuperior to the calcaneofibular ligament.

Medial talocalcaneal ligament

The medial talocalcaneal ligament connects the medial talar tubercle to the back of the sustentaculum tali and adjacent medial surface of the calcaneus. Its fibres blend with the medial (deltoid) ligament of the ankle joint; the most posterior fibres line the groove for flexor hallucis longus between the talus and calcaneus.

Interosseous talocalcaneal ligament

The interosseous talocalcaneal ligament is a broad, flat, bilaminar transverse band in the sinus tarsi (Figs 84.15A; 84.16). It descends obliquely and laterally from the sulcus tali to the calcaneal sulcus. The posterior lamina of the ligament is associated with the talocalcaneal joint, and the anterior lamina with the talocalcaneonavicular joint. Its medial fibres are taut in eversion.

Cervical ligament

The cervical ligament is just lateral to the tarsal sinus and attached to the superior calcaneal surface (Fig. 84.13C). It is medial to the attachment of extensor digitorum brevis, from where it ascends medially to an inferolateral tubercle on the talar neck (Barclay-Smith 1896). It is considered to be taut in inversion.

Synovial membrane

The synovial cavity of the talocalcaneal joint is usually quite separate and does not communicate with those of other tarsal joints. However, direct communication with the ankle joint has been observed in rare instances.

Innervation

The talocalcaneal joint is innervated by branches of the posterior tibial, medial plantar and sural nerves.

Relations

Posteromedially, in the region of the posterior aspect of the talocalcaneal joint, and viewed from anterior to posterior, lie the veins on either side of the posterior tibial artery, the tibial nerve and the tendon of flexor hallucis longus. These neurovascular structures are at risk in posteromedial approaches to the ankle and talocalcaneal joints. On the lateral side, the tendon of fibularis brevis lies anterior to the tendon of fibularis longus, both passing behind the fibular malleolus in proximity to the talocalcaneal joint. The sural nerve lies just posterior to the fibular tendons and is at risk during lateral exposure of the joint.

Factors maintaining stability

Stability is conferred by the bony contours of the hindfoot plus the above mentioned ligaments; it is not known which ligaments provide the most stability. An additional ligamentous restraint is provided by the calcaneofibular component of the lateral ligament complex. The tendons crossing the articulation also aid stability.

Muscles producing movement

Heel inversion is controlled by tibialis anterior, tibialis posterior and the gastrocnemius–soleus complex via the calcaneal tendon; the long flexors of the toes also contribute. Heel eversion results from the pull of fibularis longus, brevis and tertius in addition to the long extensors of the toes.

Talocalcaneonavicular joint

An eloquent account of the talocalcaneonavicular joint was provided by Barclay-Smith in 1896. In terms of function, and in clinical practice, it is helpful to regard this complex joint as comprising two articulations, i.e. the anterior part of the ‘subtalar’ joint and the talonavicular joint. It is a compound, multiaxial articulation.

Articulating surfaces

The ovoid talar head is continuous with the triple-faceted anterior area of its inferior surface. The whole fits the concavity formed collectively by the posterior surface of the navicular, the middle and anterior talar facets of the calcaneus, and the superior fibrocartilaginous surface of the plantar calcaneonavicular ligament (spring ligament). The bones are connected by a fibrous capsule and by the talonavicular and plantar calcaneonavicular ligaments, and the calcaneonavicular part of the bifurcate ligament.

Fibrous capsule

The fibrous capsule is poorly developed, except posteriorly, where it is thick and blends with the anterior part of the interosseous ligament filling the tarsal sinus.

Ligaments

The ligaments of the talocalcaneonavicular joint are the talonavicular and plantar calcaneonavicular (spring) ligaments.

Talonavicular ligament

The talonavicular ligament is a broad, thin band (Fig. 84.13B,C). It connects the dorsal surfaces of the neck of the talus and the navicular, and is covered by extensor tendons. The plantar calcaneonavicular ligament and the calcaneonavicular part of the bifurcate ligament (Fig. 84.13C) are the plantar and lateral ligaments of the joint, respectively. Although the calcaneus and navicular do not articulate directly, they are connected by calcaneonavicular and plantar calcaneonavicular ligaments.

Plantar calcaneonavicular (spring) ligament

The plantar calcaneonavicular (spring) ligament is a broad, thick band connecting the anterior margin of the sustentaculum tali to the plantar surface of the navicular (Figs 84.13B; 84.15A; 84.17). It ties the calcaneus to the navicular below the head of the talus as part of its articular cavity and it sustains the medial longitudinal arch of the foot. The dorsal surface of the ligament has a triangular fibrocartilaginous facet on which part of the talar head rests (Fig. 84.15A). Its plantar surface is supported medially by the tendon of tibialis posterior and laterally by the tendons of flexors hallucis longus and digitorum longus; its medial border is blended with the anterior superficial fibres of the medial (deltoid) ligament. The calcaneonavicular ligament is described below as the medial band of the bifurcate ligament.

(From Sobotta 2006.)

Synovial membrane

The talocalcaneonavicular joint is a synovial joint whose cavity sometimes communicates with that of the talocalcaneal joint.

Innervation

The talocalcaneonavicular joint is innervated by the deep fibular and medial plantar nerves.

Relations

On the medial side from dorsal to plantar lie the tendon of tibialis posterior and the tendon of flexor digitorum longus above the sustentaculum tali, and the flexor hallucis longus tendon below. At this point, flexor hallucis longus lies deep to the medial and lateral plantar branches of the posterior tibial artery and nerve. The latter structures are at risk during medial approaches to the joint, e.g. resection of talocalcaneal coalition. Dorsally from medial to lateral lie the tendons of tibialis anterior and extensor hallucis longus, the deep fibular nerve and the dorsalis pedis artery, the muscle belly of extensor hallucis brevis passing medially and deep to the tendons of extensor digitorum longus and fibularis tertius. Structures at risk during the dorsal approach to the talonavicular joint include the branches of the superficial fibular nerve superficially and the dorsalis pedis artery and deep fibular nerve deep to the inferior extensor retinaculum.

Factors maintaining stability

Stability of the joint is due to a combination of factors: bony contours, the strong plantar calcaneonavicular (spring) ligament, and the calcaneonavicular component of the bifurcate ligament.

Muscles producing movement

The muscles producing movement are as described above for the talocalcaneal joint.

Calcaneocuboid joint

The calcaneocuboid joint is at the same level as the talonavicular joint and, together, they represent the transverse tarsal joint. It is a saddle (sellar) or biaxial joint with concavo-convex surfaces.

Articulating surfaces

The articular surfaces of the calcaneocuboid joint, which is 2 cm proximal to the tubercle on the fifth metatarsal base, are between the anterior (distal) surface of the calcaneus and the posterior (proximal) surface of the cuboid.

Fibrous capsule

The fibrous capsule is thickened dorsally as the dorsal calcaneocuboid ligament. The synovial cavity of this joint is separate, and does not communicate with those of other tarsal articulations (Fig. 84.6).

Ligaments

The ligaments of the calcaneocuboid joint are the bifurcate, long plantar and plantar calcaneocuboid ligaments.

Bifurcate ligament

The bifurcate ligament is a strong Y-shaped band (Fig. 84.13C). It is attached by its stem proximally to the anterior part of the upper calcaneal surface, and distally it divides into calcaneocuboid and calcaneonavicular parts. The (lateral) calcaneocuboid ligament extends to the dorsomedial aspect of the cuboid, forming a main bond between the two rows of tarsal bones; the (medial) calcaneonavicular ligament is attached to the dorsolateral aspect of the navicular.

Long plantar ligament

The long plantar ligament is the longest ligament associated with the tarsus (Figs 84.13C; 84.17; 84.18). It extends from the plantar surface of the calcaneus (anterior to the processes of its tuberosity) and from its anterior tubercle, to the ridge and tuberosity on the plantar surface of the cuboid. Deep fibres are attached to the cuboid and more superficial fibres continue to the bases of the second to fourth, and sometimes fifth, metatarsals. This ligament, together with the groove on the plantar surface of the cuboid, makes a tunnel for the tendon of fibularis longus. It is a most powerful factor limiting depression of the lateral longitudinal arch.

Plantar calcaneocuboid ligament

This short plantar ligament (Fig. 84.17) is deeper than the long plantar ligament, from which it is separated by areolar tissue. It is a short, wide band of great strength, stretching from the anterior calcaneal tubercle and the depression anterior to it, to the adjoining part of the plantar surface of the cuboid; it also sustains the lateral longitudinal arch.

Synovial membrane

A synovial membrane lines the calcaneo-cuboid joint.

Innervation

The calcaneocuboid joint is innervated on its plantar aspect by the lateral plantar nerve, and dorsally by the sural and deep fibular nerves.

Relations

Fibularis longus and abductor digiti minimi pass in proximity to the joint, and the lateral plantar nerve passes medially. Extensor digitorum brevis overlies the lateral aspect of the joint. The sural nerve and the tendon of fibularis longus are at risk during approaches to an os peroneum.

Factors maintaining stability

The calcaneocuboid joint only permits a small amount of movement; its stability reflects the bony contours and strong ligaments described above.

Muscles producing movement

Gliding occurs between the calcaneus and cuboid, with conjunct rotation upon each other during inversion and eversion of the entire foot. The movements are brought about by the same muscles that act on the talocalcaneal and talocalcaneonavicular joints.

Naviculocuneiform joints

The naviculocuneiform joint is a compound joint, often described as plane.

Articulating surfaces

The navicular articulates distally with the cuneiform bones where the distal navicular surface is transversely convex and divided into three facets by low ridges that are adapted to the proximal, slightly curved surfaces of the cuneiforms.

Fibrous capsule

The fibrous capsule is continuous with those of the intercuneiform and cuneocuboid joints and it is also connected to the second and third cuneometatarsal joints and intermetatarsal joints between the second to fourth metatarsal bones.

Ligaments

The ligaments of the naviculocuneiform joint are the dorsal and plantar ligaments.

Dorsal and plantar ligaments

The dorsal and plantar ligaments connect the navicular to each cuneiform; of the three dorsal ligaments, one is attached to each cuneiform. The fasciculus from the navicular to the medial cuneiform is continued as the capsule of the joint around its medial aspect, and then blends medially with the plantar ligament. Plantar ligaments have similar attachments and receive slips from the tendon of tibialis posterior.

Synovial membrane

The synovial membrane lines the fibrous capsule in the manner outlined above.

Innervation

The naviculocuneiform joint is innervated dorsally by branches from the deep fibular nerve. The medial and intermediate naviculocuneiform joints receive a plantar innervation from the medial plantar nerve, and the lateral naviculocuneiform joint is innervated from the lateral plantar nerve.

Relations

The tendon of tibialis posterior sends fibres to the medial cuneiform and crosses the joint on its medial side; it is vulnerable to injury when a medial surgical approach is used, as are the dorsal venous arch and the saphenous nerve. The tendon of tibialis anterior passes over the dorsomedial aspect of the joint and the tendon of extensor hallucis longus is lateral. Running over the intermediate cuneiform, from medial to lateral, are the deep fibular nerve, the dorsalis pedis artery and the muscle belly of extensor hallucis brevis, all of which are vulnerable during dorsal exposure of the joint. On the lateral aspect of the joint, the superficial structures at risk are the superficial fibular nerve and the dorsal venous arch.

Muscles producing movement

Movements at the naviculo-cuneiform, cuboideonavicular, intercuneiform and cuneocuboid joints are slight and subtle gliding and rotational movements that occur during pronation or supination of the foot: when alterations occur in a loaded foot in contact with the ground, they increase suppleness when the forefoot is stressed, e.g. in the initial thrust of running and jumping. The muscles responsible for these slight movements are tibialis anterior, tibialis posterior, fibularis longus and brevis and the long flexors and extensors of the toes.

Cuboideonavicular joint

The cuboideonavicular joint is usually a fibrous joint, the bones being connected by dorsal, plantar and interosseous ligaments. This syndesmosis is often replaced by a synovial joint that is almost plane; its articular capsule and synovial lining are continuous with that of the naviculocuneiform joint. The dorsal ligament extends distolaterally, the plantar nearly transversely from the cuboid to the navicular. The interosseous ligament is made of strong transverse fibres and connects non-articular parts of adjacent surfaces to the two bones (Fig. 84.13C).

Intercuneiform and cuneocuboid joints

The intercuneiform and cuneocuboid joints are all synovial and approximately plane or slightly curved. Their articular capsules and synovial linings are continuous with those of the naviculocuneiform joints. The bones are connected by dorsal, plantar and interosseous ligaments (Fig. 84.13B,C; 84.15A).

Ligaments

The ligaments of the intercuneiform and cuneocuboid joints are the dorsal, plantar and interosseous ligaments.

Dorsal and plantar ligaments

The dorsal and plantar ligaments each have three transverse bands that pass between the medial and intermediate cuneiform, the intermediate and lateral cuneiform, and the lateral cuneiform and cuboid. The plantar ligaments receive slips from the tendon of tibialis posterior.

Interosseous ligaments

The interosseous ligaments connect non-articular areas of adjacent surfaces and are strong agents in maintaining the transverse arch.

Innervation

The intercuneiform and cuneocuboid joints are innervated dorsally via the deep fibular nerve. The plantar aspect of the medial two joints is innervated from the medial plantar nerve, and the plantar aspect of the lateral joints is innervated from the lateral plantar nerve.

Muscles producing movement

The muscles producing movement are as described above for the naviculocuneiform joint.

Tarsometatarsal articulations

Tarsometatarsal articulations are approximately plane synovial joints.

Articulating surfaces

The first metatarsal articulates with the medial cuneiform; the second is recessed between the medial and lateral cuneiforms and articulates with the intermediate cuneiform; the third articulates with the lateral cuneiform; the fourth articulates with the lateral cuneiform and the cuboid; the fifth articulates with the cuboid. The joints are approximately on a line from the tubercle of the fifth metatarsal to the tarsometatarsal joint of the hallux, except for that between the second metatarsal and intermediate cuneiform, which is 2–3 mm proximal (Figs 84.5A; 84.11).

Fibrous capsule

The hallucal joint has its own capsule. The articular capsules and cavities of the second and third are continuous with those of the intercuneiform and naviculocuneiform joints, but are separated from the fourth and fifth joints by an interosseous ligament between the lateral cuneiform and fourth metatarsal base.

Ligaments

The bones are connected by dorsal and plantar tarsometatarsal and interosseous cuneometatarsal ligaments.

Dorsal ligaments

The dorsal ligaments are strong and flat. The first metatarsal is joined to the medial cuneiform by an articular capsule and the other tarsometatarsal capsules blend with the dorsal and plantar ligaments. The second metatarsal receives a band from each cuneiform, the third from the lateral cuneiform, the fourth from the lateral cuneiform and the cuboid, the fifth from the cuboid alone.

Plantar ligaments

The plantar ligaments are longitudinal and oblique bands, and are less regular than the dorsal ligaments. Those for the first and second metatarsals are strongest. The second and third metatarsals are joined by oblique bands to the medial cuneiform, the fourth and fifth by a few fibres to the cuboid.

Interosseous cuneometatarsal ligaments

There are three interosseous cuneometatarsal ligaments. One (the strongest) passes from the lateral surface of the medial cuneiform to the adjacent angle of the second metatarsal (Fig. 84.17). Known as Lisfranc’s ligament, it is crucial to the stability of the tarsometatarsal joint complex. Disruption of this ligament can lead to instability and deformity and subsequent degenerative changes. A second ligament connects the lateral cuneiform to the adjacent angle of the second metatarsal: it does not divide the joint between the second metatarsal and lateral cuneiform and is inconstant. A third ligament connects the lateral angle of the lateral cuneiform to the adjacent fourth metatarsal base.

Synovial membrane

The first tarsometatarsal joint has its own capsule, with a synovial lining. The other joints are similarly arranged, but there is a communication between the second and third and between the fourth and fifth tarsometatarsal joints.

Innervation

The interosseous cuneometatarsal ligaments are innervated dorsally via the deep fibular nerve. The plantar aspects of the medial two joints are innervated from the medial plantar nerve, and the plantar aspects of the lateral joints are innervated by the lateral plantar nerve.

Relations

From medial to lateral, the following structures cross the dorsal aspect of the tarsometatarsal joints: the saphenous nerve, the dorsal venous arch, the tendon of extensor hallucis longus, the dorsalis pedis artery, the deep fibular nerve, extensor hallucis brevis, the tendons of extensor digitorum longus, extensor digitorum brevis, fibularis tertius and fibularis brevis. Branches of the superficial fibular nerve are variable in location on the dorsum. The sural nerve lies just inferior to the tendon of fibularis brevis in the subcutaneous tissues. Surgery involving the tarsometatarsal joints is performed through a dorsal approach, and therefore all of these structures are potentially at risk.

Factors maintaining stability

The major stabilizers of the tarsometatarsal joints are the associated ligaments. However, despite the strength of the ligaments, this joint complex is vulnerable to injury because of the lack of ligamentous connection between the first and second metatarsal bases. The medial interosseous ligament or

Lisfranc’s ligament is responsible for the tell-tale avulsion fracture of the second metatarsal base, which may be the only radiographic indication of abnormality after injury to this part of the foot. It is a highly significant injury that is often missed: failure to recognize and treat this injury by surgical reduction and fixation can lead to long-term disability.

Muscles producing movement

Movements between the tarsal and metatarsal bones are limited to flexion and extension, except in the first tarsometatarsal joint, where some abduction and rotation also occur. The muscles that produce this motion are tibialis anterior and fibularis longus. Flexion and extension are brought about by the long and short flexors and extensors of the toes. Movement between the medial cuneiform and first metatarsal, and between the fourth and fifth metatarsal bases and the cuboid, is moderate and allows the foot to adapt to uneven surfaces, whereas movement between the second and third metatarsal bases and their corresponding cuneiforms is very limited.

Intermetatarsal joints

The intermetatarsal interosseous ligaments are very strong and are present between all the lateral four metatarsals; they are absent between the first and second metatarsals. The base of the second metatarsal is joined to the first tarsometatarsal joint by the medial interosseous ligament (Lisfranc’s ligament) which connects the plantar aspect of the second metatarsal to the medial cuneiform.

Ligaments

The ligaments of the intermetatarsal joints include the dorsal and plantar intermetatarsal ligaments.

Dorsal and plantar intermetatarsal ligaments

As with their dorsal counterparts, the plantar intermetatarsal ligaments are longitudinal, oblique or transverse and they vary considerably in both number and organization. The plantar ligaments are significantly stronger than the corresponding dorsal ligaments. The strongest is the second oblique plantar ligament, which connects the medial cuneiform to the second and third bases (Fig. 84.17).

Other ligaments

All the metatarsal heads are connected indirectly by deep transverse metatarsal ligaments. Dorsal and plantar ligaments pass transversely between adjacent bases; interosseous ligaments are strong transverse bands that connect non-articular parts of the adjacent surfaces (Fig. 84.17).

Metatarsophalangeal articulations

Metatarsophalangeal articulations are ovoid or ellipsoid joints between the rounded metatarsal heads and shallow cavities on the proximal phalangeal bases. They are usually 2.5 cm proximal to the webs of the toes.

Articulating surfaces

Articular surfaces cover the distal and plantar, but not the dorsal, aspects of the metatarsal heads. The plantar aspect of the first metatarsal head has two longitudinal grooves separated by a ridge (the crista). Each articulates with a sesamoid bone embedded in the capsule of the joint, formed here by the two tendons of flexor hallucis brevis. The sesamoids are connected to each other by the intersesamoid ligament, which forms the floor of the tendinous canal for the tendon of flexor hallucis longus. The medial sesamoid receives an attachment from abductor hallucis and the lateral sesamoid receives an attachment from adductor hallucis.

Articular areas on the proximal phalangeal bases are concave. The ligaments are capsular, plantar, deep transverse metatarsal and collateral.

Fibrous capsules

Fibrous capsules are attached to their articular margins. They are thin dorsally, and may be separated from the long extensor tendons by small bursae, or they may be replaced by the tendons, but they are inseparable from the plantar and collateral ligaments. The plantar aponeurosis blends with the plantar capsule to form the so-called ‘plantar plate’ which inserts distally into the base of the proximal phalanx via medial and lateral bundles. Proximally, the plate is attached to the metatarsal head via a thin synovial fold. It also receives an attachment from the accessory collateral ligament.

Ligaments

The ligaments of the metatarsophalangeal joints are the plantar, deep transverse metatarsal and collateral ligaments.

Plantar ligaments

The plantar ligaments are thick and dense. They lie between and blend with the collateral ligaments, being loosely attached to the metatarsals, and firmly attached to the phalangeal bases. Their margins blend with the deep transverse metatarsal ligaments. Their plantar surfaces are grooved for the flexor tendons, the fibrous sheaths of which connect with the edges of the grooves, and their deep surfaces extend the articular areas for metatarsal heads.

Deep transverse metatarsal ligaments

The deep transverse metatarsal ligaments are four short, wide, flat bands that unite the plantar ligaments of adjoining metatarsophalangeal joints. The interossei are dorsal to, and the lumbricals, digital vessels and nerves are plantar to, these ligaments. They resemble the deep transverse metacarpal ligaments except that, in the foot, there is a deep transverse metacarpal ligament between the plantar ligament of the second metatarsophalangeal joint and that of the hallucal metatarsophalangeal joint (Fig. 84.17).

Collateral ligaments

The collateral ligaments are strong cords flanking each joint. They are attached to the dorsal tubercles on the metatarsal heads and the corresponding side of the phalangeal bases and they slope downwards and forwards. The first metatarsophalangeal joint also contains metatarso-sesamoid ligaments. On either side, the ligaments arise from the metatarsal head with a narrow origin and then fan out to insert on the border of the proximal phalanx and the plantar plate. Each collateral ligament consists of the phalangeal collateral ligament, which inserts into the base of the proximal phalanx, and the accessory collateral ligament, which inserts into the plantar plate.

Synovial membrane

Each metatarsophalangeal joint is a separate synovial joint.

Innervation

The main nerve supply of the metatarsophalangeal joints is from the plantar interdigital nerves, which supply the first, second, third and medial half of the fourth metatarsophalangeal joint on their plantar aspects. Digital branches of the lateral plantar nerve supply the lateral half of the fourth joint, and both medial and lateral aspects of the fifth joint, on their plantar sides. The dorsomedial side of the hallucal metatarsophalangeal joint is supplied by the medial dorsal cutaneous branch of the superficial fibular nerve. The deep fibular nerve supplies the dorsolateral side of the hallucal metatarsophalangeal joint and the medial side of the metatarsophalangeal joint of the second toe.

Relations

Dorsally, the tendon of extensor hallucis longus lies medial to the tendon of extensor hallucis brevis. The same arrangement occurs in the lesser toes with the tendons of extensor digitorum longus and brevis. The interossei are plantarmedial and plantarlateral, dorsal to the intermetatarsal ligament, whereas the lumbrical tendons and the digital artery and nerve are plantar to the intermetatarsal ligament. The long and short flexors lie on the plantar aspect of the joint in the midline. If approaching the metatarsophalangeal joint surgically from the plantar surface, it is important not to stray from the midline.

Factors maintaining stability

The first metatarsophalangeal joint owes its stability to its capsuloligamentous structures, and to flexor and extensor hallucis brevis, with a small contribution from flexor and extensor hallucis longus or the bony contours. The metatarsophalangeal joints of the lesser toe are stabilized principally by the collateral ligaments and plantar plates. Rupture of the plantar plate leads to hammer toe deformity.

Muscles producing movement

The types of movements that occur at these joints are like those that occur at the corresponding joints in the hand, but the range of movement is quite different. In contrast to the metacarpophalangeal joints, the range of active extension that can occur at the metatarsophalangeal joints (50–60°) is greater than that of flexion (30–40°): this is an adaptation to the needs of walking, and is most marked in the hallucal joint, where flexion is a few degrees while extension may reach 90°. When the foot is on the ground, metatarsophalangeal joints are already extended to at least 25° because the metatarsals incline proximally in the longitudinal arches of the foot (Fig. 84.8A). The range of passive movements in these joints is 90° (extension) and 45° (flexion), according to Kapandji (1974). The following muscles produce movements at the metatarsophalangeal joints:

Flexion

Flexor digitorum brevis, lumbricals and interossei, assisted by flexores digitorum longus and accessorius. In the fifth toe, flexor digiti minimi brevis assists. In the hallux, flexores hallucis longus and brevis are the only flexors.

Extension

Extensores digitorum longus and brevis, extensor hallucis longus.

Adduction

Adductor hallucis; in the third to fifth toes, the first, second and third plantar interossei, respectively.

Abduction

Abductor hallucis; in the second toe, the first and second dorsal interossei; in the third and fourth toes, the corresponding dorsal interossei; in the fifth toe, abductor digiti minimi.

Note: The line of reference for adduction and abduction is along the second digit, which has the least mobile metatarsal. The second toe may therefore be ‘abducted’ medially and laterally by the first and second dorsal interossei respectively.

Hallux valgus

Hallux valgus is a common condition, occurring mainly in individuals who have a genetic predisposition. Footwear is implicated in the condition, which presumably accounts for the greater incidence in females. Metatarsus primus varus, an adduction deformity of the first metatarsal, is commonly associated with hallux valgus.

The more spheroidal the shape of the first metatarsal head, the more likely it is to be unstable. Conversely, a flat metatarsal head is less likely to be associated with hallux valgus. No muscle inserts into the first metatarsal head, and therefore its position is determined by the position of the proximal phalanx. As the proximal phalanx moves laterally on the metatarsal head, it pushes the head medially. This leads to attenuation of the medial soft tissue structures and contracture of the lateral ones. The sesamoid sling, which is anchored laterally by adductor hallucis, remains in place as the head moves medially, displacing the sesamoids from beneath the metatarsal head. As this happens, the weakest point of the medial capsule fails, so that abductor hallucis slips under the metatarsal head. This leads to failure of the intrinsic muscles to stabilize the joint, and the pull of abductor hallucis leads to spinning of the proximal phalanx, which results in a pronation deformity. Failure to intervene surgically inevitably results in a progressive deformity.

Interphalangeal articulations

Interphalangeal articulations are almost pure hinge joints, in which the trochlear surfaces on the phalangeal heads articulate with reciprocally curved surfaces on adjacent phalangeal bases. Each has an articular capsule and two collateral ligaments, as occurs in the metatarsophalangeal joints. The plantar surface of the capsule is a thickened fibrous plate, like the plantar metatarsophalangeal ligaments, and is often termed the plantar ligament.

Innervation

The interphalangeal articulations are innervated by branches from the plantar interdigital nerves. The medial dorsal cutaneous branch of the superficial fibular nerve also supplies the hallucal interphalangeal joint. Branches of the deep fibular, intermediate dorsal cutaneous and sural nerves sometimes supply the joints of the lesser toes.

Muscles producing movement

Movements are flexion and extension, which are greater in amplitude between the proximal and middle phalanges than between the middle and distal. Flexion is marked, but extension is limited by tension of the flexor muscles and plantar ligaments. Abduction, adduction and rotation occur to a minor extent.

Flexion

Flexores digitorum longus and brevis, flexor hallucis longus. Flexor accessorius assists flexor digitorum longus.

Extension

Extensores digitorum longus and brevis, extensor hallucis longus.

ARCHES OF THE FOOT

Three main arches are recognized in the foot. They are the medial longitudinal, the lateral longitudinal and the transverse arch. The roles of the arches of the foot in standing, walking and running are discussed later in this chapter.

MEDIAL LONGITUDINAL ARCH

The medial margin of the foot arches up between the heel proximally and the medial three metatarsophalangeal joints to form a visible arch (Fig. 84.8A). It is made up of the calcaneus, talar head, navicular, the three cuneiforms and the medial three metatarsals. The posterior and anterior pillars are the posterior part of the inferior calcaneal surface and the three metatarsal heads, respectively. The bones themselves contribute little to the stability of the arch, whereas the ligaments contribute significantly. The most important ligamentous structure is the plantar aponeurosis, which acts as a tie beam between the supporting pillars (Hicks 1953). Dorsiflexion, especially of the hallux, draws the two pillars together, thus heightening the arch: the so-called 'windlass' mechanism. Next in importance is the spring ligament, which supports the head of the talus. If this ligament fails, the navicular and calcaneus separate, allowing the talar head, which is the highest point of the arch, to descend. The talocalcaneal ligaments and the anterior fibres of the deltoid ligament, from the tibia to the navicular, also contribute to the stability of the arch.

Muscles play a role in the maintenance of the medial longitudinal arch. Flexor hallucis longus acts as a bowstring. Flexor digitorum longus, abductor hallucis and the medial half of flexor digitorum brevis also contribute, but to a lesser extent. Tibialis posterior and anterior invert and adduct the foot, and so help to raise its medial border. The importance of tibialis posterior is manifest by the collapse of the medial longitudinal arch that accompanies failure of its tendon (see below).

LATERAL LONGITUDINAL ARCH

The lateral longitudinal arch is much less pronounced arch than the medial one. The bones making up the lateral longitudinal arch are the calcaneus, the cuboid and the fourth and fifth metatarsals: they contribute little to the arch in terms of stability (Fig. 84.8B). The pillars are the calcaneus posteriorly, and the lateral two metatarsal heads, anteriorly. Ligaments play a more important role in stabilizing the arch, especially the lateral part of the plantar aponeurosis and the long and short plantar ligaments. However, the most important contribution to the maintenance of the lateral arch is made by the tendon of fibularis longus. The lateral two tendons of flexor digitorum longus (and flexor accessorius), the muscles of the first layer (lateral half of flexor digitorum brevis and abductor digiti minimi) and fibularis brevis and peronius tertius also contribute to the maintenance of the lateral longitudinal arch.

TRANSVERSE ARCH

The bones involved in the transverse arch are the bases of the five metatarsals, the cuboid and the cuneiforms (Fig. 84.5B). The intermediate and lateral cuneiforms are wedge-shaped and thus adapted to maintenance of the transverse arch. The stability of the arch is mainly provided by the ligaments, which bind the cuneiforms and the metatarsal bases, and also by the tendon of fibularis longus, which tends to approximate the medial and lateral borders of the foot. A shallow arch is maintained at the metatarsal heads by the deep transverse ligaments, transverse fibres that bind together the digital slips of the plantar aponeurosis, and, to a lesser extent, by the transverse head of adductor hallucis.

PES PLANUS AND PES CAVUS

The term pes planus denotes an excessively flat foot. There is no precise degree of flatness that defines pes planus, but it may be either physiological or pathological. In physiological pes planus, the feet are flexible and rarely problematic. In marked contrast, pathological pes planus is often associated with stiffness and pain. The windlass (or 'Jack's great toe') test involves passively dorsiflexing the hallux at the metatarsophalangeal joint. This tightens the plantar aponeurosis and, in flexible pes planus, results in accentuation of the medial longitudinal arch. In pathological pes planus, no accentuation of the arch is seen. This test can also be carried out by asking the individual to stand on tiptoe and viewing the hindfoot from behind. In flexible flat feet, the calcaneus swings into a varus position; in pathological pes planus it does not. Causes of pathological pes planus include tarsal coalition, disruption of the tendon of tibialis posterior, rupture of the spring ligament, tarsometatarsal arthritis (and subsequent collapse) and hindfoot (talo-calcaneal or subtalar joint) degenerative or inflammatory arthritis.

Pes cavus denotes an excessively high-arched foot. The majority of cases arise as a result of a neurological disorder (e.g. Charcot–Marie–Tooth disease, diastematomyelia, poliomyelitis). According to the anatomical location of the deformity, pes cavus may be classified into hindfoot, midfoot or forefoot cavus. When pes cavus involves all three parts of the foot it is called 'global' cavus.

In Charcot–Marie–Tooth disease, an overactive fibularis longus leads to plantar hyperflexion of the first metatarsal. To keep the forefoot in contact with the ground, the affected individual develops a progressive compensatory hindfoot varus. If ignored, the hindfoot varus, which is initially flexible, becomes fixed. The Coleman block test involves standing with the lateral part of the forefoot on a wooden block (Coleman & Chesnut 1977). This effectively balances the forefoot supination and the hindfoot deformity corrects itself spontaneously, provided the hindfoot varus is flexible. If the hindfoot is still flexible, surgery need only address the forefoot supination. If fixed, however, the hindfoot deformity also needs to be surgically corrected.

MUSCLES

The muscles acting on the foot may be divided into extrinsic and intrinsic groups.

EXTRINSIC MUSCLES

The extrinsic muscles are described in Chapter 83. Their tendons cross the ankle, and move and stabilize this joint. Distally, the tendons also act on the small joints of the foot and help to stabilize these joints. The muscles can be grouped according to their arrangement in the leg. The extensors arise in the anterior compartment of the leg and their tendons pass anterior to the ankle, where they are bound down by the extensor retinacula. The lateral group arises in the relatively narrow lateral compartment of the leg and their tendons pass posterior to the lateral malleolus, bound down by the fibular retinacula. The flexors arise in the posterior compartment of the leg and their tendons pass posterior to the ankle, where the tendons of the superficial group of flexors are inserted into the calcaneus (see below) and the tendons of the deep group of flexors are bound down by the flexor retinaculum.

Anterior group

Tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius are all described in Chapter 83.

Lateral group

Fibularis longus and fibularis brevis are described in Chapter 83.

Posterior group

Superficial group

Gastrocnemius and soleus are described in Chapter 83; the calcaneal tendon is described below.

Calcaneal (Achilles) tendon

The calcaneal tendon is the thickest and strongest tendon in the human body (see Fig. 82.3). It is approximately 15 cm long, and begins near the middle of the calf, although its anterior surface receives muscle fibres from soleus almost to its lower end. It gradually becomes more rounded until approximately 4 cm above the calcaneus, below this level it expands and becomes attached to the midpoint of the posterior surface of the calcaneus. The fibres of the calcaneal tendon are not aligned strictly vertically and they display a variable degree of spiralization (Cummins et al 1946).

Vascular supply

The blood supply to the calcaneal tendon is poor: the predominant artery is a recurrent branch of the posterior tibial artery which mainly supplies peritendinous tissues (Taylor & Razaboni 1994). There is an additional supply proximally from intramuscular arterial branches and distally from the calcaneus. The vascularity of the mid-substance of the tendon is relatively poor, although some blood enters the tendon at this point through its anterior surface. During surgery, the paratenon is therefore best left intact in this region.

The calcaneal tendon is not the only plantar flexor of the ankle, which is one of the reasons ruptures of the calcaneal tendon may not always be clinically apparent. However, it is a frequent site of pathology because of its susceptibility to rupture, degenerative change (tendinosis) and inflammation (paratendonitis): the area of relative avascularity in the mid-substance of the tendon is where the majority of problems occur.

Relations

The calcaneal tendon is subcutaneous. The sural nerve crosses its lateral border about 10 cm above its insertion: the nerve is especially vulnerable here to iatrogenic injury during surgery. Distally, there are bursae superficial and deep to the tendon. The muscle belly of flexor hallucis longus lies deep to the deep fascia on the anterior surface of the tendon.

Action

Plantar flexion of the ankle joint. The tendon fibres spiral laterally through 90° as they descend, so that the fibres associated with gastrocnemius come to insert on the bone more laterally, and those associated with soleus more medially.

Heel bursae

There are three locations about the heel where bursae occur. The most common is the retrocalcaneal bursa, which lies between the calcaneal tendon and the posterior surface of the calcaneus. An almost constant finding, it has an anterior bursal wall composed of fibrocartilage and a thin posterior wall which blends with the thin epitenon (epitendineum) of the calcaneal tendon. Dorsiflexion of the ankle results in compression of the bursa. Less common are an adventitious bursa superficial to the calcaneal tendon, and a subcalcaneal bursa between the inferior surface of the calcaneus and the origin of the plantar aponeurosis. A prominent superolateral calcaneal tuberosity may impinge on the deep aspect of the calcaneal tendon where it inserts onto the calcaneus (Haglund’s disease). It is often associated with a retrocalcaneal bursa, and symptoms are exacerbated by dorsiflexion of the ankle, because this movement increases the pressure within the bursa and causes impingement of calcaneus against the tendon insertion.

Plantaris

Plantaris is described in Chapter 83.

Deep group

The deep flexors of the calf include popliteus, which acts on the knee joint, and flexor hallucis longus, flexor digitorum longus and tibialis posterior, which all act on the ankle joint and joints of the foot.

Flexor hallucis longus

Flexor hallucis longus is described in Chapter 83. The tendon of flexor hallucis longus is described below.

Flexor digitorum longus

Flexor digitorum longus is described in Chapter 83.

Tibialis posterior

Tibialis posterior is described in Chapter 83.

INTRINSIC MUSCLES

The intrinsic muscles, i.e. those contained entirely within the foot, follow the primitive limb pattern of plantar flexors and dorsal extensors.

The plantar muscles in the foot can be divided into medial, lateral and intermediate groups. The medial and lateral groups consist of the intrinsic muscles of the hallux and minimus, respectively, and the central or intermediate group includes the lumbricals, interossei and short digital flexors. It is customary to group the muscles in four layers, because this is the order in which they are encountered during dissection. However, in clinical practice and in terms of function, the former grouping is often more useful.

Plantar muscles of the foot: first layer

This superficial layer includes abductor hallucis, abductor digiti minimi and flexor digitorum brevis (Fig. 84.19A). All three extend from the calcaneal tuberosity to the toes, and all assist in maintaining the concavity of the foot.

Abductor hallucis

Attachments

Abductor hallucis arises principally from the flexor retinaculum, but also from the medial process of the calcaneal tuberosity, the plantar aponeurosis, and the intermuscular septum between this muscle and flexor digitorum brevis. The muscle fibres end in a tendon that is attached, together with the medial tendon of flexor hallucis brevis, to the medial side of the base of the proximal phalanx of the hallux. Some fibres are attached more proximally to the medial sesamoid bone of this toe. The muscle may also derive some fibres from the dermis along the medial border of the foot.

Relations

Abductor hallucis lies along the medial border of the foot and covers the origins of the plantar vessels and nerves (Fig. 84.20).

Fig. 84.20 Plantar nerves and vessels in relation to muscle layers.

(From Sobotta 2006.)

Vascular supply

Abductor hallucis is supplied by the medial malleolar network, medial calcaneal branches of the lateral plantar artery (Fig. 84.9), the medial plantar artery (directly and via superficial and deep branches), the first plantar metatarsal artery and perforators from the plantar arterial arch.

Innervation

Abductor hallucis is innervated by the medial plantar nerve, S1 and S2. Contraction of the muscle confirms an intact medial plantar nerve when the integrity of this nerve is in question.

Action

Abductor hallucis produces abduction of the hallux.

Testing

Abductor hallucis is tested clinically by instructing the subject to resist a forcibly applied lateral deviation of the proximal phalanx.

Clinical anatomy

The deep fascia has been implicated in chronic heel pain, because it can cause entrapment of the first branch of the lateral plantar nerve that lies immediately deep to it. The abductor hallucis fascia is strong and can be used in soft tissue augmentation following correction of hallux valgus. Rarely, persistent, exaggerated tonus in the muscle may be a cause of varus deformity of the foot, necessitating surgical intervention. An abductor hallucis flap is sometimes used for provision of soft tissue cover.

Flexor digitorum brevis

Attachments

Flexor digitorum brevis arises by a narrow tendon from the medial process of the calcaneal tuberosity, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and adjacent muscles. It divides into four tendons, which pass to the lateral four toes; the tendons enter digital tendon sheaths accompanied by the tendons of flexor digitorum longus, which lie deep to them. At the bases of the proximal phalanges, each tendon divides around the corresponding tendon of flexor digitorum longus; the two slips then reunite and partially decussate, forming a tunnel through which the tendon of flexor digitorum longus passes to the distal phalanx. The short flexor tendon divides again and attaches to both sides of the shaft of the middle phalanx. The way in which the tendons of flexor digitorum brevis divide and attach to the phalanges is identical to that of the tendons of flexor digitorum superficialis in the hand. The slip to a given toe may be absent, or it may be replaced by a small muscular slip from the long flexor tendon or from flexor accessorius. Conversely, the slip may be joined by a second, supernumerary slip.

Relations

Flexor digitorum brevis lies immediately deep to the central part of the plantar aponeurosis (Fig. 84.19A). Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia.

Vascular supply

Flexor digitorum brevis is supplied by the lateral and medial plantar arteries, the plantar metatarsal arteries and the plantar digital arteries to the lateral four toes.

Nerve supply

Flexor digitorum brevis is innervated by the medial plantar nerve, S1 and S2.

Actions

Flexor digitorum brevis flexes the lesser toes at the proximal interphalangeal joint, with equal effect in any position of the ankle joint.

Testing

To test the action of flexor digitorum brevis, the examiner passively extends the distal interphalangeal joint and asks the individual to flex the toes at the proximal interphalangeal joint. Contracture of the flexor tendon can lead to toe deformities, and release or lengthening procedures may be required. The muscle belly is sometimes excised as a flap to cover a soft tissue defect.

Abductor digiti minimi

Attachments

Abductor digiti minimi arises from both processes of the calcaneal tuberosity, from the plantar surface of the bone between them, from the plantar aponeurosis and from the intermuscular septum between the muscle and flexor digitorum brevis. Its tendon glides in a smooth groove on the plantar surface of the base of the fifth metatarsal and is attached, with flexor digiti minimi brevis, to the lateral side of the base of the proximal phalanx of the fifth toe; hence it is more a flexor than an abductor. Some of the fibres arising from the lateral calcaneal process usually reach the tip of the tuberosity of the fifth metatarsal (Figs 84.8B; 84.11) and may form a separate muscle, abductor ossis metatarsi digiti quinti. An accessory slip from the base of the fifth metatarsal is not infrequent.

Relations

Abductor digiti minimi lies along the lateral border of the foot, and its medial margin is related to the lateral plantar vessels and nerve (Fig. 84.20).

Vascular supply

Abductor digiti minimi is supplied by the medial and lateral plantar arteries (Fig. 84.20; see Fig. 84.24A), the plantar digital artery to the lateral side of minimus, branches from the plantar arch, the fourth plantar metatarsal artery and end twigs of the arcuate and lateral tarsal arteries (Fig. 84.9).

Fig. 84.24 The plantar arteries of the left foot. **A**, Superficial dissection. **B**, Deep dissection.

Innervation

Abductor digiti minimi is innervated by the lateral plantar nerve, S1, S2 and S3.

Action

Despite its name, abductor digiti minimi is more a flexor than an abductor of the metatarsophalangeal joint of the little toe.

Plantar muscles of the foot: second layer

The second layer consists of flexor digitorum accessorius and four lumbrical muscles. The tendons of flexor hallucis longus and flexor digitorum longus run in the same plane as the muscles of the second layer (Fig. 84.19B): flexor hallucis longus and flexor digitorum longus are described in Chapter 83.

Flexor tendon sheaths

The terminations of the tendons of the long and short flexor muscles are contained in osseo-aponeurotic canals similar to those which occur in the fingers. These canals are bounded above by the phalanges, and below by fibrous bands, the digital fibrous sheaths, which arch across the tendons and attach on either side to the margins of the phalanges (Fig. 84.19B). Along the proximal and intermediate phalanges, the fibrous bands are strong, and the fibres are transverse (anular part); opposite the joints they are much thinner and the fibres decussate (cruciform part). Each osseo-aponeurotic canal has a synovial lining, which is reflected around its tendon; within this sheath, vincula tendinum are arranged as they are in the fingers.

Flexor digitorum accessorius

Attachments

Flexor digitorum accessorius (Fig. 84.19B), also known as quadratus plantae, arises by two heads, with the long plantar ligament situated deeply in the interval between the two heads. The medial head is larger and more fleshy and is attached to the medial concave surface of the calcaneus, below the groove for the tendon of flexor hallucis longus. The lateral head is flat and tendinous and is attached to the calcaneus distal to the lateral process of the tuberosity, and to the long plantar ligament. The muscle belly inserts into the tendon of flexor digitorum longus at the point where it is bound by a fibrous slip to the tendon of flexor hallucis longus and where it divides into its four tendons.

The muscle is sometimes absent altogether. Its distal attachment to the tendons of flexor digitorum longus may vary, which means that the fourth and fifth long flexor tendons may, at times, fail to receive slips from the accessorius.

Relations

The medial plantar nerve passes medial to and the lateral plantar nerve passes superficial to flexor accessorius.

Vascular supply

Flexor digitorum accessorius is supplied by the stem of the medial plantar artery (to the medial head), the lateral plantar artery and the plantar arch.

Innervation

Flexor digitorum accessorius is innervated by the lateral plantar nerve, S1, S2 and S3.

Action

By pulling on the tendons of flexor digitorum longus, flexor digitorum accessorius provides a means of flexing the lateral four toes in any position of the ankle joint.

Lumbrical muscles

Attachments

The lumbrical muscles are four small muscles (numbered from the medial side of the foot) which are accessory to the tendons of flexor digitorum longus (Fig. 84.19A,B). They arise from these tendons as far back as their angles of separation, each springing from the sides of two adjacent tendons, except for the first lumbrical, which arises only from the medial border of the first tendon. The muscles end in tendons that pass distally on the medial sides of the four lesser toes and are attached to the dorsal digital expansions on their proximal phalanges.

Relations

The lumbricals are intimately related to the tendons of flexor digitorum longus before the latter enter their corresponding fibrous flexor sheaths. The lumbricals remain outside the fibrous flexor sheaths and cross the plantar aspects of the deep transverse metatarsal ligaments before reaching the dorsal digital expansions.

Vascular supply

The lumbricals are supplied by the lateral plantar artery and plantar arch, and by four plantar metatarsal arteries (four distal perforating arteries joined by three proximal perforating arteries). Their tendons are supplied by twigs from the dorsal digital arteries (and their parent dorsal metatarsal arteries) to the lateral four toes.

Innervation

The first lumbrical is supplied by the medial plantar nerve, and the remainder are supplied by the deep branch of the lateral plantar nerve, S2 and S3.

Action

The lumbricals help to maintain extension of the interphalangeal joints of the toes. In injuries of the tibial nerve, and in conditions such as the hereditary motor–sensory neuropathies (e.g. Charcot–Marie–Tooth disease), lumbrical dysfunction contributes to clawing of the toes.

Plantar muscles of the foot: third layer

The third layer of the foot contains the shorter intrinsic muscles of the hallux and minimus, i.e. flexor hallucis brevis, adductor hallucis and flexor digiti minimi brevis (Fig. 84.21).

(From Sobotta 2006.)

Flexor hallucis brevis

Attachments

Flexor hallucis brevis has a bifurcate tendon of origin (Figs 84.19A,B; 84.21). The lateral limb arises from the medial part of the plantar surface of the cuboid, posterior to the groove for the tendon of fibularis longus, and from the adjacent part of the lateral cuneiform. The medial limb has a deep attachment directly continuous with the lateral division of the tendon of tibialis posterior, and a more superficial attachment to the middle band of the medial intermuscular septum. The belly of the muscle divides into medial and lateral parts, the twin tendons of which are attached to the sides of the base of the proximal phalanx of the hallux. The medial part blends with the tendon of abductor hallucis, and the lateral with that of adductor hallucis, as they reach their terminations.

A sesamoid bone usually occurs in each tendon near its attachment. Clinical problems with flexor hallucis brevis are usually related to the associated sesamoid bones. However, excision of both sesamoids leads to disruption of both tendons and a subsequent extension deformity at the first metatarsophalangeal joint: such surgery is therefore not recommended.

Accessory slips may arise proximally from the calcaneus or long plantar ligament. A tendinous slip may extend to the proximal phalanx of the second toe.

Relations

Flexor hallucis brevis lies on the underside of the first metatarsal shaft; abductor hallucis lies medially. The medial digital nerve to the hallux and the tendon of flexor hallucis longus pass to the hallux on its plantar surface. The medial plantar nerve lies more superficially on its lateral side.

Vascular supply

Flexor hallucis brevis is supplied by branches of the medial plantar artery, the first plantar metatarsal artery, the lateral plantar artery and the plantar arch.

Innervation

Flexor hallucis brevis is supplied by the medial plantar nerve, S1 and S2.

Action

Flexor hallucis brevis flexes the proximal phalanx of the hallux.

Testing

The individual is asked to flex the first metatarsophalangeal joint with the interphalangeal joint extended, thereby eliminating the action of flexor hallucis longus.

Adductor hallucis

Attachments

Adductor hallucis arises by oblique and transverse heads (Figs 84.19B; 84.21). The oblique head springs from the bases of the second, third and fourth metatarsal bones, and from the fibrous sheath of the tendon of fibularis longus. The transverse head, a narrow, flat fasciculus, arises from the plantar metatarsophalangeal ligaments of the third, fourth and fifth toes (sometimes only from the third and fourth), and from the deep transverse metatarsal ligaments between them. The oblique head has medial and lateral parts. The medial part blends with the lateral part of flexor hallucis brevis and is attached to the lateral sesamoid bone of the hallux. The lateral part joins the transverse head and is also attached to the lateral sesamoid bone and directly to the base of the first phalanx of the hallux. There is no phalangeal attachment for the transverse part of the muscle; fibres that fail to reach the lateral sesamoid bone are attached with the oblique part.

The transverse part of adductor hallucis is sometimes absent; part of the muscle may be attached to the first metatarsal, constituting an opponens hallucis; a slip may also extend to the proximal phalanx of the second toe.

Relations

Adductor hallucis lies plantar to the metatarsal shafts and interossei and the long and short toe flexors. The medial and lateral plantar arteries and nerves are superficial, and flexor hallucis brevis is proximal and medial.

Vascular supply

Adductor hallucis is supplied by branches of the medial plantar artery, the lateral plantar artery, the plantar arch and the first to fourth plantar metatarsal arteries.

Innervation

Adductor hallucis is innervated by the deep branch of the lateral plantar nerve, S2 and S3.

Action

Adductor hallucis partly flexes the proximal phalanx of the hallux, but also stabilizes the metatarsal heads.

Clinical anatomy

Adductor hallucis is one of the deforming forces in hallux valgus and needs to be released during a distal soft tissue release when there is a fixed deformity.

Flexor digiti minimi brevis

Attachments

Flexor digiti minimi brevis arises from the medial part of the plantar surface of the base of the fifth metatarsal bone, and from the sheath of fibularis longus (Figs 84.19B; 84.21). It has a distal tendon that inserts into the lateral side of the base of the proximal phalanx of the minimus; this tendon usually blends laterally with that of abductor digiti minimi. Occasionally, some of its deeper fibres extend to the lateral part of the distal half of the fifth metatarsal bone, constituting what may be described as a distinct muscle, opponens digiti minimi.

Relations

The fifth metatarsal shaft lies on the deep surface of flexor digiti minimi brevis, the interossei lie medially and abductor digiti minimi is lateral. The most lateral branch of the lateral plantar nerve lies superficially and just medial to flexor digiti minimi brevis.

Vascular supply

Flexor digiti minimi brevis is supplied by end twigs of the arcuate and lateral tarsal arteries, and the lateral plantar artery and its digital (plantar) branch to the lateral side of minimus.

Innervation

Flexor digiti minimi brevis is innervated by the super-ficial branch of the lateral plantar nerve, S2 and S3.

Action

Flexor digiti minimi brevis flexes the metatarsophalangeal joint of the little toe.

Plantar muscles of the foot: fourth layer

The fourth layer of muscles of the foot consists of the plantar and dorsal interossei and the tendons of tibialis posterior and fibularis longus (tibialis posterior and fibularis longus are described in Ch. 83). The interossei resemble their counterparts in the hand except that, when describing adduction and abduction of the toes, the axis of reference is a longitudinal axis corresponding to the shaft of the 2nd metatarsal (unlike the hand where reference is made to the long axis of the third metacarpal).

Dorsal interossei

Attachments

The dorsal interossei (Fig. 84.22A) are situated between the metatarsal bones. They consist of four bipennate muscles, each arising by two heads from the sides of the adjacent metatarsal bones. Their tendons are attached to the bases of the proximal phalanges and to the dorsal digital expansions. The first inserts into the medial side of the second toe; the other three pass to the lateral sides of the second, third and fourth toes.

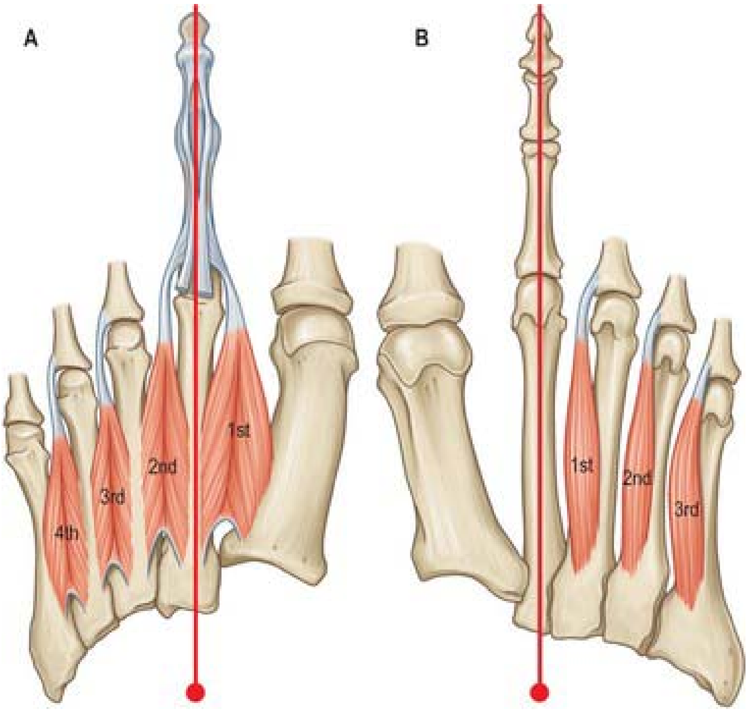

Fig. 84.22 The interossei of the left foot. **A**, Dorsal interossei viewed from the dorsal aspect. **B**, Plantar interossei viewed from the plantar aspect. The axis to which the movements of abduction and adduction are referred is indicated.

Relations

Between the heads of each of the three lateral muscles, there is an angular space through which a perforating artery passes to the dorsum of the foot. Between the heads of the first muscle, the corresponding space transmits the terminal part of the dorsalis pedis artery to the sole (see Fig. 84.1).

Vascular supply

Dorsal interossei are supplied by the arcuate artery, lateral and medial tarsal arteries, the first to fourth plantar arteries and the first to fourth dorsal metatarsal arteries (receiving proximal and distal perforating arteries), and by the dorsal digital arteries of the lateral four toes.

Innervation

Dorsal interossei are supplied by the deep branch of the lateral plantar nerve (S2 and S3), except that of the fourth interosseous space, which is supplied by the superficial branch of the lateral plantar nerve.

Action

Dorsal interossei abduct the toes relative to the longitudinal axis of the second metatarsal. They also flex the metatarsophalangeal joints and extend the interphalangeal joints of the lesser toes. The hallux and little toe have their own abductors.

Clinical anatomy

Denervation of the interossei leads to claw-toe deformities. Development of claw toes should alert the clinician to the possibility of a neuropathic process (e.g. Charcot–Marie–Tooth disease, diastematomyelia).

Plantar interossei

There are three plantar interossei (Fig. 84.22B). They lie below, rather than between, the metatarsal bones, and each is connected to one metatarsal bone only. They arise from the bases and medial sides of the third, fourth and fifth metatarsal bones, and insert into the medial sides of the bases of the proximal phalanges of the numerically corresponding toes, and into their dorsal digital expansions.

Relations

The plantar interossei lie plantar to the dorsal interossei and deep to the muscles of the third layer.

Vascular supply

Plantar interossei are supplied by the lateral plantar artery, the plantar arch, the second to fourth plantar metatarsal arteries and the dorsal digital arteries of the lateral three toes.

Innervation

Plantar interossei are supplied by the deep branch of the lateral plantar nerve (S2 and S3), except that of the fourth interosseous space, which is supplied by the superficial branch of the lateral plantar nerve.

Action

Plantar interossei adduct the third, fourth and fifth toes, flex the metatarsophalangeal joints and extend the interphalangeal joints.

Clinical anatomy

The clinical anatomy of the plantar interossei is similar to that of the dorsal interossei.

Extensor muscles of the foot

Extensor digitorum brevis and extensor hallucis brevis

Attachments

Extensor digitorum brevis (Fig. 84.2A) is a thin muscle which arises from the distal part of the superolateral surface of the calcaneus in front of the shallow lateral groove for fibularis brevis, from the interosseous talocalcaneal ligament, and from the deep surface of the stem of the inferior extensor retinaculum. It slants distally and medially across the dorsum of the foot, and ends in four tendons. The medial part of the muscle is usually a more or less distinct slip, ending in a tendon that crosses the dorsalis pedis artery superficially to insert into the dorsal aspect of the base of the proximal phalanx of the hallux; this slip is sometimes termed extensor hallucis brevis. The other three tendons attach to the lateral sides of the tendons of extensor digitorum longus for the second, third and fourth toes.

The muscle is subject to much variation, e.g. accessory slips from the talus and navicular, an extra tendon to the fifth digit, an absence of one or more tendons. It may be connected to the adjacent dorsal interosseous muscles.

Relations

The most medial tendon, that of extensor hallucis brevis, courses dorsomedially and passes superficial to the dorsalis pedis artery and the deep fibular nerve. The remaining three tendons pass obliquely deep to the corresponding tendons of extensor digitorum longus.

Vascular supply

Extensor digitorum brevis is supplied by the anterior perforating branch of the fibular artery, the anterior lateral malleolar artery, lateral tarsal arteries, dorsalis pedis arteries, arcuate artery, the first, second and third dorsal metatarsal arteries, proximal and distal perforating arteries, and the dorsal digital arteries to the medial four toes (including the hallux).

Innervation

Extensor digitorum brevis is supplied by the lateral terminal branch of the deep fibular nerve, L5, S1.

Actions

The muscle assists in extending the phalanges of the middle three toes via the tendons of extensor digitorum longus; in the hallux, it assists in extension of the metatarsophalangeal joint.

Clinical anatomy

Laceration of extensor digitorum brevis leads to little in the way of functional impairment, because the long extensors can compensate for the loss of the muscle. The proximal part of the muscle can be used as interposition material to prevent bone fusion after resection of a calcaneonavicular bar (a common tarsal coalition). The muscle belly and tendon of extensor hallucis brevis serve as guides to the location of the dorsalis pedis artery and deep fibular nerve. The tendon of extensor hallucis brevis can be used as a local graft.

VASCULAR SUPPLY

ARTERIES

Dorsalis pedis artery

The dorsalis pedis artery is the dorsal artery of the foot (Figs 84.1; 84.23), and is the continuation of the anterior tibial artery distal to the ankle. It passes to the proximal end of the first intermetatarsal space, where it turns into the sole between the heads of the first dorsal interosseous to complete the plantar arch, and provides the first plantar metatarsal artery.

Fig. 84.23 Dorsal arteries of the foot.

The artery may be larger than normal, to compensate for a small lateral plantar artery. It may be absent, in which event it is replaced by a large perforating branch of the fibular artery. It often diverges laterally from its usual route.

Relations

The dorsalis pedis artery crosses, successively, the talocrural articular capsule, talus, navicular and intermediate cuneiform and their ligaments; superficial to it are the skin, fasciae, inferior extensor retinaculum and, near its termination, extensor hallucis brevis. Medial to it is the tendon of extensor hallucis longus and lateral to it are the medial tendon of extensor digitorum longus and medial terminal branch of the deep fibular nerve. The tendons are useful landmarks in the planning of safe anatomical approaches in surgery of the ankle and foot.

Surface anatomy

The pulsation of the dorsal artery of the foot is palpable from the midpoint between the malleoli to the proximal end of the first intermetatarsal space.

Branches

The dorsalis pedis artery gives off the tarsal, arcuate and first dorsal metatarsal arteries.

Tarsal arteries

There are two tarsal arteries, lateral and medial (Fig. 84.23). They arise as the dorsalis pedis artery crosses the navicular. The lateral runs laterally under extensor digitorum brevis; it supplies this muscle and the tarsal articulations, and anastomoses with branches of the arcuate, anterior lateral malleolar and lateral plantar arteries, and the perforating branch of the fibular artery. Two or three medial tarsal arteries ramify on the medial border of the foot and join the medial malleolar network.

Arcuate artery

The arcuate artery (Fig. 84.23) arises near the medial cuneiform, passes laterally over the metatarsal bases, deep to the tendons of the digital extensors, and anastomoses with the lateral tarsal and plantar arteries. It supplies the second to fourth dorsal metatarsal arteries, running distally superficial to the corresponding dorsal interossei, and divides into two dorsal digital branches for the adjoining toes in the interdigital clefts. Proximally, in the interosseous spaces, these branches receive proximal perforating branches from the plantar arch. Distally, they are joined by distal perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery sends a branch to the lateral side of the fifth toe.

First dorsal metatarsal artery

The first dorsal metatarsal artery (Fig. 84.23) arises just before the dorsalis pedis artery enters the sole. It runs distally on the first dorsal interosseous and divides at the cleft between the first and second toes. One branch passes under the tendon of extensor hallucis longus and supplies the medial side of the hallux; the other bifurcates to supply the adjoining sides of the hallux and the second toe.

Cutaneous vessels from the dorsalis pedis artery

The dorsalis pedis artery and its first dorsal metatarsal branch give rise to small direct cutaneous branches that supply the dorsal foot skin between the extensor retinaculum and the first web space. This vessel provides the basis for a fasciocutaneous flap raised from this region, and which may be used to cover superficial defects elsewhere.

Plantar arch

The plantar arch (Fig. 84.24) is deeply situated, extending from the fifth metatarsal base to the proximal end of the first interosseous space. Convex distally, it is plantar to the bases of the second to fourth metatarsal bones and corresponding interossei, but dorsal to the oblique part of adductor hallucis.

Branches

The plantar arch gives off three perforating and four plantar metatarsal branches, and numerous branches that supply the skin, fasciae and muscles in the sole. Three perforating branches ascend through the proximal ends of the second to fourth intermetatarsal spaces, between the heads of dorsal interossei, and anastomose with the dorsal metatarsal arteries. Four plantar metatarsal arteries extend distally between the metatarsal bones in contact with the interossei (Fig. 84.24). Each divides into two plantar digital arteries, supplying the adjacent digital aspects. Near its division, each plantar metatarsal artery sends a distal perforating branch dorsally to join a dorsal metatarsal artery. The first plantar metatarsal artery springs from the junction between the lateral plantar and dorsalis pedis arteries, and sends a digital branch to the medial side of the hallux. The lateral digital branch for the fifth toe arises directly from the lateral plantar artery near the fifth metatarsal base. Haemorrhage from the plantar arch is difficult to stem, because of the depth of the vessel and its important close relations.

Surface anatomy

The lateral plantar artery begins between the heel and medial malleolus, and crosses obliquely to a point 2.5 cm medial to the tuberosity of the fifth metatarsal. With a slight distal convexity, it reaches the proximal end of the first intermetatarsal space.

Posterior tibial artery

Before the posterior tibial artery divides into its two main terminal branches, it gives off a communicating branch which runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, and joins a communicating branch of the fibular artery; calcaneal branches, which arise just proximal to the termination of the posterior tibial artery, pierce the flexor retinaculum and supply the skin and fat behind the calcaneal tendon; the artery of the tarsal canal. The terminal branches of the posterior tibial artery are the medial and lateral plantar arteries.

Branches

Medial plantar artery

The medial plantar artery is the smaller terminal branch of the posterior tibial artery (Fig. 84.24). It arises midway between the medial malleolus and the medial calcaneal tubercle and passes distally along the medial side of the foot, with the medial plantar nerve lateral to it. At first deep to abductor hallucis, it runs distally between abductor hallucis and flexor digitorum brevis, supplying both. Near the first metatarsal base, when its calibre is already diminished as a result of supplying numerous muscular branches, it is further diminished by a superficial stem. It passes to the medial border of the hallux, where it anastomoses with a branch of the first plantar metatarsal artery. Its superficial stem then trifurcates and supplies three superficial digital branches that accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries.

Lateral plantar artery

The lateral plantar artery is the larger terminal branch of the posterior tibial artery (Fig. 84.24). It passes distally and laterally to the fifth metatarsal base; the lateral plantar nerve is medial. The plantar nerves lie between the plantar arteries. Turning medially, with the deep branch of the nerve, it gains the interval between the first and second metatarsal bases, and unites with the dorsalis pedis artery to complete the plantar arch. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi and is covered by the plantar aponeurosis, superficial fascia and skin.

Muscular branches supply the adjoining muscles. Superficial branches emerge along the intermuscular septum to supply the skin and subcutaneous tissue over the lateral part of the sole. Anastomotic branches run to the lateral border, and join branches of the lateral tarsal and arcuate arteries. Sometimes, a calcaneal branch pierces abductor hallucis to supply the skin of the heel.

Perforator flaps in the ankle and foot region

The arteries around the ankle and in the foot are the medial and lateral calcaneal artery, medial and lateral plantar artery and the dorsalis pedis artery. In the foot the two plantar arteries with communicating arteries from dorsalis pedis give out multiple small perforators. In the sole of the foot the perforators emerge on either side of the plantar aponeurosis, and also pass through it, to supply the skin. ‘Island flaps’ from these perforators may be advanced to reconstruct small defects in the weight bearing area. The skin of the sole of the foot is highly specialized and therefore ideally defects in this region should be reconstructed using local skin.

DEEP AND SUPERFICIAL VENOUS SYSTEMS IN THE FOOT

Plantar digital veins arise from plexuses in the plantar regions of the toes. They connect with dorsal digital veins to form four plantar metatarsal veins which run proximally in the intermetatarsal spaces and connect via perforating veins with dorsal veins, then continue to form the deep plantar venous arch which is situated alongside the plantar arterial arch. From this venous arch, medial and lateral plantar veins run near the corresponding arteries and, after communicating with the great and small saphenous veins, form the posterior tibial veins behind the medial malleolus.

The principal named superficial veins are the great and small saphenous. Their numerous tributaries are mostly (but not wholly) unnamed; named vessels will be noted (see Fig. 79.9A,B). As in the upper limb, the vessels will be described centripetally from peripheral to major drainage channels.

Dorsal digital veins receive rami from the plantar digital veins in the clefts between the toes and then join to form dorsal metatarsal veins, which are united across the proximal parts of the metatarsal bones in a dorsal venous arch. Proximal to this arch, an irregular dorsal venous network receives tributaries from deep veins and is continuous proximally with a venous network in the leg. At each side of the foot, this network connects with medial and lateral marginal veins, which are both formed mainly by veins from more superficial parts of the sole. In the sole, superficial veins form a plantar cutaneous arch across the roots of the toes and also drain into the medial and lateral marginal veins. Proximal to the plantar arch there is a plantar cutaneous venous plexus, especially dense in the fat of the heel. It connects with the plantar cutaneous venous arch and other deep veins, but drains mainly into the marginal veins. The veins of the sole are an important part of the lower limb ‘venous pump’ system aiding propulsion of blood up the limb. Intermittent foot compression devices are available to enhance this flow and so reduce the risk of deep vein thrombosis during periods of increased risk, e.g. after surgery.

INNERVATION OF THE FOOT

Superficial fibular nerve

The superficial fibular nerve is described in Chapter 83.

Deep fibular nerve

The deep fibular nerve is described in Chapter 83.

Tibial nerve

The branches of the tibial nerve that innervate structures in the ankle and foot are articular, muscular, sural, medial calcaneal and medial and lateral plantar nerves. The course and distribution of the tibial nerve in the calf are described in Chapter 83.

Medial calcaneal nerve

The medial calcaneal nerve arises from the tibial nerve and perforates the flexor retinaculum to supply the skin of the heel and medial side of the sole.

Medial plantar nerve

The medial plantar nerve is the larger terminal division of the tibial nerve, and lies lateral to the medial plantar artery. From its origin under the flexor retinaculum, it passes deep to abductor hallucis, then appears between it and flexor digitorum brevis, gives off a medial proper digital nerve to the hallux, and divides near the metatarsal bases into three common plantar digital nerves.

Cutaneous branches pierce the plantar aponeurosis between abductor hallucis and flexor digitorum brevis to supply the skin of the sole of the foot. Muscular branches supply abductor hallucis, flexor digitorum brevis, flexor hallucis brevis and the first lumbrical. The first two arise near the origin of the nerve and enter the deep surfaces of the muscles. The branch to flexor hallucis brevis is from the hallucal medial digital nerve, and that to the first lumbrical from the first common plantar digital nerve. Articular branches supply the joints of the tarsus and metatarsus.

Three common plantar digital nerves pass between the slips of the plantar aponeurosis, each dividing into two proper digital branches. The first supplies adjacent sides of the hallux and second toe and the second supplies adjacent sides of the second and third toes; the third supplies adjacent sides of the third and fourth toes, and also connects with the lateral plantar nerve. The first gives a branch to the first lumbrical. Each proper digital nerve has cutaneous and articular branches: near the distal phalanges a dorsal branch supplies structures around the nail, and the termination of each nerve supplies the ball of the toe.

The common digital branches of the medial plantar nerve are distributed in a manner similar to those of the median nerve, as are the motor branches of the two nerves. In the hand, the median nerve supplies abductor and flexor pollicis brevis, opponens pollicis and the first and second lumbricals. An opponens is absent in the foot, but abductor hallucis, flexor hallucis brevis and the first lumbrical are all supplied by the medial plantar nerve. Flexor digitorum brevis and flexor digitorum superficialis (innervated by the median nerve) correspond, but the innervation of the second lumbrical of the foot does not mirror the arrangement in the hand.

Lateral plantar nerve

The lateral plantar nerve supplies the skin of the fifth toe, the lateral half of the fourth toe, and most of the deep muscles of the foot (Fig. 84.20). Its distribution therefore closely resembles that of the ulnar nerve in the hand. It passes laterally forwards medial to the lateral plantar artery, towards the tubercle of the fifth metatarsal. Next, it passes between flexores digitorum brevis and accessorius, and ends between flexor digiti minimi brevis and abductor digiti minimi by dividing into superficial and deep branches. Before division, it supplies flexor digitorum accessorius and abductor digiti minimi and gives rise to small branches that pierce the plantar fascia to supply the skin of the lateral part of the sole (Fig. 84.25). The superficial branch splits into two common plantar digital nerves: the lateral supplies the lateral side of the fifth toe, flexor digiti minimi brevis and the two interossei in the fourth intermetatarsal space; the medial connects with the third common plantar digital branch of the medial plantar nerve and divides into two to supply the adjoining sides of the fourth and fifth toes. The deep branch accompanies the lateral plantar artery deep to the flexor tendons and adductor hallucis and supplies the second to fourth lumbricals, adductor hallucis and all the interossei (except those of the fourth intermetatarsal space). Branches to the second and third lumbricals pass distally deep to the transverse head of adductor hallucis, and curl round its distal border to reach them.

Nerve entrapment syndromes in the foot

All nerves of the foot can be affected by entrapment, leading classically to a burning sensation in the distribution of that nerve. Tarsal tunnel syndrome is much less common than carpal tunnel syndrome. The flexor retinaculum may compress the tibial nerve or either of its branches (medial and lateral plantar nerves). However entrapment at this level is most commonly due to a space-occupying lesion, e.g. ganglion, or compression by a leash of vessels or the deep fascia associated with abductor hallucis. Compression of the first branch of the lateral plantar nerve by the deep fascia of abductor hallucis can lead to heel pain. The medial plantar nerve can be compressed at the 'knot of Henry': this is usually related to jogging. The 'knot of Henry' is the anatomical landmark where the tendon of flexor hallucis longus crosses deep to the tendon of flexor digitorum longus, to reach its medial side in the sole of the foot. The superficial fibular nerve can be damaged in severe inversion injuries of the ankle, and the deep fibular nerve is sometimes compressed by osteophytes in the region of the second tarsometatarsal joint. Sural nerve entrapment is usually not due to compression by fascial elements; rather, it is secondary to distal fibular trauma and subsequent scar formation around the nerve. Entrapment of the common digital nerve as it passes under the intermetatarsal ligament of the third (or less commonly the second) webspace can result in a Morton's neuroma, which is probably the most common form of nerve entrapment in the foot.

BIOMECHANICS OF STANDING, WALKING AND RUNNING

PLANES OF MOTION

Much confusion surrounds the descriptive terms for movement in the foot and ankle. Plantar flexion and dorsiflexion refer to movement in the sagittal plane and occur principally, but not exclusively, at the ankle, metatarsophalangeal and interphalangeal joints. Inversion is tilting of the plantar surface of the foot towards the midline, and eversion is tilting away from the midline. This is motion in the coronal plane and takes place principally in the talocalcaneal and transverse tarsal joints. Adduction is movement of the foot towards the midline in the transverse plane; abduction is movement away from the midline. This movement occurs at the transverse tarsal joints and, to a limited degree, the first tarsometatarsal joint and the metatarsophalangeal joints.

Supination describes a three-dimensional movement and is a combination of adduction, inversion and plantar flexion. Pronation is the opposite motion, i.e. a combination of abduction, eversion and dorsiflexion. Pronation and supination are usually better terms than eversion and inversion, as the latter rarely occur in isolation and the former describe the ‘compound’ motion that usually occurs.

Active movements occur at the ankle, talocalcaneonavicular and subtalar joints. Movements at the ankle joint are almost entirely restricted to dorsi- and plantar flexion, but slight rotation may occur in plantar flexion. The ranges of movement at the talocalcaneonavicular and subtalar joint are greater: inversion and eversion mainly occur here.

STANDING

Humans are bipedal: we stand and walk with an erect trunk and knees which are almost straight. Moreover, we are plantigrade, i.e. we set the whole length of the foot down on the ground, whereas most medium to large mammals are digitigrade, i.e. they stand and walk on their toes, and ungulates stand on hooves on the tips of their toes.

When we stand motionless, the ground exerts a force on the feet called the ‘ground reaction force’, which is equal and opposite to body weight. The latter acts at the ‘centre of gravity’, a point a little above the hip joints and anterior to the vertebral column. The force on the ground is centred vertically below it, at the centre of pressure. When we stand comfortably, the centre of pressure is usually midway between the insteps of our two feet. We do not remain absolutely still, but sway slightly. As we age, our postural control deteriorates, which is a factor in the development of unsteadiness and risk of falling.

When considering the distribution of load in the lower limb, a knowledge of limb alignment is important. The ‘anatomic axis’ is produced by lines passing along the shafts of the femur and tibia, and is therefore angled at the knee by 5° to 7°. The ‘mechanical axis’ is a straight line connecting the centres of the femoral head and ankle. Exactly where the line passes through the knee has yet to be defined: for convenience it is usually taken to pass through the centre, but may well lie more medially. For the tibia, the lines of the mechanical and anatomic axes coincide. Whilst the weight of the body acts in a vertical line from the centre of gravity to the ground, the line of the mechanical axis of the lower limbs is inclined 3° to this in normal stance, with the ankles closer than hips.

In the sagittal plane, body weight acts along a line which passes a few centimetres anterior to the tibiotalar joint, exerting a moment that must be balanced by the plantar flexor muscles. Some electromyographic investigations of standing have found activity mainly in soleus, but others have found moderate activity in gastrocnemius as well. In either case it seems likely that the activity is mainly in type I (slow oxidative) fibres, since these can maintain tension more economically than faster fibres could do under the same conditions. Soleus contains mostly type I fibres, and gastrocnemius contains approximately 50%.

In normal standing, the weight of the body above the knee joint acts slightly anteriorly to the axes of the knees: it exerts a moment that is balanced passively by tension in the ligaments and posterior capsule which prevent hyperextension. If the knees are kept straight, there is little or no electrical activity in the hamstrings and only moderate levels in the quadriceps. Generally, the combined weight of the trunk, arms and head seems to act slightly behind the hip joints, exerting a small moment that is balanced largely by iliopsoas. Thus a relaxed stance, with trunk erect and knees straight, requires very little activity in thigh muscles. This demands low energy consumption and permits long periods of standing. In single leg stance the weight of the upper parts of the body exerts a moment about the supporting hip which must be balanced by the abductor muscles, especially tensor fasciae latae and glutei medius and minimus. Damage to the glutei or their nerve supply, e.g. during hip surgery, is a potent cause of a limp.

PROPULSION

The contraction of tibialis posterior, gastrocnemius and soleus is the chief factor responsible for propulsion in walking, running and jumping. The propulsive action of these calf muscles is enhanced by arching of the foot and flexion of the toes. In walking, the weight of the foot is taken successively on the heel, lateral border and the ball of the foot. The last part of the foot to leave the ground is the anterior pillar of the medial longitudinal arch and the medial three toes. In the act of running, the heel does not touch the ground, but the point of take-off is still the anterior pillar of the medial longitudinal arch. As the heel leaves the ground, the toes gradually extend. Extension, of the hallux particularly, tightens the plantar aponeurosis and thus heightens the arch. At the same time, flexor hallucis longus and flexor digitorum longus elongate, which increases their subsequent contraction. The long and short toe flexors increase the force of take-off by exerting pressure on the ground. The most important muscle in this respect is flexor hallucis longus, which is strongly assisted by the short toe flexors. The lumbricals provide a balancing action to the long toe flexors and prevent buckling of the toes during the toe-off phase of gait.

Walking

In walking, each foot is on the ground (stance phase) for approximately 60% of the stride, and off the ground (swing phase) for approximately 40% (Fig. 84.26). Thus single-support phases (one foot on the ground) alternate with double-support phases (two feet on the ground). The knee is straight at heel strike and remains nearly straight (10–30°) for most of the stance phase of that leg, bending more only immediately before toe-off. During the swing phase the knee flexes to a maximum of 60° at mid-swing.

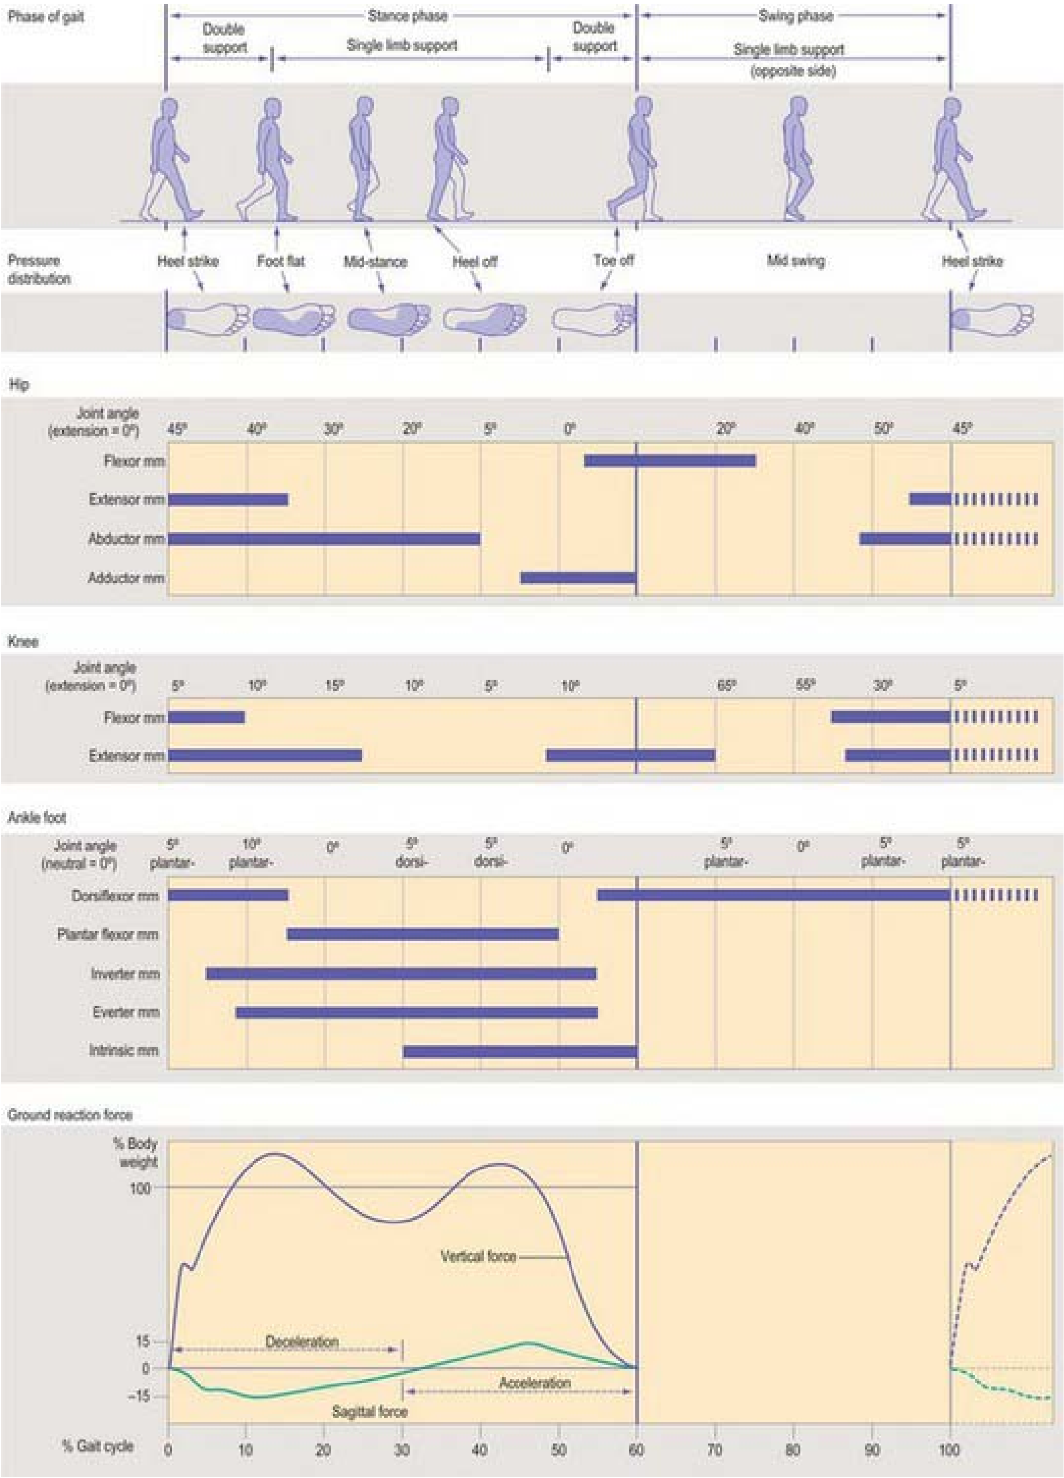

Fig. 84.26 The events that occur during the different phases of a normal gait cycle. Depicted are: distribution of pressure on the plantar surface of the foot; changes in the angles of hip, knee and ankle joints, together with activity in the corresponding muscle groups; and vertical and horizontal

(sagittal plane) components of the ground reaction force during stance phase. (Chart collated from various sources by Michael Gunther, Department of Human Anatomy and Cell Biology, University of Liverpool.)

Stance phase starts with ‘heel strike’. With the foot still planted in front of the body, ‘foot flat’ is reached, and becomes ‘mid-stance’ when the body comes to be directly above the planted foot. The heel then rises as the contralateral foot makes contact with the ground (the ‘double stance’ phase). The last event of stance is ‘toe off ’ when the ‘swing phase’ starts. Early in the stance phase, while it is ‘foot flat’ in front of the trunk, the foot pushes downwards and forwards on the ground, decelerating the body as well as supporting it. Later, when the foot is behind the trunk, it pushes downwards and backwards, re-accelerating the body (Fig. 84.26). The speed, and therefore the kinetic energy, of the body passes through a maximum in each double-support phase, and a minimum in each single-support phase.

The height of the centre of gravity, and therefore the potential energy of the body, also fluctuates. This is inevitable if the knee is kept nearly straight, making the hip move in a near-circular arc about the ankle of the supporting foot. The vertical component of the total force exerted by both feet on the ground in the double-support phase is greater than body weight, giving the body an upward acceleration. The vertical component of the ground force during the single-support phase is less than body weight, giving the body a downward acceleration. The force fluctuations have to be larger at higher speeds, to give the same vertical movement in less time.

During walking, the potential energy of the body is high when its kinetic energy is low, and *vice versa*. Energy can thus be swapped back and forth between the two forms, as in a swinging pendulum. A frictionless pendulum would continue swinging forever with no fresh input of energy. In walking, the exchange of potential and kinetic energy is less perfect, and the leg muscles have to do work to replace the energy which is lost at each impact of a foot with the ground. Even so, much less work is needed because of the pendulum principle. A second pendulum effect can be seen in the forward swing of the legs. If the leg were a rigid rod swinging from a fixed pivot, it would swing forward too slowly for normal walking: because it is free to bend at the knee, and because the hip from which it swings rises and falls, the leg swings forward faster with very little need for muscular work.

These pendulum effects ensure that relatively little work is needed to drive the fluctuations of kinetic and potential energy which occur in walking. The additional work needed to overcome air resistance and joint friction is very small, because we travel slowly and have well-lubricated joints. Human walking is economical of energy. Measurements of oxygen consumption show that 70-kg men use only 230 joules of metabolic energy for every metre they walk at their most economical speed (approximately 1.3 metres per second), which is 140 J/m more than they would use if they stood still. Running uses 260 J/m more than standing. Walking is economical only near the optimum speed, and the energy cost of fast walking overtakes that of running at 2 m/s, at which speed adults usually break into a run. Children, with their shorter legs, start running at lower speeds: the theoretical expectation is that the critical speed should be proportional to the square root of leg length.

The function of arm swinging in walking is not fully understood but it aids postural stability. For further discussion of standing and walking see Alexander (1992).

Development of walking

The average child sits at 6 months, crawls at 9 months, walks with support at 12 months, and without support at 18 months. The characteristic early gait matures rapidly and is similar to that of the adult by 3 years. Some minor changes occur up to 7 years which are largely a reflection of neurological development, but are also related to stature. Early gait is jerky, unsteady, and wide-based. The arms are held abducted at the shoulder and initially flexed at the elbows. Initial ground contact varies, and heel-toe, whole foot, and toe-heel are all possible. Generally a plantarflexed posture is adopted which contrasts with the adult pattern. In adults, heel strike is accompanied by a straight knee which then flexes. A child strikes the ground with a flexed knee which is then extended in response to weight-bearing, and a short time is spent in single leg stance (Fig. 84.27). Maturation is associated with diminution of base width, and increase in step length and velocity. The earliest changes are development of heel-strike, knee flexion during stance, and reciprocal upper limb swing. The period of single leg stance increases.

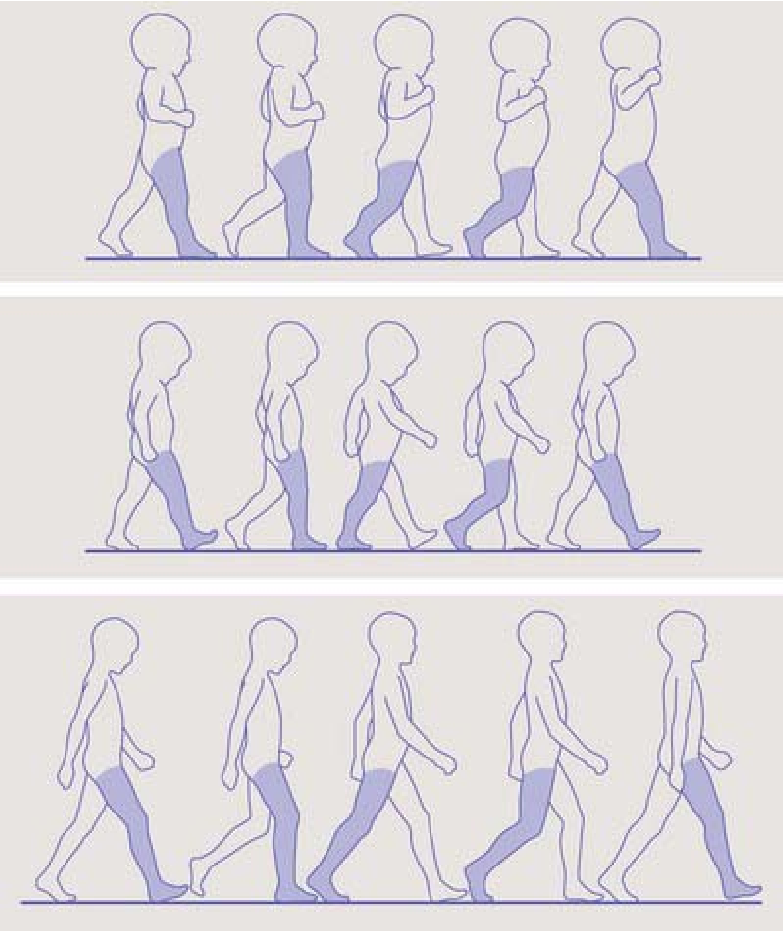

Fig. 84.27 Development of a mature gait. Top: 1-year-old. Note the flexed elbows and lack of arm swing. The foot is plantar flexed at contact. Middle: 3-year-old. Arm swing is now present as is heel strike. Bottom: 6-year-old. There is now an adult-type gait.

Running

Walking involves dual-support phases, but in running each foot is on the ground for 40% (jogging) to 27% (sprinting) of the stride, so there is an aerial phase, the ‘double float’ phase, when neither foot is on the ground. The faster the subject runs, the shorter the stance phase: world-class sprinters spend approximately 22% of the gait cycle in stance. During each aerial phase the body rises and then falls under gravity, which means that its height and potential energy are maximal in the middle of this phase and minimal at mid-stance, when, in marked contrast to walking, the knee of the supporting leg bends. Walking has been described as ‘controlled falling’, as the centre of gravity falls from a peak in mid-stance to a low during double support. The analogy that is used for running is an individual on a ‘pogo stick’. The runner propels himself from a low point in mid-stance to a peak during double float. During walking, efficiency is maintained by the interchange of potential and kinetic energy. During running, when potential and kinetic energies are in phase, efficiency is maintained in two ways: storage and release of potential energy in the elastic structure of tendons, and transfer of energy between limb segments via muscles which cross two joints (e.g. rectus femoris and hamstrings). The changes in muscle belly lengths are relatively slight during running. The muscles are acting as tensioners of the tendons, indeed, most of the change of length is produced by the stretch and recoil of the tendons. It has been estimated that, of the kinetic and potential energy lost and regained in each stance phase, 35% is stored temporarily as elastic strain energy in the calcaneal tendon, and 17% in the ligaments of the arch of the foot. Together these springs approximately halve the work required from the muscles.

A tendon is capable of withstanding stresses (force per unit cross-sectional area) of at least 100 N/mm^2 (10 kg force/mm^2). It stretches elastically by approximately 8% before breaking, and its recoil returns 93% of the energy used to stretch it. This high energy return is important, not only because it reduces the work required from the muscles, but also because the lost mechanical energy becomes heat: leg tendons with poor energy return would overheat in running, and be damaged. The calcaneal tendon is the most important ‘spring’ in the leg. Most runners strike the ground first with the heel, and the centre of pressure moves rapidly forward to the distal heads of the metatarsals, where it remains for most of the stance phase. A large force is then required in the calcaneal tendon to balance the moments about the tibiotalar joint. For a 70-kg man running at middle-distance speed, the peak force in the tendon is 5000 N (0.5 tonne force), which is enough to stretch it by approximately 6%. The parts of the tendon that run alongside the muscle bellies of gastrocnemius and soleus must be stretched, as well as the free distal part.

The mean vertical force on the ground during a complete stride cycle of any gait must equal body weight. If the foot is on the ground for only a small fraction of the stride, the forces must then be high. Peak vertical forces on one foot are approximately 1.0 times body weight in walking, 2.5 times in jogging, and 3.5 times in sprinting. Leg muscles have to exert much larger forces in running than in walking because the ground reaction forces are higher and also because, for a given ground force, flexion of the knee increases the moments about it. The main sources of power are the gastrocnemius–soleus complex at push-off; quadriceps femoris after ‘stance phase reversal’ (when the lower limb muscles change from a decelerating role to one of generating power, the generation phase); the hip extensors during late swing and early stance; the hip abductors just after stance phase reversal.

As in walking, the ground force acts more or less in line with the leg, so the body is decelerated and reaccelerated during each stance phase. The stance phase starts with deceleration and absorption of energy. Power is generated after stance phase reversal as the limb pushes up with the knee extending and foot plantarflexed, and this continues in the swing phase as the limb is accelerated forward. Once the limb is ahead of the trunk, the final phase of swing phase absorption is initiated, during which the limb is decelerated.

The ground force acts upward on the metatarsal heads, and the calcaneal tendon pulls upwards on the calcaneus. The necessary balancing reaction occurs at the ankle, where the tibia presses downwards on the talus. Together these three forces flatten the longitudinal arch of the foot, forcing the ankle 10 mm nearer to the ground than it would be if the foot was rigid.

Mechanical tests on amputated feet have shown that the foot is a reasonably good spring, giving an energy return of nearly 80%. The plantar aponeurosis, long and short plantar ligaments and the plantar calcaneonavicular ligament are all involved in the spring action: they are predominantly collagenous, and presumably have elastic properties similar to those of tendon.

A runner’s foot is still moving, typically at about 1.5 m/s, when the heel hits the ground. The impact is cushioned by the subcalcaneal foot pad, supplemented (when shoes are worn) by the compliance of the heel of the shoe. On contact the foot is supinated, which ‘locks’ the foot as a rigid structure, and is ideal for shock absorption. Immediately after heel strike the trunk progresses over the foot: passive pronation is initiated which makes the foot more flexible and therefore able to adapt to the running surface. As the foot approaches push-off, it becomes supinated again and as a consequence stiffens, which provides an excellent lever. These changes in foot posture cause rotational changes in the leg, and these in turn impact on the knee.

Eighty per cent of runners heel strike, and 20% have a mid foot strike. In sprinting the forefoot makes contact first to provide the greatest leverage. The knees never fully extend during running: at first contact, the knee is 25° flexed, increasing to a maximum during stance of 45° at stance phase reversal, and decreasing to 20° at toe-off. In running, the swing phase knee flexion increases 90° at the end of swing phase generation (up to 125° in sprinting), then decreases until contact with the ground again. (All values are approximate.)

Movements of the foot

With the foot on the ground, body weight causes some supination and flattening of the longitudinal arches; about one-third of the weight borne by the forefoot is taken by the head of the first metatarsal. When a resting position becomes active, as occurs on starting to walk, the foot is pronated by muscular effort, and the first metatarsal is depressed (the second less so), which accentuates the longitudinal arch to its maximum height (Hicks 1953). Similar changes can be imposed on a weight-bearing foot by active lateral femoral rotation, which is transmitted through the tibia to the talus and entails passive supination of the foot. Medial femoral rotation has an opposite effect. When the foot is grounded and immobile, muscles which move it when it is freely suspended may exert effects on the leg, e.g. the dorsiflexors can then pull the leg forwards at the ankle joint.

The foot has two major functions: to support the body in standing and progression, and to lever it forwards and absorb shock in walking, running and jumping. To fulfil the first function, the pedal platform must be able to spread the stresses of standing and moving and be pliable enough to accommodate walking or running over uneven and sloping surfaces. To fulfil the second function, the foot must be transformable into a strong adjustable lever in order to resist inertia and powerful thrust: a segmented lever can best meet such stresses if it is arched.

In infants and young children, fatty, connective tissue on the plantar aspect may give the foot a flat appearance, indeed, soft tissues modify its appearance to varying degrees at all ages. However, the skeleton of the human foot is normally arched, and the sole of the foot is usually visibly concave. This curvature is customarily analysed into longitudinal and transverse arches. These arches vary individually in height, especially the longitudinal in its medial part. Since they are dynamic, their heights also differ in different phases of activity.

The medial longitudinal arch contains the calcaneus, talus, navicular, cuneiform and medial three metatarsal bones. Its summit, at the superior talar articular surface, takes the full thrust from the tibia and passes it backwards to the calcaneus, and forwards through the navicular and cuneiforms to the metatarsals. When the foot is grounded, these forces are transmitted through the three metatarsal heads and calcaneus (especially its tuberosity). The medial arch is higher, and more mobile and resilient than the lateral arch; its flattening progressively tightens the plantar calcaneonavicular ligament and plantar fascia. The lateral arch is adapted to transmit weight and thrust rather than to absorb such forces: the long plantar and plantar calcaneocuboid ligaments tighten as it flattens.

The lateral arch makes contact with the ground more extensively than the medial arch. As the foot flattens, an increasing fraction of load traverses soft tissues which are inferior to the entire arch. The whole lateral border usually touches the ground, whereas the medial border does not. However the medial border is visibly concave, usually even in standing, which explains the familiar outline of human footprints (though this varies with the position of the feet (Fig. 84.28), the development of associated soft tissues, and the nature of the surface). In any activity, as soon as the heel rises, the toes are extended and muscular structures (including the plantar aponeurosis) tighten up in the sole, accentuating the longitudinal arches. It has been suggested that tension diminishes in the deeper plantar ligaments in this phase.

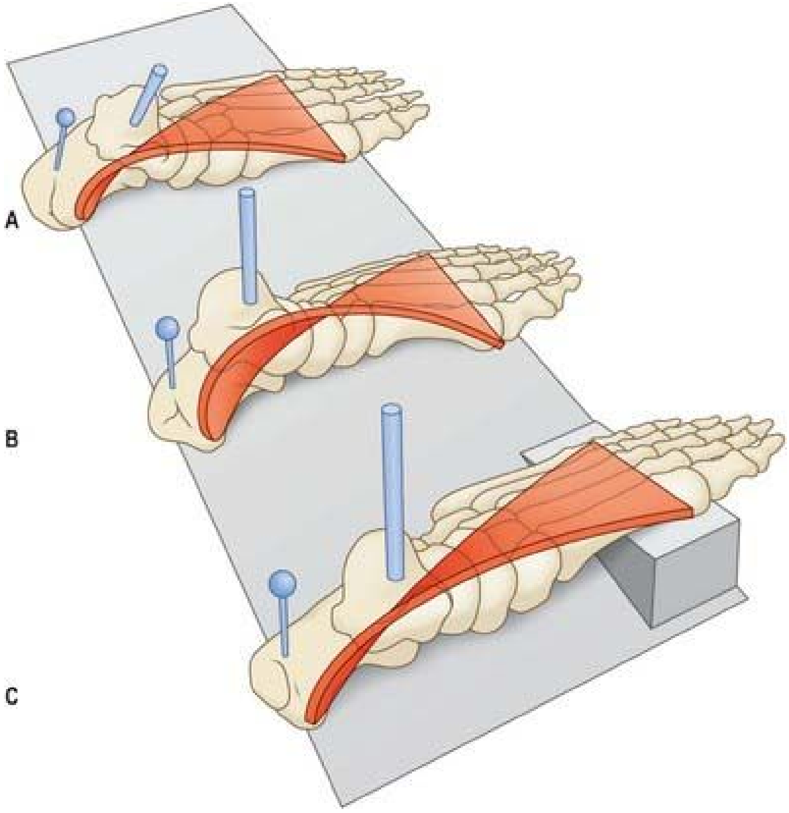

Fig. 84.28 The concept of the foot skeleton as a twisted plate which may be untwisted (supination) or further twisted (pronation) during the maintenance of a plantigrade stance in various positions of the foot. (Based upon MacConaill 1945, 1950.) **A**, The foot skeleton in supination, as in standing with the feet widely separated. Note the marked medial tilting of the talus and, to a lesser degree, of the calcaneus and the depression of the medial longitudinal arch. **B**, Relative pronation of the foot, as in standing

with the feet close together. **C**, Supination of the foot when standing on an inclined surface; if the position of the wedge had been reversed, the foot skeleton would, of course, approach maximal pronation.

The sole is transversely concave, both in skeletal form and usually in external appearance, and serial transverse arches are most developed inferior to the metatarsus and adjoining tarsus. Transmission of force occurs at the metatarsal heads, to some degree along the lateral border of the foot, and through subjacent soft tissues.

In standing, with only body weight to support, both the intrinsic and extrinsic muscles appear to relax. If the longitudinal arches are allowed to sink as a result of muscular relaxation, the plantar ligaments tie the bones into an arched form. The medial arch is more elevated when the feet are together than when they are apart, i.e. inversion with supination increases as the feet are separated. This medial sag can be countered by voluntary contraction of muscles such as tibialis anterior. Pronation and supination ensure that in standing, whatever the position of the feet, a maximal weight-bearing area is grounded, from the metatarsal heads along the lateral border of the foot to the calcaneus. The twist imparted by pronation (which is partly undone in supination) prompts the likening of the foot to a twisted but resilient plate (Fig. 84.28), where adequate ground contact was ensured whatever the angle between the foot and leg, and adaptable resilience was imparted in standing and progression.

CHAPTER 85

Development of the pelvic girdle and lower limb

STAGES OF LOWER LIMB DEVELOPMENT

The lower limb is first recognizable as a laterally projecting ridge at stage 13 and by stage 14 it is closely associated with the wide umbilical cord. During stages 15–17 the limb projects laterally and outgrowth is fairly symmetrical.

By stage 17 the lower limb still has a flattened foot plate and although a hip region can be identified, there is no true knee as yet. In stage 18 the lower limb appears to be flexed and abducted at the hip with the knee bent, giving the appearance that the knee is facing laterally. Very little skin of the thigh is visible. The soles of the feet face the umbilical cord, and the foot plate has digit rays. During stages 20–23 the digit rays separate, and toes are clearly defined by stage 23. The feet can finally touch at stage 21, when the umbilical cord becomes proportionally smaller and the embryo larger.

The pelvis forms from two hemipelves each of which develops from one cartilaginous focus. Ossification of the pelvis starts with the ilium, which undergoes endochondral ossification at 9.5 weeks. The femur and tibia form in cartilage and the sciatic nerve extends distally to the tibia by stage 18. Cavitation of the hip joint has been reported at 7–8 weeks. The sacroiliac joint can be recognized from 7 weeks; its development is slightly different from that of other synovial joints in that the development of the ilium is ahead of that of the sacrum.

VESSELS IN THE LOWER LIMB

The axial artery of the lower limb arises from the dorsal root of the umbilical artery and courses along the dorsal surface of the thigh, knee and leg (Fig. 85.1). Below the knee it lies between the tibia and popliteus, and in the leg it lies between the crural interosseous membrane and tibialis posterior. It gives off a perforating artery that traverses the sinal tarsus to form a dorsal network and ends distally in a plantar network. The femoral artery passes along the ventral surface of the thigh, opening a new channel to the lower limb. It arises from a capillary plexus that is connected proximally with the femoral branches of the external iliac artery and distally with the axis artery. At the proximal border of popliteus the axis artery splits into primitive posterior tibial and fibular branches which run distally on the dorsal surface of popliteus and tibialis posterior to gain the sole of the foot. At the distal border of popliteus the axis artery gives off a perforating branch which passes ventrally between the tibia and the fibula and then courses to the dorsum of the foot, forming the anterior tibial and dorsalis pedis arteries. The primitive fibular artery communicates with the axis artery at the distal border of popliteus and in its course in the leg.

Fig. 85.1 Stages in the development of the arteries of the leg. The original path of the axis artery is indicated by a dashed line.

The femoral artery gradually increases in size. Coincidentally, most of the axis artery disappears, but proximal to its communication with the femoral artery, the root of the axis artery persists as the inferior gluteal artery and the arteria comitans nervi ischiadici.

The proximal parts of the primitive posterior tibial and fibular arteries fuse but they remain separate distally. Ultimately, much of the primitive fibular artery disappears; a part of the axis artery is incorporated in the permanent fibular artery. The same considerations apply to anomalies and variations as were described for the developing forelimb (see Ch. 52).

The preaxial vein becomes the long saphenous vein, which drains into the femoral vein at the saphenous opening. The postaxial vein becomes the short saphenous vein, which passes deep and joins the popliteal vein.

NEONATAL LOWER LIMB

In the neonate the pelvis is cone-shaped. The transverse diameter of the true pelvis is 2.2 cm, its anteroposterior diameter 2.8 cm, and the length between the inlet and outlet is 2 cm. The sacrum is proportionately larger than in the adult and the sacral promontory is higher. When walking begins, the sacrum descends between the ilia and the promontory develops. The ilia, ischia and pubic bones are variably ossified at birth: they meet at the acetabulum, which in the neonate is cartilaginous, relatively large and shallow.

The lower limbs are underdeveloped in the neonate when compared to the upper limbs. They are retained in a flexed position and the leg is proportionately shorter than the thigh. Although the legs appear to be bowed, the tibia and fibula are straight: the illusion of bow legs is caused by the shape of the soft tissues and the slightly more advanced development of the lateral head of gastrocnemius compared to its medial head. The femoral neck is much shorter and forms an acute angle with the shaft. The latter is quite straight, because the adult curvature is acquired with walking. The head of the femur is larger than the acetabular fossa and nearly one-third remains external, which means that the ligamentum teres is relatively very long. Dislocation of the hip joint is relatively easy; the femoral head can be removed from the acetabular fossa laterally, but not posteriorly. The calcaneus and the talus have an ossification centre at birth, and a centre is present in the cuboid in 50% of neonates.

The muscles of the lower limb are much less developed than those in the upper limb. The fetal position often assumed by postnatal babies keeps the thighs in continuous abduction, stretching the adductors. The muscles that will be used for walking are weak; the lack of gluteal development in particular gives the typically diminutive buttocks of the neonate.

In neonates, the feet are usually inverted and they have a greater degree of dorsiflexion, caused by the relatively greater area of the trochlea of the talus. Plantar flexion is limited, in part reflecting the shortness of the extensor muscles of the foot. At birth the footprint outlines the whole plantar surface, reflecting the deposition of subcutaneous fat beneath the longitudinal and transverse arches, and so most babies appear flat-footed.

LOWER LIMB ANOMALIES

The categories of limb defects described by Swanson (1976) are given in Chapter 52. Although devised for the upper limb, they apply in the same manner to the lower limb.

Developmental dysplasia of the hip is a term that covers an alteration in hip development before and after birth. The term is now preferred to ‘congenital dislocation of the hip’. In the most extreme cases, the femoral head is completely dislocated out of the acetabulum. This condition occurs in approximately 1 in 100 live births; the ratio of females to males is 6 : 1. The aetiology is considered to be multifactorial and is associated with first pregnancies, suggesting that both maternal and uterine musculature restrict fetal movement and put postural strain on the fetal hips. Developmental dysplasia of the hip is seen more frequently in breech delivery, especially if the child’s knees are extended. The left hip is more frequently affected than the right, which may be because in breech presentation the fetus lies with the right shoulder anterior and the left thigh closest to the maternal sacrum. The physiological effects that cause the maternal ligaments to become temporarily lax prior to delivery are also considered to affect the fetus and to contribute to laxity of the hip capsule.

Congenital talipes equinovarus, or club foot, derives its name from a combination of *talus* and *pes*, together with terms describing an elevated heel resembling that of a horse (*equino*), which is also turned inwards (*varus*). It is a common neonatal anomaly and occurs in approximately 1 per 1000 live births, with males affected twice as often as females. There is some degree of inheritance, so it is not entirely an effect of intrauterine positioning or of oligohydramnios (abnormally little amniotic fluid). Both bones and soft tissues are affected and it is difficult to tell which are primary effects and which are secondary. A number of theories have been proposed to explain the underlying pathogenetic mechanism(s), including abnormal tendon and ligament attachments and delayed muscle maturation. The most widely held theory is that the talus undergoes defective development and that all the other deformities arise as a consequence of this initial defect. The talus is decreased in size by up to 25%. It has a foreshortened neck and decreased body/neck angle, and the subtalar facets are medially rotated. The navicular is small and medially deviated relative to the talus. The calcaneus is also small and shows varus displacement and equinus tilt: the anterior facets correspond to those of the talus (Barlow & Clarke 1994). The entire affected foot and calf are smaller than their normal counterparts. The foot is inverted and supinated and the forefoot is adducted. The heel is small, rotated inwards and elevated. The calcaneus is inverted beneath the talus. Treatment varies between splintage and repeated complex surgery, which reflects the highly variable severity of the condition and individual response to therapy.

‘Flat feet’ are common in childhood. The majority are ‘flexible’ and simply related to posture, whereas ‘rigid’ flat feet are caused by structural abnormalities. The description of ‘rocker bottom’ foot is associated with many congenital syndromes. The foot is flat and rigid and the plantar surface appears curved with the apex of the curve at the midtarsal joint. The condition shows an equinus position of the hindfoot. The talus may be vertical and palpable on the plantar surface. A majority of infants with this condition have neurological abnormalities.

INDEX

Note:

Index structure

This index is in a *classified* form, i.e. arteries, ducts, muscles, nerves, veins, etc. are all listed under these respective main entries, e.g. 'arteries (named)'. This includes subjects/structures such as cells, connections, diseases, syndromes and tracts, e.g. lymphocytes are to be found under 'cells (named)'. Bones are an exception, and specific bones are listed as main entries, e.g. tibia is listed as tibia, not under 'bones'.

Organs and regional structures have their own main entries and subentries (e.g. oesophagus). Cross-references to individual arteries, veins, muscles, etc. are assumed, not explicit.

In most cases structures are listed under singular nouns, with the plural in brackets.

Index entry order

This index is in a *letter-by-letter* order, whereby hyphens and spaces between words are excluded from the alphabetization (e.g. 'lymphatic' precedes 'lymph node'). Characters in brackets are excluded from alphabetization. For example: arc(s) precedes arcade or arch(es).

Terms such as first, second, third (as in arch(es), pharyngeal) are in numerical order ahead of alphabetical sub (or sub-sub) entries.

Page numbers

Page numbers suffixed with 'f' refer to figures; those suffixed with 't' refer to tables.
